
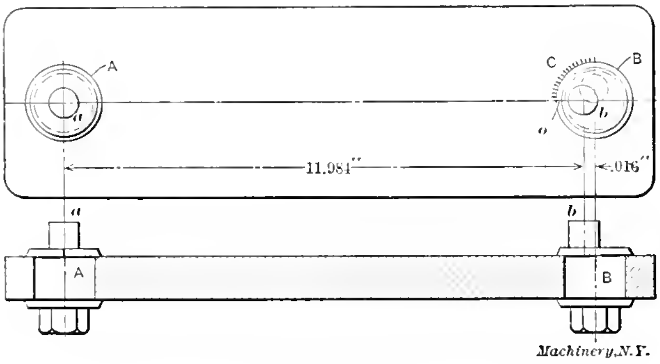

Fig. 1. Tool which is to be Graduated as shown at C, so that the Distance between the Pins a and b may be varied by Thousandths.

A.—A graphic solution to the problem, which answers all practical requirements, is comparatively simple. It is unnecessary to take into account the slight increase due to the angularity, as the eccentric pin *b* is rotated toward the right-angle position, as the difference, because of the angularity, between the distance from the stationary to the eccentric pin when the latter is in the right-angle position, and the distance between these pins when they are in the same horizontal line, is only 0.00001 inch. That is to say, if the distance between the pins in the same horizontal line is 12 inches, the distance between them when the eccentric pin is removed 0.016 inch at right angles, as shown by the dotted lines, will only be 12.00001. Hence, this effect may be ignored entirely, and we may proceed as though the eccentric pin remained in the same horizontal line as the stationary pin and simply receded from it in a straight line as the movable bushing *B* is turned. To locate the graduating marks graphically, draw a quadrant as shown in Fig. 2, with a radius of, say 4 inches, the center being on the horizontal line *A*—*B*. Divide the radius into 16 equal divisions. Each one of these divisions will correspond to a movement of 0.001 of an inch in the ratio of 250 to 1. Then, from each of these division points erect perpendiculars cutting the circumference of the quadrant at 1, 2, 3, 4, 5, etc., and from the points of intersection draw radial lines to the center *C*. These lines subtend the angles to which the graduating marks on the table should be laid out. These angles can also be obtained directly without the trouble of laying out, by referring to a table of sines and cosines, or better to a table of versed-sines. A versed-sine of an angle is the difference between the cosine and 1. Inasmuch as all tables of natural trigonometrical functions are for a radius of 1 and the eccentric bushing is to move on a radius of 0.016, it will be necessary to multiply the respective departures of 0.001, 0.002, 0.003 inch, etc., by 62.5 (which is obtained by dividing 1 by the radius 0.016) to make them agree with the versed-sines given in the table. Thus we find that the first departure from the circumference, indicated as 1 in the accompanying diagram, Fig. 2, multiplied by 62.5 equals 0.0625 which is the versed-sine of 20 degrees and 22 minutes, and 0.002 multiplied by 62.5 equals 0.1250, the versed-sine of 28 degrees, 58 minutes. In the same way we find the versed-sines for the sixteen angles as follows:

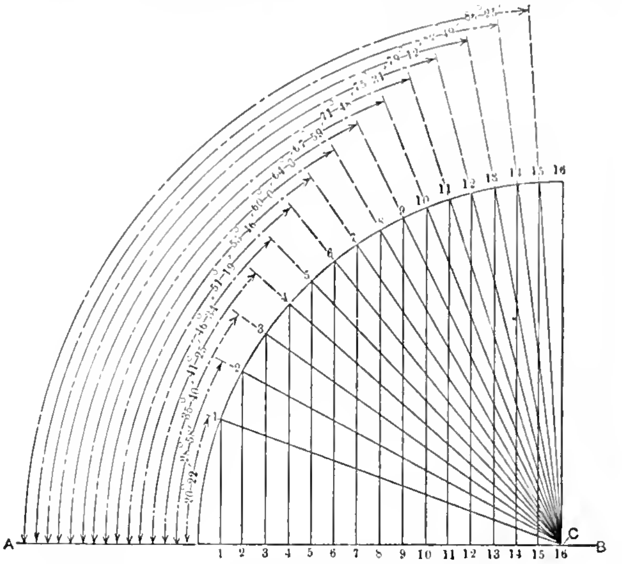

Fig. 2. Graphical Method of obtaining the Angular Positions of the Graduation Marks.

.0625 = 20 degrees, 22′
.1250 = 28 degrees, 58′
.1875 = 35 degrees, 40′
.2500 = 41 degrees, 25′
.3125 = 46 degrees, 34′
.3750 = 51 degrees, 19′
.4375 = 55 degrees, 46′
.5000 = 60 degrees, 0′
.5625 = 64 degrees, 3′
.6250 = 67 degrees, 59′
.6875 = 71 degrees, 48′
.7500 = 75 degrees, 31′
.8125 = 79 degrees, 12′
.8750 = 82 degrees, 49′
.9375 = 86 degrees, 25′
1.0000 = 90 degrees, 0′

Most handbooks do not include tables of versed-sines, and if a table is not available, first subtract the result obtained by multiplying 0.001 by 62.5 from 1, the result being 0.9375, which is the cosine of 20 degrees and 22 minutes. Proceed in the same way for all the others, first multiplying the departure by 62.5 and substracting the result from 1 to get the natural cosine of the angle.

* * *

The operating cost of the Brooklyn Bridge is found to be as high as $360,000 a year, according to an investigation made by the Comptroller of New York City. This figure is the average of ten years' maintenance and operating costs, beginning with 1898. In 1907 the cost slightly exceeded $400,000. The city's revenue from the bridge has exceeded $400,000 per year during the same period, and has always been larger than the cost until 1907, when there was a deficit of $3,250.

New York, April 1, 1909.

Dear Sir:-

Not long ago a well known firm of machine tool builders, of whom we made some enquiries regarding their apprenticeship system, wrote us that they had discontinued employing apprentices, and now employ, instead, laboring men twenty to thirty-five years of age, under a three year contract which calls for continuous service on one line of work.* These manufacturers do not lack public spirit by any means; they were forced into this common practice† by competition, as many other concerns are; but it is time for us all to consider the effect on our mechanical future of the almost total lack of opportunity to learn machine shop practice in our works. Unless such conditions materially change, we are not likely to be the leading mechanical nation in the world twenty-five years from now.

As you know, thousands of our mechanics, young and old, lack sufficient elementary education to read a mechanical journal intelligently or profitably; and for them such papers do not exist. They should be educated to a point where the mechanical journal begins; yet the general tendency of shop work is to deprive them of whatever ambition to acquire an education they may possess.

We acknowledge that the tastes and inclinations of perhaps three-quarters of the young men in our shops are away from, rather than towards, educational work; but let us consider the remaining fourth, among whom must be found the designers, superintendents and mechanics of the next generation. This aspect of the proposition should appeal to everyone connected with the manufacture of machinery; and we need not point out the results of even a modicum of education--the awakening of a man's ambition, the quickening of interest in his work, the increased chance of an appeal to his reason on questions between employer and employee.

MACHINERY began fifteen years ago as a shop paper--an educator-- but the character of its reading matter gradually and necessarily improved as its readers advanced in age and knowledge. For eight years we have kept a careful record of their occupations, and a majority now occupy positions of responsibility. There is now no publication which contains matter of sufficiently elementary

---

*The text of the letter referred to will be found in an editorial, "The Apprenticeship Problem" on page 609 Engineering Edition.
†Common with the exception of the three-year contract provision.

character to supply the educational requirements of the shop man. The naked truth is that such a publication would not pay, because shop men are not buyers to any extent; advertisers therefore do not care to reach them, and it is the advertiser and not the reader from whom three-fourths of the income is derived.

Considerations for the future have appealed to a number of public spirited manufacturers, and have added impetus to the movement for training apprentices; but in thousands of shops it is impracticable to institute such a system, and out of the 600,000 workmen of all kinds in the machinery industry a small fraction only is systematically reached through that or any other educational method.

To supply this need--this great need--and not primarily as a money-making proposition, MACHINERY began in January, 1908, a system of self-education in mathematics and mechanics, planned to cover the entire field of mechanical practice, which should be available by every mechanic without regard to his means, and which he could pursue in connection with his work. The development of this system has been gradual and the cost considerable; but the results have been satisfactory and the future of the work looks bright, although we are only at THE BEGINNING. During 1908 we invested in this undertaking about $16,000, a portion of which has come back; and in 1909 we plan to expend about $24,000. We regard this work as of such far-reaching importance that we are quite willing to invest therein the major part of MACHINERY'S earnings for some years to come--say a hundred thousand dollars--and we believe this investment will prove a profitable one, both for the machinery industry and for ourselves.

But of equal importance with the educational work, and fully as necessary to results, is the cultivation of sentiment in its favor among manufacturers; and for that reason we are sending you this letter. If your position is one of authority, you can help us materially by encouraging the men in your employ to study systematically, and by rewarding them for improvement; if it is a subordinate one, you can help the movement by your influence and by a good word whenever you have an opportunity to speak it.

Will you do this?

Very truly yours,

THE INDUSTRIAL PRESS.

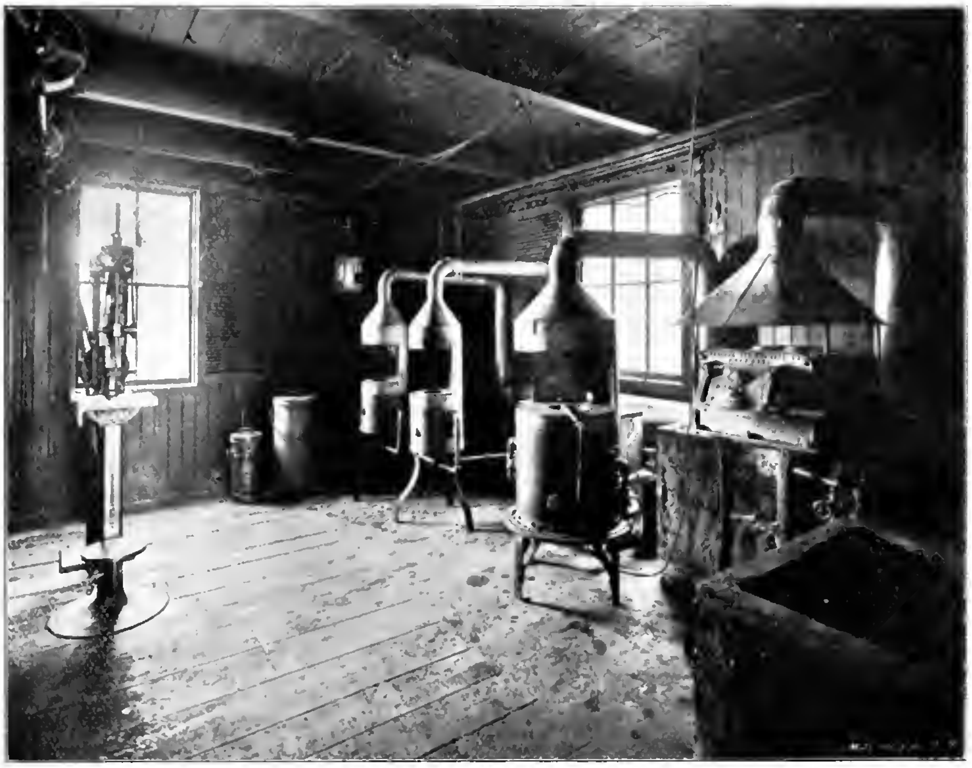
President.

THE HEAT TREATMENT OF STEEL.

From time immemorial when iron in its most crude form was introduced into the manufacturing and commercial field, it has been a well-known and accepted fact that heat with its varying degrees of intensity has a direct action on both the physical and chemical properties of the metal when the iron is submitted to its action; and, as a direct result, the entire structure of the iron is altered, and by altering or changing the method of application of the heat treatment, any desired structure of the metal, either steel or cast iron, may be obtained. In spite of the fact that the truth of the above exposition was generally acknowledged, very little, if any, use was made of it; but as science developed, competition grew keener and keener, and the general cry in the manufacturing world became "reduced cost and greater output." To balance the effect of increased power and consequently larger machines, the working strength of the cutting tool, together with the working stress of the machine members, had to be greatly increased, and, during the past decade, the heat treatment has done more than its share in the work of accomplishing the desired results. Therefore, the Worcester Polytechnic Institute, following its old and well-established custom of being the pioneer in all branches of scientific investigation, has, during the past year, through its department of Mechanical Engineering, designed, constructed and equipped a modern plant devoted exclusively to the heat treatment of steel; the more important operations to be performed are hardening, annealing, tempering and case-hardening. From the very general description given in the following paragraphs of the equipment and facilities of this plant, it will be easily seen that all grades of steel from the 15 point carbon steel to the high-speed, alloy, air- and water-hardening steel may be conveniently and efficiently handled and treated.



Plant for the Heat Treatment of Steel, in the Worcester Polytechnic Institute.

The plant consists of a room of spacious size, in the design of which the comfort of the operator was well provided for. The temperature and ventilation of the room is controlled both by a fan and large windows which admit subdued natural light but exclude the direct sunlight, which is so undesirable in this kind of work. These windows are provided with shutters so that the natural light may be excluded; artificial illumination is obtained by means of incandescent electric bulbs. The room appears to a visitor, at first, somewhat like a dungeon, as the walls and ceiling are painted a "dead black," which color prevents any reflection of the various colored rays when the operator is experimenting on "color work." After this first impression has left the visitor and he has become accustomed to the light, the next thing that catches his eye is the row of various shaped furnaces placed symmetrically on the right side of the room. For convenience and simplicity, we will designate these furnaces (from right to left in the engraving) by the letters *A*, *B*, *C* and *D*. Furnace *A* (constructed by the American Gas Furnace Co.) is built on the principle of the muffle furnace, is of the box type, and will readily heat a block of steel 8 x 4 x 14 inches. A temperature of from 2,000 to 2,100 degrees F may readily be obtained by means of this heater, which is used to heat such work as requires an even heat and which would be destroyed by oxidation and the decarbonizing action of the air; reamers, mandrels, taps and drills in their finished state are good examples of this type of work. Furnace *B*, known as the "barium chloride heater," is circular in form and lined with fire-brick, and the chloride solution is heated in a crucible built of fire-resisting material. This furnace is of sufficient size to accommodate all ordinary tools and is employed to heat such grades of steel as require a rather high temperature, as high speed steels, and which, at the same time, must be well protected in heating. This form of heat treatment is well adapted to those types and forms of tools which tend to heat unevenly, thus producing an unbalanced distribution of the shrinkage strains with the accompanying cracks. Furnace *C* is of the same general design as furnace *B*, with the exception that this heater is made use of in connection with the lead bath. As the lead melts at a comparatively low temperature, this furnace is used when a lower temperature than that obtained with the chloride solution is desired; for example, when heating carbon alloy steel. Furnace *D* is devoted to an entirely different operation, namely, oil tempering. Either linseed or machine oil is used in this heater, which is brought into action when the desired range of temperature is between the limits of 300 and 630 degrees F. The fuel used in all of these furnaces is the ordinary city gas, due to its convenience and ready accessibility, but oil fuel could be employed if so desired by the operator. As will be seen from the engraving, all the furnaces are provided with hoods of convenient form connected with an exhaust line, so that all poisonous fumes and gases such as lead, cyanide, barium chloride, etc., may be eliminated from the atmosphere of the room. At various and convenient positions about the plant are to be found rectangular tanks of convenient size, containing water and brine of varying densities. All the other baths, as for example, the various grades of oil and other cooling baths, are kept in covered cylindrical galvanized iron tanks. In order to properly care for and treat the air-hardening steels, an air jet is provided with a pressure of about 2 pounds.

The one feature which removes this plant from the class of the ordinary manufacturing establishment and places it in the ranks of those of scientific research and investigation, is its complete set of measuring instruments, including the Bristol and Le Chatelier pyrometers and thermometers covering a range of temperature between the limits of 0 and 2,960 degrees F. On one of the walls of the room is to be found the Bristol pyrometer, which is of the thermo-electric type, and consists of a permanent magnet moving coil type of galvanometer. The scale is graduated to read direct in degrees. Leads from the instrument extend over the entire room, so that it is a matter of a few seconds only to connect with the thermo-couple and obtain any desired temperature. If any question as to the accuracy of the instrument, or the action

of gravity on its oscillating parts is advanced, a Le Chatelier pyrometer, operating on the same principle but having a vertical support, may be brought into action and the first readings verified

In order to facilitate the preparation of test specimens and other work, a Washburn drill and also a grinder are provided and placed on the opposite side of the room. The work in this new plant is not confined to experimental work alone, because the range of equipment provides all the requisites necessary for performing outside commercial work for those who have not the facilities to properly treat their own tools. This heat treatment room offers excellent opportunities for those taking the mechanical engineering course to become thoroughly conversant with the most approved and up-to-date methods of heat treating steel, and with this in mind, the attention of the student is frequently called to both the scientific and also the economic features of this work, which, during the senior year, has its position in the curriculum of the school.

IMPROVED METHOD OF CUTTING SCREWS.

An interesting method for the manufacture of power, lead- and feed-screws of all dimensions has been developed by the Screw Cutting Co. of America, 150 Berkley St., Wayne Junction, Philadelphia, Pa. The principle of the method employed by this company for cutting screws is conducive to a high degree of accuracy, and makes it possible to absolutely duplicate the lead-screw used in cutting the thread. The method is, briefly, as follows: A hollow lead-screw is employed, on one end of which a chuck is mounted; this chuck clamps the blank stock on which the thread is to be cut, the stock passing through the hole in the lead-screw; thus the lead-screw, the chuck, and the work on which the thread is to be cut, revolve together. The lead-screw passes through a stationary nut and thus feeds forward when revolving. The thread is cut by a milling cutter mounted in a stationary head provided with an arrangement permitting the cutter to be swiveled to the angle of the thread. The fact that the cutter head is stationary and that the work is attached directly to the lead-screw, makes it possible to exactly duplicate the thread on the lead-screw, there being practically no chance for lost motion of any kind. The lead-screw being comparatively short can be made with great accuracy, but its length in no way limits the length of the thread to be cut, as an arrangement is provided by means of which the lead-screw with its carriage can be returned to its original starting position at regular intervals. The blank stock is guided in bushings so as to run concentric, and the overhanging portions outside of the machine are supported by roller bushings, thus preventing any bending or springing action due to the weight of the over-hanging part. By the employment of the means referred to, it is possible to cut screws of any length for which blanks can be provided. The accompanying illustrations show some interesting examples of work carried out on the machines of the company. One interesting job lately completed was a 5/16-inch diameter screw threaded for a length of 18 feet, and on the same machine threads down to 1/16 inch in diameter have been cut. The highest capacity of the present machines is 12 inches diameter.

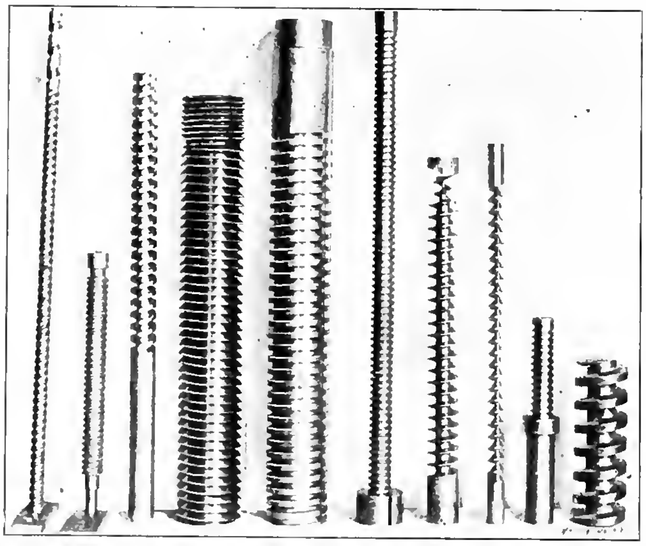

Fig 1. Examples of Screws cut by the Method Developed by the Screw Cutting Co. of America.

The upper view in Fig. 2 shows an interesting test applied to some of the screws cut by this method, indicating the truth of the lead of the screw. One-half of the screw is milled away in each of the two parts shown, and the two halves are put together as indicated, the thread of the one half matching exactly the thread of the other half. The supreme test of the truth of the lead is that the halves may be reversed, end for end, and put together, and still the same relation remains. If the lead were not correct, or if the shape of the thread were not uniform or the screw not exactly straight, it would not be possible to show so satisfactory a result when testing the screws in this manner. As the manufacture of accurate screws is one of the most difficult problems known, this method of producing screws is extremely interesting, and the production of screws with unlimited length of thread is a new departure in screw manufacture which undoubtedly will interest many mechanics.

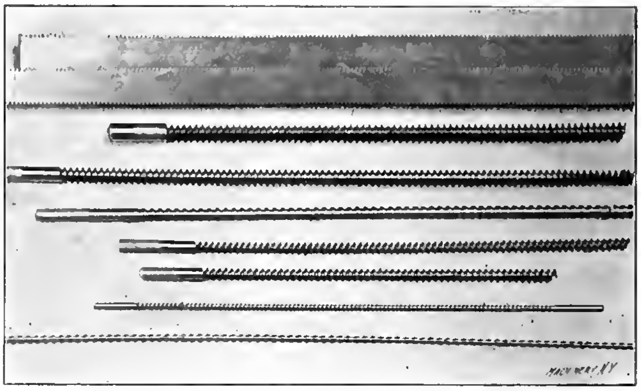

Fig. 2. Method of Testing Accuracy of Pitch of Thread, and Examples of Threaded Work of Small Diameter.

The Screw Cutting Company of America devotes itself exclusively to the making of screws, but the machines on which the screws are manufactured are not made for the market. The company is at the present time building a larger factory in order to meet the increased demands for its product. The heavier machines will be placed on the concrete ground floor so as to eliminate vibrations that tend to impair the character of the product.

PROFIT IN TECHNICAL BOOK-MAKING.

Fiction is far from being the only big money making department of book publishing. Indeed, it is perhaps the most risky, because its public is the most fickle. On the other hand, no public is so faithful as that of technical publications, like law books and mechanical handbooks. More than one firm that very few people outside of technical circles ever heard of clears more than $1,000,000 profit every year out of just such publications, and most of the profit in each case goes into the pocket of one man. Take a volume like Kent's "Mechanical Engineer's Pocket Book," largely composed of tables and data. It was first published in 1895 and has been revised from time to time so as to keep it up to date. It has now sold a total of 60,000 copies, though it is an expensive book. Its author has made $5,000 yearly from its sale ever since it was published. Still another similar publication constitutes a family estate. This is Trautwine's "Civil Engineers' Pocket Book." It was written in 1882 by John C. Trautwine; its first revision was made by John C. Trautwine, Jr., and its third revision by John C. Trautwine, 3rd. It is strictly a family affair. It is a $5 book and its total issue to date is 94,000 copies. From its sale the Trautwine family has been in continuous receipt of an income of something like $6,500 yearly. Yet it is probable that not one person in a thousand who reads these words ever heard of the Trautwines.—*New York Sun.*

NEW MACHINERY AND TOOLS.

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP.

HOEFER MFG. CO.'S VALVE INSERTING MACHINE.

Machines for making pipe connections with water mains under pressure have been in use for a great many years and it would be difficult to get along without them. They are a part of the equipment of every water works plant and of every large manufacturing establishment. Their use permits making extensions to the piping system without the annoyance and danger involved in shutting off the main on which the work is to be done. But while this operation is common enough, so far as we know no one has up to this time attempted to insert a stop valve in a main without reducing the pressure or interfering with the flow. This feat is now easily performed by the aid of the ingenious valve inserting machine, shown herewith, made by the Hoefer Mfg. Co., of Freeport, Ill. This device was suggested by a water works superintendent, who felt the need of replacing old and worn out valves in his water system and of inserting new ones as well. The device is simple and ingenious, and its action will be readily understood from the following description and illustrations.

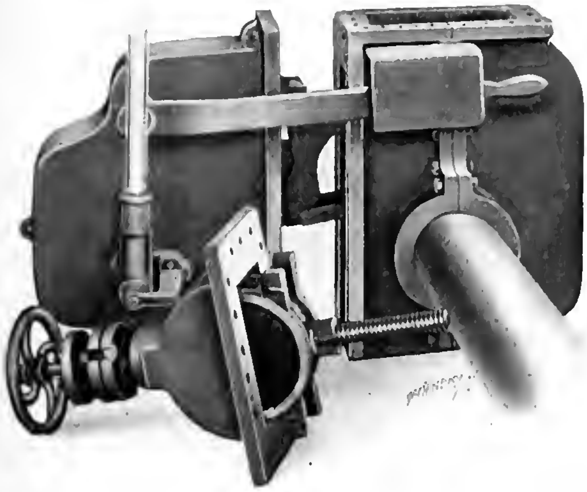

Fig. 1. A Device for Inserting a Stop Valve in a Pipe under Pressure.

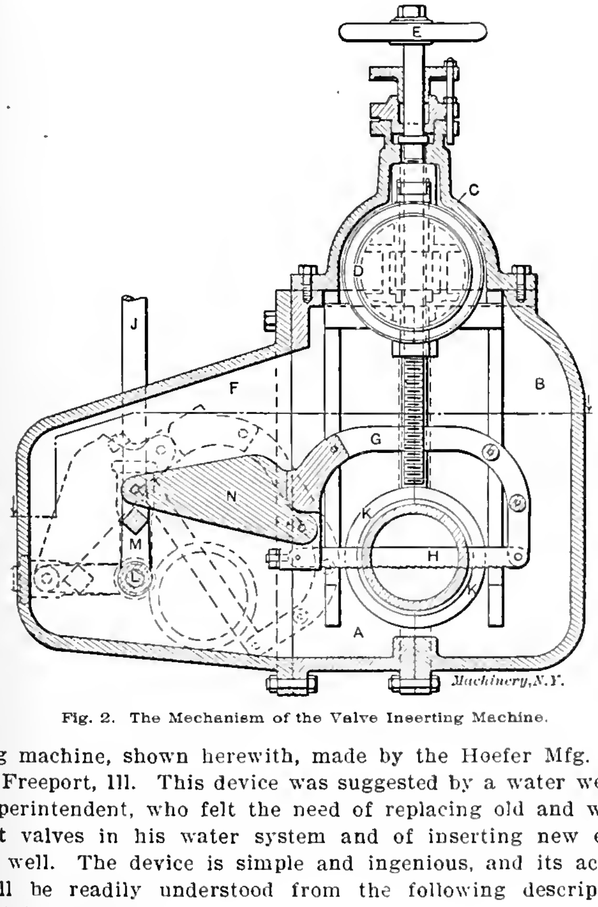

Fig. 2. The Mechanism of the Valve Inserting Machine.

Description of the Machine.

Figs. 1 and 2 show external and sectional views respectively. The casing of the machine is made in two halves, *A* and *B*, which are clamped around the pipe and permanently secured there. The joint between the two halves is made fluid tight by means of the bolts and faced joints shown. The semi-cylindrical flanges which embrace the pipe are calked against the pressure by the usual lead joint. To the rectangular opening at the top of the casing is clamped the valve dome *C*, which contains a valve stem and valve of the double expansion seat, gate variety, made by the Ludlow Valve Co., Troy, N. Y. The two circular valve plates *D* are forced against corresponding faced seats in the valve casing surrounding the pipe.

The pipe cutting mechanism is carried by casing *F*, which is clamped to the permanent valve casing at the left. This member carries a double hack-saw frame *G*, provided with two blades *H* and rocked by handle *J* which extends outside of the casing where it can be operated by the workman. The hack-saw is obviously a suitable tool to use in cutting the pipe owing to its cheapness, the convenience of replacing worn blades, their ease of operation on account of the narrowness of the cut, and the familiarity of the workman with its use. These characteristics have brought the hack-saw into very extensive use for cutting off metal bars and pipes of all kinds.

Fig. 3. Sawing Arrangement Clamped in Place, ready to begin Cut.

The double hack-saw frame *G* carries the two saws *H*, spaced apart about 3/8 inch narrower than the distance between the valve seats *K* in the valve casings. This permits the pipes to extend beyond these seats approximately 1/8 inch when the middle section has been cut out. The cutting is effected by rocking handle *J*, thereby operating rock shaft *L*, which passes through a water-tight stuffing box into casing *F*. Here the crank *M* transmits the reciprocating movement to connecting rod *N* and then to hack-saw frame *G* with its two saws *H*. With the original construction shown in Fig. 2, the feed of the saw was dependent on the weight of the heavy connecting rod *N*. In the later design shown in Figs. 1, 3, and 4, the feed is effected by a weight mounted adjustably on the horizontal arm shown, which is connected to a second rock shaft passing through the casing and carrying an arm with a roller, which bears on top of the hack-saw frame as it is reciprocated back and forth. By adjusting the weight to different positions on the outside lever, the pressure of the

roller on the saw and the consequent rate of downward feed is altered as desired by the workman.

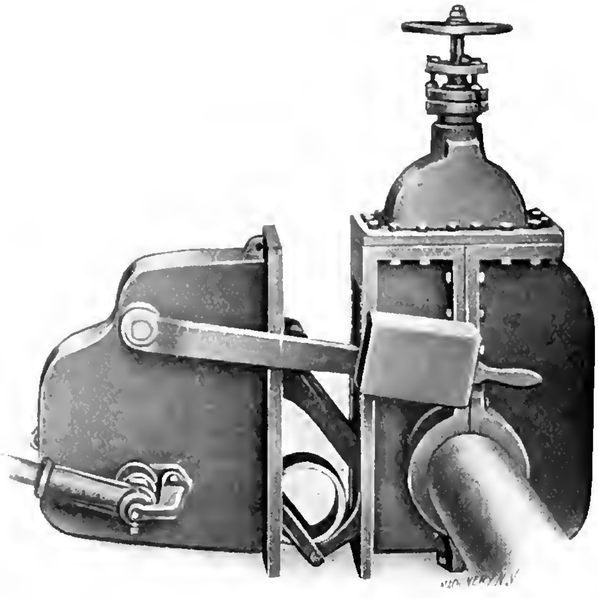

Fig. 4. Removing the Sawing Mechanism and the Severed Section of Pipe.

Use of the Device.

The operation of inserting a stop valve is as follows: After clamping casings *A* and *B* to the pipe and calking them to a tight fit by the means described, casing *F* with saw frame *G* and two sharp saws *H* is clamped into place, with the saws resting on top of the pipe. The workman now rocks the vertical handle *J* back and forth and the two saws begin to cut into the pipe. It is not necessary to fasten dome *C* in place with the valve disks and spindle, until the cut has been properly started, with the saws equally spaced. When this has been done, the dome must be permanently fastened into place, as shown in Fig. 3, before the saws have cut through into the interior of the pipe. The cutting is then continued with the feed weight adjusted properly to suit the conditions, until the section has been cut entirely out of the pipe. By tipping handle *J* back to a horizontal position, the saw will draw the severed section of the pipe back into casing *F*, as shown by the dotted lines in Fig. 2. Then by turning hand-wheel *E*, valve *D* is screwed down into place. This valve is of the type in which the two faces are spread apart to a bearing on flat parallel seats. It is thus possible for them to pass between the sawed edges of the pipe and expand over these onto the valve seats *K* in casings *A* and *B*. When the valve has been thus closed, casing *F* may be removed, as shown in Fig. 4, bringing with it the saws and the separated portion of the pipe. The rectangular opening thus left in casing *A* is closed by a cover plate as seen in Fig. 5, which shows the completed form of stop valve.

Of course, the casing fills with water the minute the saws cut through into the interior of the pipe. To keep this water out of the trench or floors where the workmen are at work, a drain cock is provided which permits the water to be run off into a pail before removing casing *F*. It will be observed that the flow through the pipe is interrupted only for the very few minutes that *F* is being removed and the cover-plate substituted.

The advantages of this device will be readily recognized. It is a comparatively inexpensive machine and can be operated by any competent foreman. It avoids the shutting off of water from customers or from fire hydrants in the case of an unexpected demand for water. It makes possible the installing of new hydrants or the replacing of old pipes with new hydrants having steamer nozzles. Its simplicity, reliability and ease of operation for these uses should make the machine particularly adapted to water works service. The same considerations make the device useful for industrial purposes as well. Not only is it useful for the installation of valves, but it can be employed in every-day shop work for cutting pipe, in which case one saw blade may be removed and special pipe holders attached to the machine.

HART'S "BUCKEYE" RATCHET-DRIVEN DIE-STOCK.

An extended description of the design and operation of the "Buckeye" die-stock, manufactured by the Hart Mfg. Co., 10 Wood St., Cleveland, Ohio, was given in the April, 1908, issue of MACHINERY; a gear-driven, large size die-stock of the same make was described in the January, 1909, issue. As will be remembered from these previous descriptions, the principal feature of the construction of the "Buckeye" die-stock is that the chasers which cut the taper thread on the pipe, and which while not as wide as the length of the thread, will still cut a full length thread of correct taper by means of a mechanism which permits the chasers to recede from the work as they progress along the pipe. Another feature of the die is the provision for automatically releasing the chasers when the full length of thread has been cut. A wide range of sizes may be cut with the same chasers by simply loosening a screw and setting a stop to the required graduation.

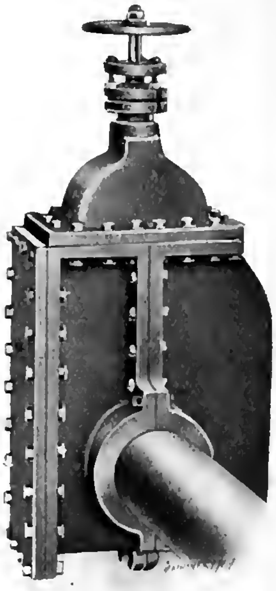

Fig. 5. Cover Plate Clamped in Place, and Valve Ready for Use.

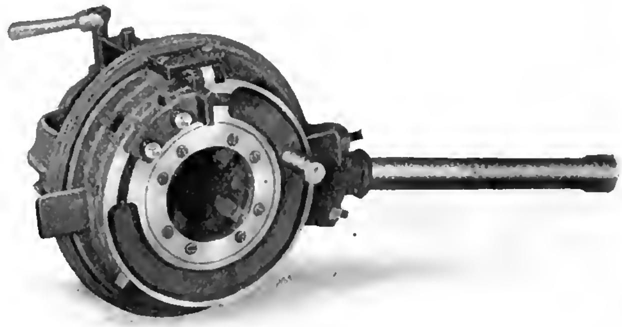
The Hart Mfg. Co. has now brought out a "Buckeye" die-stock provided with a ratchet drive as illustrated in the accompanying engraving. The ratchet is enclosed by a ring provided with a projection into which the handle and two latches are fitted. The latches are so spaced that but one will be in engagement with the ratchet at a time, but the use of the two latches minimizes the amount of lost motion. They can be swiveled around so that the die can be used for cutting either right-hand or left-hand threads. The die-stock provided with this driving arrangement is intended for cutting pipe from one-half inch up to two inches in diameter. It is of especial advantage when it is required to thread pipe in close quarters, as it is not necessary to have more than five inches clear radius around the pipe, and, of course, space enough for working the ratchet handle. All other features of the die-stock are the same as those described in the April, 1908, issue of MACHINERY, mentioned above, where an extended illustrated description was given of the die-stock and the mechanical devices by means of which it is operated.



Ratchet Die-stock for Threading Pipe in Close Quarters.

RANSOM 18-INCH LEVER-FEED DISK GRINDER.

The Ransom Mfg. Co., Oshkosh, Wis., has placed on the market a disk grinder of new design shown herewith. The principal improvements relate to the thrust collars on the

arbor, oiling provisions for the counter-shaft and the use of steel disks in place of cast iron as commonly employed.

The spindle is made of high carbon steel, turned and ground, supported in babbitt lined bearings. The thrust collars have nine square inches of surface, and are made of hardened steel. The disks are also made of steel, and are turned true to within one-thousandth inch on their faces. They are fastened to the collars on the arbor with bolts and nuts, instead of by beveled head screws. These disks are provided with or without grooves, as desired, though it is the builders' belief that better work is obtained with the plain-faced disks.

Improved Design of Ransom Disk Grinder.

The counter-shaft has self-oiling hangers and a ground shaft. The loose pulley has an improved self-oiling bushing fastened to the shaft, drilled full of holes to retain a sufficient supply of oil to last several weeks. This insures lubrication of the loose pulley while the machine is standing still.

With the equipment shown in the engraving, a fixed table is provided at the left having a surface of 6 by 18 inches, square with the face of the disk. The oscillating table at the right has a surface of 7 by 12 inches, provided with two T-slots. The usual adjustments and movements are provided. The disks are 18 inches in diameter by ¾ inch thick. The bearings are 7 inches in diameter by 12 inches long. The counter-shaft, which should make 500 revolutions per minute, has tight and loose pulleys 10 inches in diameter.

DIAMOND DETACHABLE LINK TRANSMISSION CHAIN.

The Diamond Chain & Mfg. Co., 240 W. Georgia St., Indianapolis, Ind., has recently developed the detachable link form of chain shown herewith. It is designed to meet the objection urged at times against the chain drive, on the score that it cannot be conveniently altered in length, and that individual links and blocks cannot be quickly replaced when broken. These difficulties are here obviated by making every link detachable without the use of special tools.

A Chain Separable at Any Point without the use of Tools.

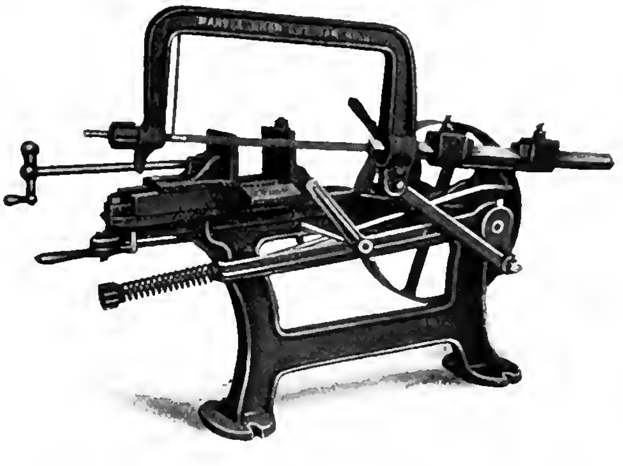
The construction is evident from the engraving. The thin strip steel lock on top of each outside link slips into a groove around a rivet at one end, and, turning about that rivet as a center, enters a similar groove in the other rivet. This thin metal strip is locked in position by being slightly warped inward, and by having at its center a slight projection which snaps into a corresponding depression in the side bar. When so locked, it cannot be removed except by intention.

This new form of chain is being made in all standard sizes, of the same materials and workmanship and at the same price as the makers' regular Diamond riveted chains. The links and other parts of each are interchangeable with each other, and detachable links may be used for replacing those of the older type. The neat appearance and unusually compact design of the new chain are plainly shown in the engraving.

NO. 2 "MARVEL" DRAW-CUT HACK-SAW.

The power hack-saw shown herewith is made by the Armstrong-Blum Mfg. Co., 113 N. Francisco Ave., Chicago, Ill., and is called by its makers the No. 2 "Marvel" draw-cut hack-saw. A number of original features are included in its design. One of these is the method of feed employed; instead of using a weight, as with the usual construction, the saw is pressed down on the work by the action of a compression spring seen projecting from the front of the machine at the left of the engraving. This spring draws on a rod which reaches back to the guiding frame of the hack-saw which is thus forced down into the work. The pressure of the saw on the cut and the consequent rate of feed may be varied by adjusting the thumb-screw against which the spring bears. The pressure of the saw is relieved on the return stroke. This is effected by an eccentric just back of the saw crank, which relieves the compression on the feeding spring as the saw comes back, and stiffens it up again on the draw, or cutting stroke.

Means are provided for raising and lowering the saw frame and holding it in any position. This is a great convenience in measuring. The frame is guided, as shown, by a square bar directly in the line of travel of the saw. The crank by which it is driven is slotted to vary the stroke from 4 inches to 6¾ inches. The wear can be taken up in the bearings of the saw guide rod so as to permit of good work throughout the life of the machine. The drive shaft has bronze bearings. The starting lever and automatic stop are at the front of the machine. This tool has a capacity for work up to 6 by 6 inches on the long stroke, and up to 8 by 8 inches on the short stroke. It takes blades from 12 to 17 inches long.



A Hack-saw with Spring-operated Feed releasing on Return Stroke.

The heavy vise furnished can be swiveled in either direction, so that the cutting of angles is conveniently provided for. The entire vise can be removed, leaving a T-slotted table for holding irregular shapes. The vise itself will be found a useful tool for holding work on the drill press, milling machine, etc.

SEARIGHT COMPOUND-LEVER MECHANICS SHEARS.

The mechanics' shears or snips shown herewith are made by the Detroit Shear Co., Detroit, Mich. They have the advantage, as may be readily seen, of bringing into small space and

convenient form all the power that is obtainable from much larger and heavier instruments. They are designed for small work in all mechanical lines. The tool is 7 inches long, and weighs only 5 ounces, but has the cutting power of a 12-inch tinner's snip.

The arrangement of the levers will be easily understood from the engraving, and it will be seen that a toggle-joint action is introduced which gives a more powerful leverage when the jaws are cutting near their points. In other words, the mechanism is such that the shears cut with equal facility throughout the whole length of the blades. This is a feature not found in other tools of this kind. The blades are curved slightly away from the cutting edges, for cutting circles or square corners. They are made of Ibsen steel, tempered and drawn by the Mallatt process, and nicely finished. These snips will cut tin, soft steel or galvanized iron up to 26 gage, and soft brass or copper up to 20 gage.

A Compact Pair of Snips, with the Power of a much Larger Tool.

MUELLER $2\frac{1}{2}$-FOOT CONE-DRIVEN RADIAL DRILL.

In Figs. 1 and 2 are shown the smallest size of a line of short-arm cone-driven radial drills built by the Mueller Machine Tool Co., Cincinnati, O. These machines are an evidence of a growing tendency to do work on the radial type of machine which was formerly handled on the upright drill press. To meet the conditions of the work for which it is intended, close attention has been given to the matter of providing the greatest possible convenience in operation; in fact, practically all of the conveniences of the builders' line of standard radial drills have been retained. Special effort has been made, however, to produce an inexpensive design, to meet the requirements of purchasers whose work does not require a high-priced radial machine.

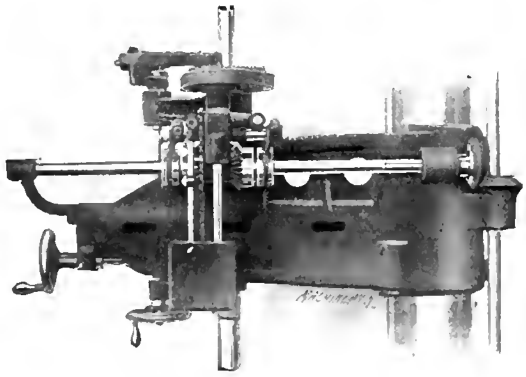


Fig. 1. Rear of Head of Radial Drill showing Feed and Reversing Mechanism.

The framework of the machine is strongly designed and carefully built. The stationary column is of heavy section, bolted to the base by a flange of large diameter. A pipe section arm is employed, which is very rigid against the torsional force produced by heavy drilling. It is clamped to the column by the two handles shown, and is adjusted vertically by a power movement, controlled by an easily reached lever. The head is traversed by a double threaded screw and is equipped with a firm locking device.

Ten changes of speed are provided, immediately available. The correct speeds for all classes of drilling within the range of the machine are shown on a bronze plate attached to the arm, thus enabling the operator to select the proper speeds at a glance and change them while the machine is in motion. A tapping attachment is provided, which is so arranged in connection with an adjustable gage screw as to permit the tap to slip when it reaches the bottom of the hole. The starting, stopping and reversing lever is conveniently located on the head, directly in front of the operator. Four feed changes are provided, so selected as to be especially adapted to high-speed drills. The changes may be made while the drill is at work, the mechanism being similar to that described for another machine by the same builders, in the August, 1907 issue of MACHINERY. Either a positive or a friction feed may be employed as desired. All gears, both spur and miter, are planed to theoretically correct outlines. All shafts as well as the column itself are ground to size.

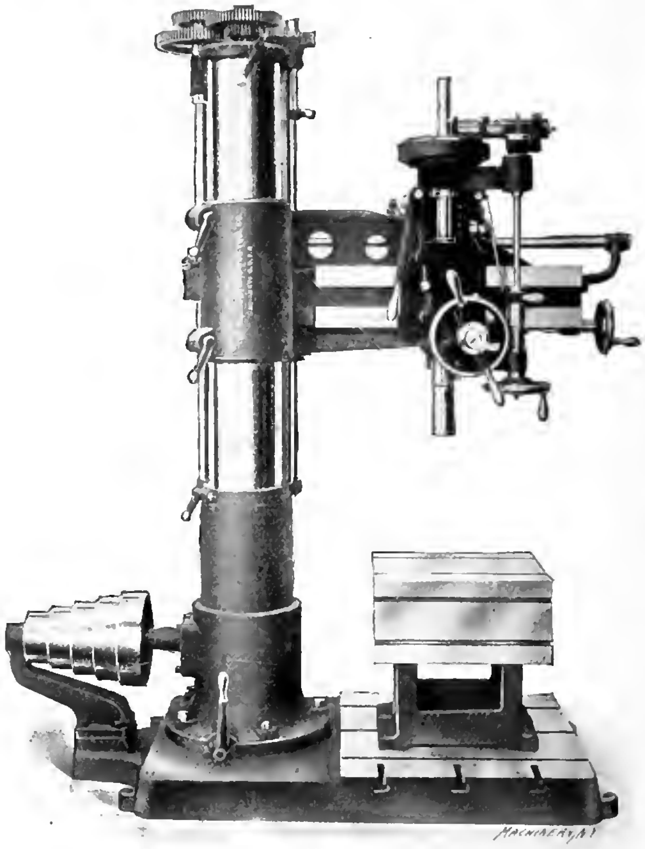

Fig. 2. A Small Radial Drill of Simple and Convenient Design.

Any style of table desired will be furnished. These machines are made in $2\frac{1}{2}$, 3 and $3\frac{1}{2}$ foot sizes.

BLISS DOUBLE CRANK TOGGLE DRAWING PRESS.

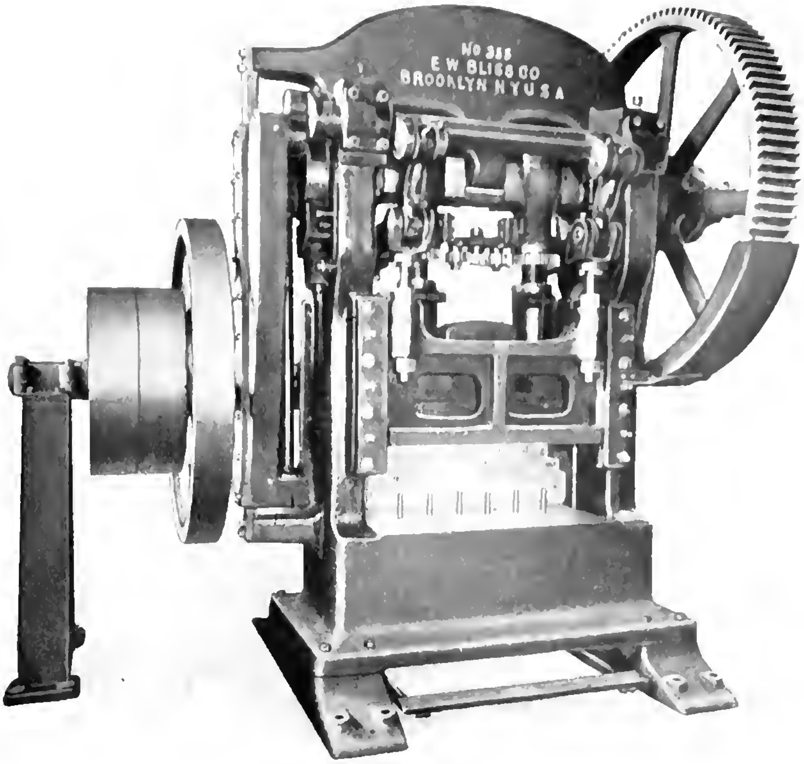
The machine shown herewith, built by the E. W. Bliss Co., No. 5 Adams St., Brooklyn, N. Y., is designed for the simultaneous drawing and stamping of large forms of irregular shapes, such as required for trays, stove tops, seamless roasters and an extended line of similar work. The usual press for work of this kind is of the double crank type, with a spring-actuated blank holder. Where work has to be drawn to any considerable depth, the use of blank holders of this kind is objectionable, since there is a varying pressure on the work, increasing from the beginning to the end of the operation. This means also a larger power consumption than would otherwise be necessary, since the pressure on the blank, if of the proper degree at the beginning of the operation, is much greater than necessary at the bottom of the stroke. In the press shown herewith a toggle mechanism is used which gives an even holding pressure and a consequent reduction in power consumption.

The original design of this press was brought out three years ago. It has been redesigned, however, embodying such changes and improvements in detail as recent experience has indicated to be advantageous. The frame is heavy, and cast in one piece. The crank-shaft is of high carbon, hammered steel, and of very large diameter. The punch slide has its pressure applied by two cranks, which may be adjusted for length simultaneously by means of screw connections which are geared together and work in unison, assuring accurate alignment at all times. This adjustment is effected by the operation of a ratchet lever.

The blank holder slide surrounds the punch slide, and receives the pressure evenly distributed on four points through the heavy steel screws shown. This slide is operated by the makers' patent toggle motion, which has been used with satisfactory results for many years. The toggles which are of steel, are operated from rock-shafts through an outside slide, which is operated by a crank connection on the end of the main crank-shaft. The blank holder slide mechanism is balanced, to avoid undue strains. The construction gives assurance that all the strains borne by the blank holder will be taken up by the press frame. A knock-out is provided, actuated by the blank holder slide.

The press will receive and work a 42- by 22-inch blank of No. 14 gage steel, or smaller blanks of heavier stock in proportion.

It will take a drawing punch 12 by 36½ inches. The press makes 30 strokes per minute, with the driving shaft running at 205 revolutions per minute. The stroke of the punch is 8 inches, and that of the blank holder is 6 inches. The floor space occupied is 12 feet 2 inches, by 7 feet 3 inches over all, and the weight of the machine complete is approximately 42,000 pounds.



A Press for Simultaneously Drawing and Stamping Large Work.

MUMMERT, WOLF & DIXON HIGH-POWER PLURALITY DIE BOLT-CUTTER.

In the August, 1907, issue of MACHINERY, in the department of New Machinery and Tools, we described a plurality die bolt-cutter built by the Mummert, Wolf & Dixon Co., Hanover, Pa. This firm has recently developed a single speed pulley gear-driven machine, illustrated and described herewith, working on the same principle but incorporating a number of improvements in design, especially fitting it for the use of high speed steel chasers.

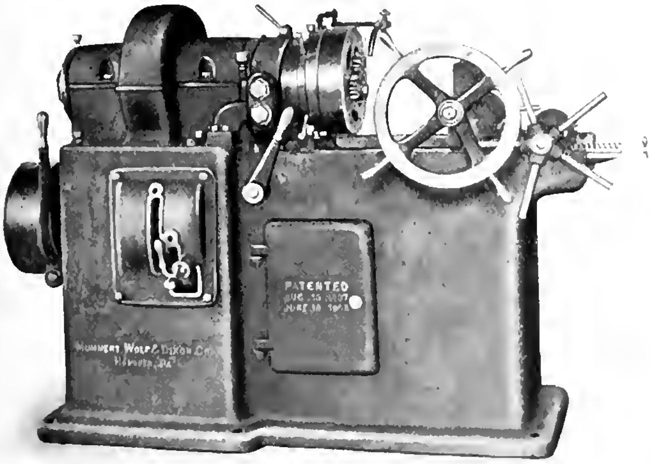


Fig. 1. A Plurality Die Bolt-cutter, adapted to the Use of High-speed Steel Chasers.

The principal feature of novelty in this machine, it will be remembered, is the construction of the die-head. This carries three multiple chasers as shown in Fig. 2. Each of these has six cutting faces, and they may be adjusted so as to cut any one of six pitches of thread. The head in which they are mounted permits adjustment for size without stopping the spindle, by turning the internal threaded collar *A* (Fig. 3) by means of handles *B* with which it is provided. The head is operated either automatically or by hand. The adjusting collar is graduated so that it can be set to the required diameter without the usual cut-and-try operation. The head when closed for threading is positively locked. The multiple chasers shown in Fig. 2 differ from those previously illustrated, in that inserted blades of high-speed steel are employed, set in soft steel bodies.

The driving gearing is plainly shown in Fig. 3. A constant speed driving pulley may be connected or disconnected from driving shaft by the operation of the clutch shown. This makes the use of a counter-shaft unnecessary. The triple tumbler gear arrangement, shown at *C*, operated by the handles seen projecting through the base in Fig. 1, is employed for giving the various speed changes. Any one of the three gears on stud *C* may be set to engage with the driving gear *D* on the spindle. It will be seen that this mechanism is simple and direct. All the gearing is enclosed within a frame. The base has a solid bottom, and is so constructed that all the oil drains to the suction pipe of the pump, which is enclosed within the frame. The oil tank at the bottom is provided with an overflow division, which serves to catch particles of metal which may be carried with the oil past the chip pan *E*. These metallic particles naturally settle to the bottom of the first compartment, while the top oil is delivered to the pump in a fairly well filtered condition, thus reducing the wear on the pump, as well as delivering a clean stream of oil on the dies when cutting. As this oil naturally permeates the mechanism of the head when in

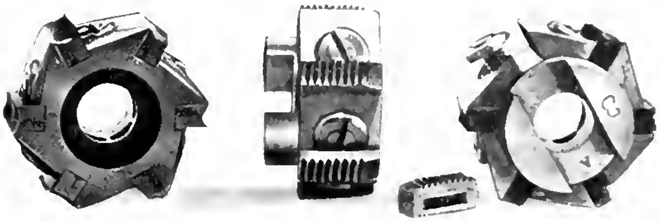

Fig. 2. Style of Chasers used, having Inserted Teeth

use, the grit would otherwise work into the wearing parts and reduce the life of the mechanism to some extent. The vise jaws on the carriage can be adjusted off the center, sidewise, when an irregular-shaped piece is to be held. A dowel pin locks it in the central position.

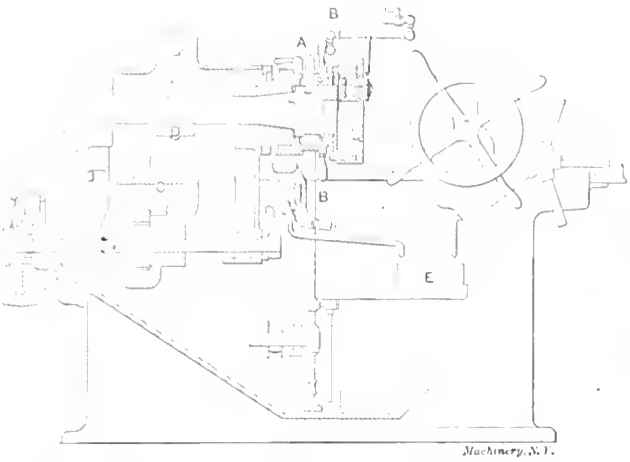

Fig. 3. Section through Machine, showing Driving Mechanism.

MOTOR-DRIVEN GUN BARREL DRILLING AND RIFLING MACHINERY.

The Pratt & Whitney Co., Hartford, Conn., has been known from the beginning of its existence for its line of machinery adapted to the manufacture of fire arms. It has, in fact, done much in the way of completely equipping armories in all parts of the world. The well-known Lincoln milling machine was first developed for this work, and other machine tools now in common use for other purposes were first particularly applied to the making of fire arms. Two most important machines for such work are the gun barrel drilling machine and the rifling machine. The former of these has been adapted to the general drilling of deep holes in ordinary shop practice, as well as for the special work for which it was originally designed. The rifling machine is, of course, still a special tool not used outside of fire arm factories. While retaining their original principles, these tools have been recently redesigned, particularly in the largest sizes, and have been adapted to the motor drive.

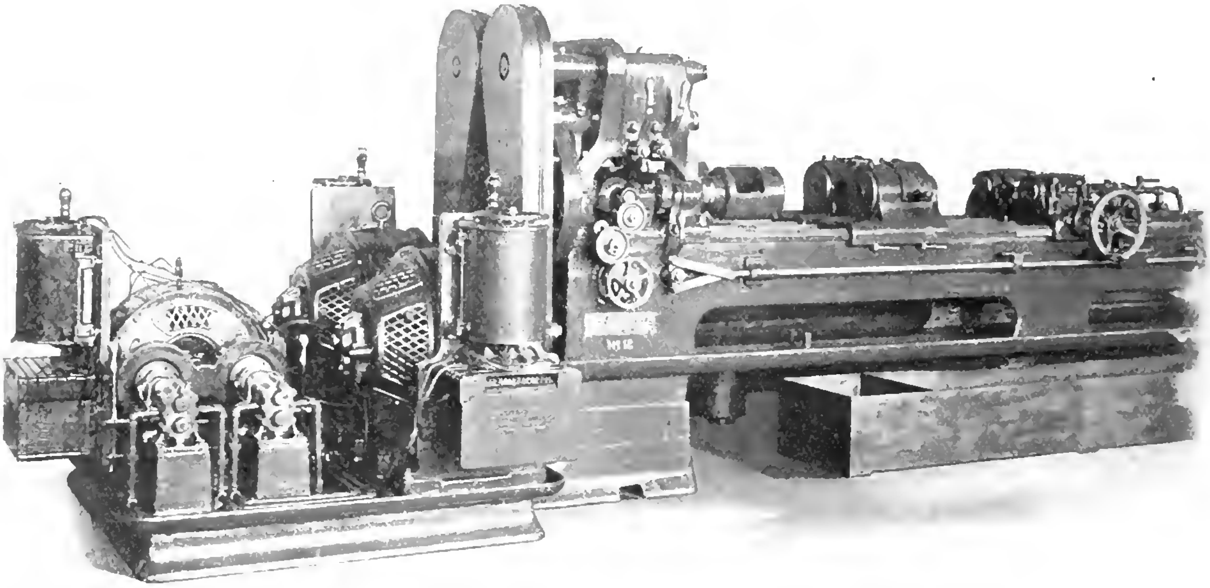

Fig 1. Large, Motor-driven, Pratt & Whitney Gun Barrel Drilling Machine.

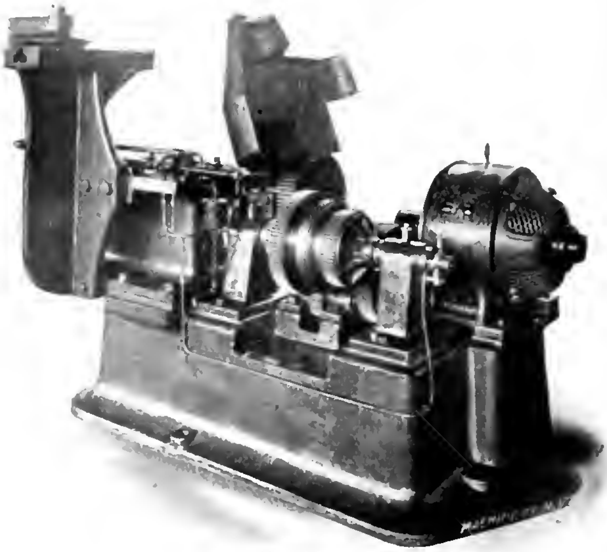

Fig. 2. Driving Mechanism of Rifling Machine.

In Fig. 1 is shown the largest size of the gun barrel drilling machines, called by the makers the No. 12. It is motor-driven, as may be seen, there being a separate drive for each of the two spindles and a third for the oil pumps which form a very important part of the mechanism. The separate drive for the spindles allows the work to be done to the best advantage, as they may be operated as two separate machines. The general arrangement of the mechanism is well-known. On the outer end of the spindles are chucks for holding and revolving the gun barrel, or other part to be drilled. The outer ends of the work are supported by bushings in the brackets shown, which are adjustable to any desired point on the bed. The drill holding carriages are provided with chucks for holding the drills by their shanks. These carriages have independent hand and power feed, driven from the spindles, with automatic knock-off. The mechanism is such that any abnormal resistance to the full cutting action of the drill arrests the feed. Two rotary oil pumps are provided, one for each drill. These continuously force oil from a large tank underneath the machine through telescopic tubing into the drill. The oil not only cools the cutting edges, and gives a fine finish to the work, but serves also the very important office of carrying off the chips from the deep holes. The oil carrying the chips flows into a basin in the tank, where the chips are separated; the oil then returns to the reservoir for use again. In large installations, it is often considered best to install a single high-pressure pump to supply oil to all the machines, doing away with the individual service for each tool. The drill used is of the single lipped type, with a spiral closed channel in its periphery which leads the oil to its cutting edge. This cutting edge is in the form of a series of steps which break the chip and make it more easily

removed by the flow of oil. This is especially useful on large drills, and provision is made for grinding these steps in the grinding machine furnished with the equipment.

Four sizes of rifling machines are made, of which the largest (the No. 5) is shown in Figs. 2 and 3. This has a head for holding and indexing the gun barrel, and a sliding carriage, provided with a spindle for carrying the rifling bar. Over the carriage is a bracket, as shown, carrying an adjustable taper bar, which, in combination with the longitudinal movement of the sliding carriage controls the rotation and pitch of the rifling bar, by means of a transverse movement given to a cross-slide, carrying a rack; the latter is in mesh with a gear on the rifling bar spindle. The taper or former bar is pivoted at the central point, and may thus be adjusted to give a true helix of any desired twist. Where an "increased twist" is required for the rifling, the form bar is curved to suit the requirements.

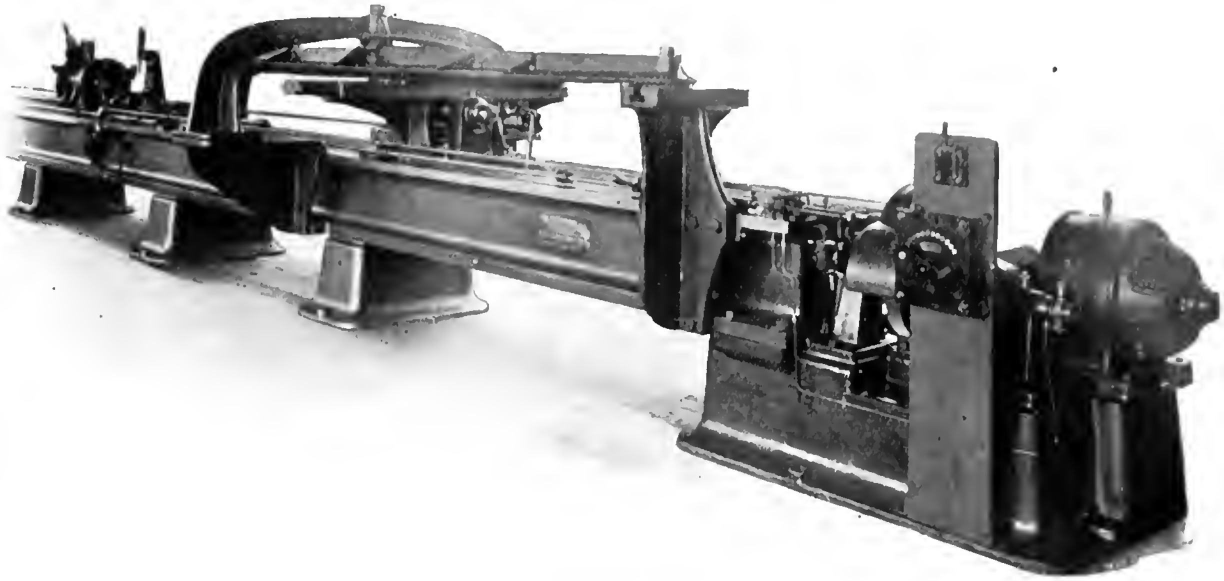

Fig. 3. No. 5 Rifling Machine.

The carriage travels backward and forward continually, being controlled by an automatic reversing mechanism. In the case of this large machine a pneumatic control is employed. A stop rod which extends along the front edge of the bed in Fig. 3, operates a valve at the upper left of Fig. 2, controlling the air pressure in pipes leading to each end of the reversing spindle shown in the foreground. This reversing spindle has two loose gears mounted on it, driven directly and through intermediate gearing from the motor, so as to run in opposite directions. The friction clutch pneumatically controlled by the valve just mentioned, connects either of these gears with the shaft, which, in turn, carries a pinion meshing with the driving gear of the lead-screw which operates the sliding carriage.

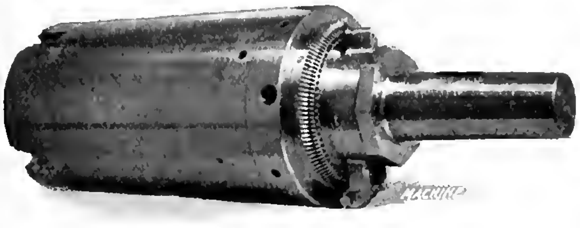

Fig. 4. A Large Rifling Head, showing Rotating Adjustment.

Fig. 5. End of Rifling Head, showing Adjustment for Depth of Cut.

In the smaller machines, the work is indexed automatically at the end of each stroke. On the larger machines this indexing is done by hand. Suitable provision is made for getting rid of backlash in the indexing device. The smaller machines also are completely automatic, to the extent that after the carriage reversing dogs and stock nuts are adjusted, and the barrel is placed in the head and clamped, the machine, being started, causes the carriage to travel backward and forward continually, indexing the rifling bar head at the end of each stroke, and feeding out the cutters automatically until the grooves have been cut to the proper dimensions. The feed is then discontinued, and the machine is stopped by the operator for the removal of the work.

Figs. 4 and 5 show the form of rifling tool used for large work. The whole tool may be rotated for adjustment around the bar, to match grooves previously cut. The tool cuts on the draw stroke, producing grooves free from chatter marks. The blades are automatically withdrawn from contact with the work on the return stroke, so that the slot and the keen edge of the cutters are preserved from damage. In smaller work, of course, a single bladed cutter is used, in which the automatic feeding and relieving provisions are retained. Mechanism is provided to automatically remove any chip that may lodge in front of the cutter.

LYON EXPANSIBLE STEEL RACKS WITH ADJUSTABLE SHELVING.

The Lyon Metallic Mfg. Co., Aurora, Ill., has developed a system of steel rack construction, combining to an unusual degree the qualities of strength, convenience, adjustability and simplicity. The manner in which the details of the design have been worked out, as shown in the accompanying illustrations, gives evidence of careful thought, and full appreciation of the requirements which shop furniture of this kind must meet.

As is shown in Fig. 1, the rack is built up of upright partitions, tie-rods and shelving. The shelving rests on the tie-rods which are made in separate lengths for each section, but are threaded together onto continuous rods for all shelving on the same level. The tightening of the rods puts them in tension, and the flanged edges of the shelving in compression, making as rigid a construction as is possible for any structure built of members placed at right angles to each other. The strength of the various members and their method of holding permits each section to take care of its own load, without requiring the additional stiffening effect of adjoining members. When a number of units are bound together, how-

ever, the carrying capacity is increased above that guaranteed. The stated capacity of the shelves makes provision for uneven loading, so that care does not have to be taken in this particular. No diagonal braces are required, thus making the shelving equally accessible from front and back.

The upright partitions are made of 20-gage cold-rolled sheet steel of special manufacture. The edges are faced and bound on each edge with doubled and beaded strips of 12-gage steel, which greatly increase the stiffness of this member, which is specially rolled from a metal high in carbon. The upright partitions are alike on each face and each end, so that they may be assembled either side to, or either end up. The face strips are all punched with holes spaced on 3-inch centers, thus permitting the adjustment of the shelving to 3-inch dimensions.

The shelves are each made of a single piece of No. 16 gage, patent leveled, cold-rolled steel. The front and back of the shelf is given three continuous right-angled turns, each, as is shown in Fig. 3, leaving a smooth 1-inch surface at the front of the shelf, an equal parallel surface underneath, and an inner flange projecting upward inside. This makes a smooth finish and strengthens the shelf, as well, at the points where strength is most required. This strength at the front and back of the shelf is increased by the tie-rods which pass through and immediately in back of this flange. This is the place where an overload is likely to occur, as it is natural when hoisting a heavy weight into position to raise it a little above the shelf and drop it on the edge of the shelf for a rest before it is pushed into place. The shelves are reversible, and fit snugly against the partition so that even the smallest materials are prevented from dropping through.

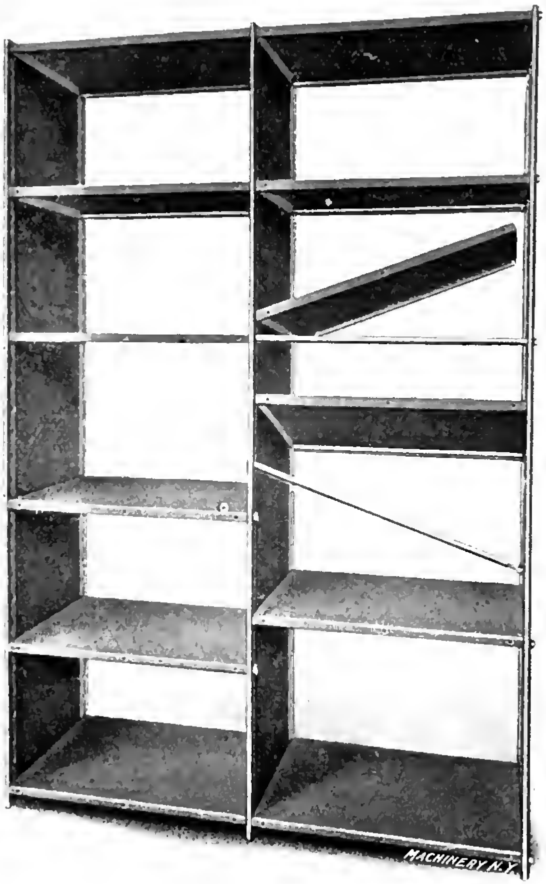

Fig. 1. Sectional and Expansible Steel Rack.

The connecting rods, shown in Fig. 2, by which the vertical sections are tied together and the shelves supported, are made, as explained, in lengths to suit the width of each section. They are made of No. 16 gage, but jointed steel tube, 7/8 inch in diameter. Each tube is fitted at the end with a threaded stud-bolt, which is brazed in place. At the other end is a steel bushing, which is tapped to receive the stud-bolt of the adjoining rod. At the outside of the partitions, tap bolts are used at one end and nuts at the other, as is also the case where a shelf is at a different height from those in the adjoining section. Making each rod the length of the shelf permits independent adjustments. A simple pin wrench entering the holes shown in the tubing is used for screwing the parts together.

Numerous special conveniences are provided for adapting this shelving to the varied work of the customer. Fig. 3 shows an attachment which converts the shelf into a bin, when it is desired to store loose materials. This can be fitted to flat shelves already in position, without making any alterations whatever. It is locked over the front flange of the shelf, as shown, thus forming a tight joint for the whole length of the front. Adjustable angle clamps fasten it to the vertical partitions at the ends. This attachment makes the shelves so tight that leakage is prevented even when such materials as seeds and other fine stuff are placed therein. The interlocking flange at the bottom prevents the attachment from bulging out, even when subjected to pressure from within. At the same time it strengthens this shelving against both vertical and lateral strains.

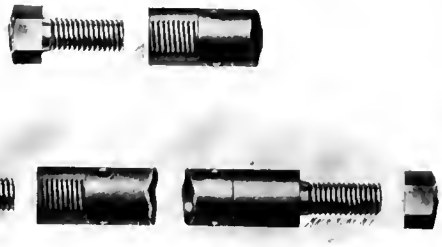

Fig. 2. Design of Tie-bolts used for Holding Rack together and Supporting Shelves.

A shelf extension is provided which may be used on the lower portion of the rack after the regular shelves have been installed, to increase their capacity, or to convert them into large bins. They consist of upright partitions of the same construction as the uprights, which are attached to the facing strips of the racks already in position by means of clips. The shelves can then be installed on a line with the rack shelving, making one continuous shelf throughout.

A number of minor conveniences are provided. Label holders are furnished for attachment to the front of the shelves. They are held in place by three longitudinal clips or tongues punched on the metal, which register with corresponding square holes in the face of the shelf. They are fastened in place by pressing them backwards with a special tool provided for the purpose. When it is desired to use boxes in the shelving reaching approximately half the depth of the shelf, a box stop is fastened to the center of the shelf, which prevents the box when being pushed into position from displacing another immediately back of it. A back stop for the rear side of the shelf may also be provided when large boxes are to be stored from one side only; or, if desired, complete backs may be fastened to each section of shelving by means of clips.

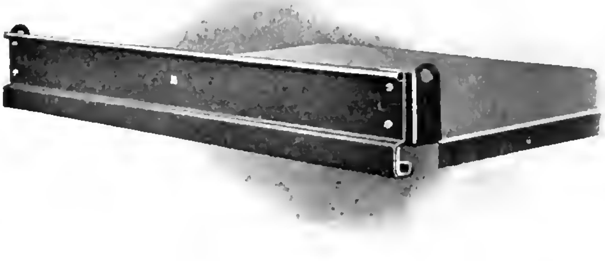

Fig. 3. Rim Attachment for Converting Shelf into Storage Bin.

Removable partitions are provided by means of which shelves may be divided lengthwise from end to end. The shelves are punched with holes every six inches for this purpose. The partitions are the same depth as the shelves, and are furnished in heights to fit into the clearance permit-

ted by the 3-inch height adjustment. Bracket shelves may be attached to any sections or to all the sections in a series. They are fastened to the uprights, and are convenient for resting boxes when desired, or as a counter for sorting material. They are strong enough to hold the weight of a man should it be desired to use them for a step for reaching shelves higher up.

These shelves are furnished in a wide variety of sizes to fit every imaginable requirement on the part of the customer. While no effort has been made in the way of ornamentation, the simplicity of the design and the general smoothness of finish give the whole arrangement a strong and pleasing appearance. All the parts are regularly finished in a good durable quality of black enamel, which protects the metal as well as adding to its attractiveness. Other and lighter colors may be used if it is required. This is advisable where the room in which the racks are to be used is dark, as the light will be increased by reflection.

FILING ATTACHMENT FOR THE POWER HACK-SAW.

In the department of New Machinery and Tools of last month's issue of MACHINERY, we illustrated the "Royal 1909" power hack-saw made by the Robertson Drill & Tool Co., 1848 Niagara St., Buffalo, N. Y. It will be remembered that in this machine, the drive is carried in a frame *A*, pivoted about the driving shaft. As this frame also carries the guides *B* for the saw holder, it is possible to tip the whole mechanism to any position about the axis of the driving shaft. This peculiarity of construction allows the saw, with suitable attachments, to be used as a filing machine in the way illustrated in Figs. 1 and 2.

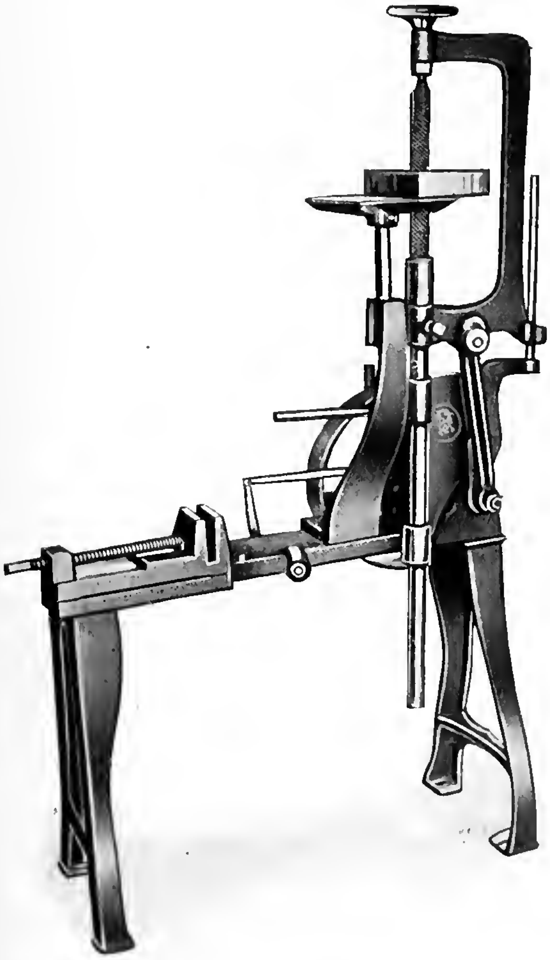

Fig. 1. Robertson's "Royal" Power Hack-saw arranged to be used as a Filing Machine.

The filing table *D* and supporting arm *C* are mounted on the bed. The file *E* is supported at its lower end in a cone-shaped cup *F* set on a stud where the saw is ordinarily connected. On the upper end is a special threaded socket *G* having a hole to receive the file tang, on which it is tightened by a knurled nut. The swivelling adjustment of the hack-saw frame provides for the filing of any desired angle, or relief for die work. It can be used for the regular work of the filing machine for cutting out the centers of dies, etc. This device can be applied to the machine at any time, as proper provision for attaching it is made in the original design.

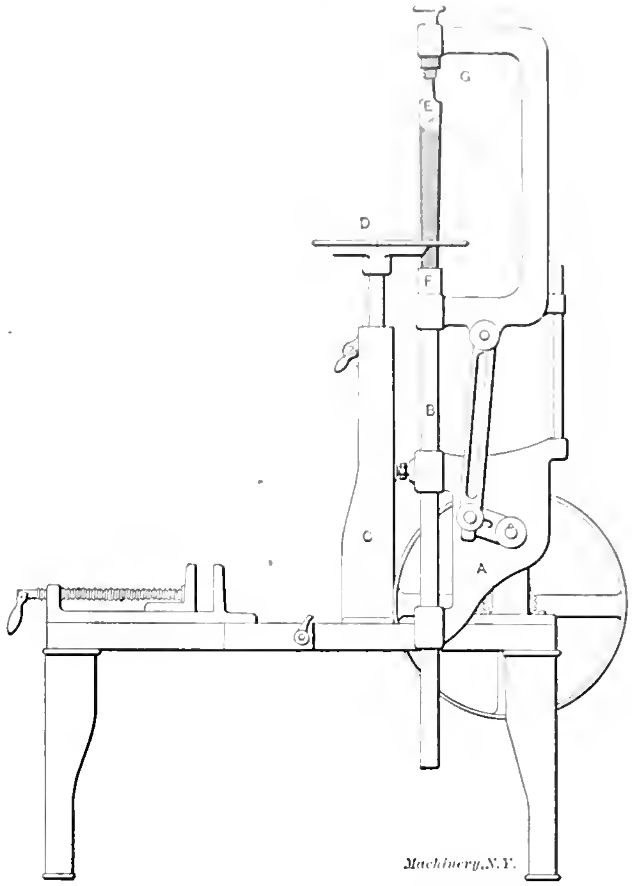

Fig. 2. Details of Mechanism of Filing Attachment.

GRAHAM KNURL HOLDER FOR TURRET MACHINES.

The Graham Mfg. Co., Providence, R. I., is making the knurl holder shown herewith. It is adapted to be used in the turret heads of lathes, screw machines, chucking machines, etc. The advantages of this tool are, first, that it is adjustable to any size within its range (that is, for work up to 2½ inches in diameter by 2½ inches long); second, the knurls work on opposite sides of the material, so the pressure is equalized and there is no tendency to push light stock to one side, and it is thus possible to knurl to a very small diameter; third, it leaves the cross-slide tool-post free for the use of any special tool that may be required, not suitable for the turret head itself.

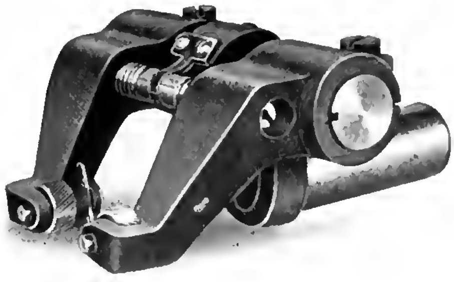

Fig. 1. An Adjustable Knurl Holder.

The knurl holder is held by the usual round shank *A*, of a diameter to fit the hole in the turret. This shank is bored to permit the passage of long work, and has an offset boss holding a finished bar of stock *B*, on which slide two projecting arms *C*, to which the knurls *G* are pivoted. Bar *B* is splined to engage a key on each arm *C*, thus holding the

knurls in line with the axis of the shank. A right- and left-hand screw *D* is threaded in tap holes in the two arms. It is locked against endwise movement by clip *E*, which engages a recess turned in its shank. By turning this screw with an ordinary screw-driver, the arms are adjusted to suit different diameters of work. When the correct size is obtained, the clamping screws *F* in each arm lock the adjustment.

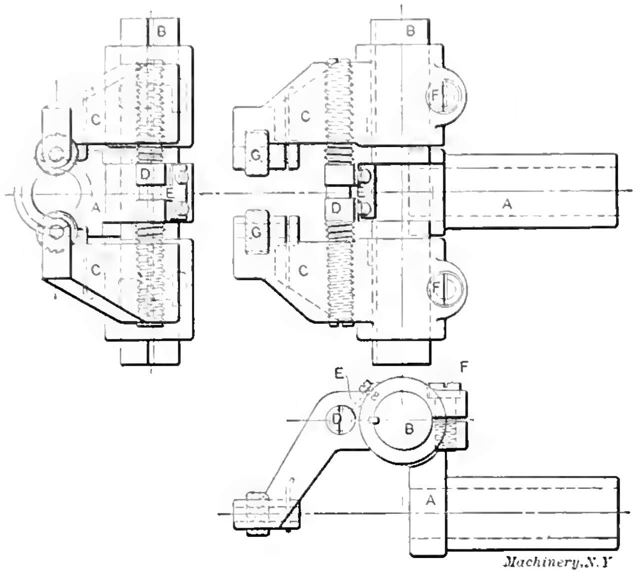

Fig. 2. Construction of Knurling Tool.

The peculiar shape of the tool is the result of experiment in giving a construction which would clear the other turret and cross-slide tools, and would at the same time be simple to manufacture. The device may be fastened in the turret at any angle that may be necessary for clearance, or to bring it to a position where its work can be watched by the operator.

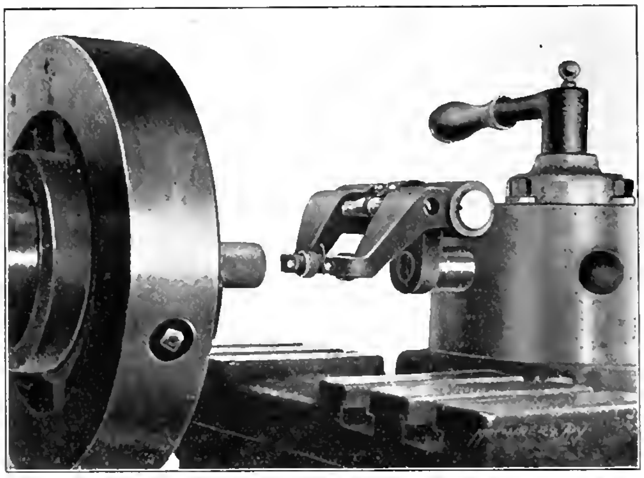

Fig. 3. Tool in Use in Turret Lathe.

The knurls *G* are mounted on pivots, which are held in place as shown by wire springs with projecting ends, which enter notches cut in the pivots. These notches are provided at each end of the pivots, so that the latter may be reversed, doubling their life so far as wear is concerned.

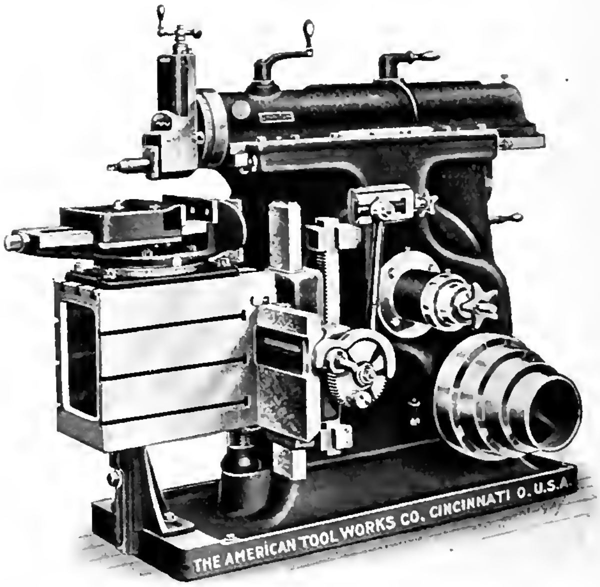
AMERICAN TOOL WORKS BACK-GEARED CRANK SHAPER.

The accompanying engraving shows the 21-inch size of a new line of back-geared crank shapers built by the American Tool Works Co., Cincinnati, O. These tools are of new design throughout, based on the results of investigation into the needs of shaper users, and experience of these tools in the shops of builders. They are intended to combine the accuracy required in tool-room work with the qualities demanded of a machine which is to be used for manufacturing purposes.

An inspection of the illustration shows that much care has been taken in the design of the column and other main members of the structure. The column, base, ram and table are all of heavy section and internally braced. The column projects both front and rear at the top, providing a very long bearing for the ram. The latter is designed to give uniform rigidity as nearly as possible throughout the length of the stroke. Its bearing on the column is taken up by a continuous taper gib, with end-screw adjustment for wear. The apron is similarly gibbed to the cross-rail, which is of box form and strongly ribbed. An improved arrangement of the bearing on the column prevents the cross-rail from dropping when the binder bolts are loosened. A telescopic elevating screw is provided to obviate the necessity for boring holes in the floor.

The stroke of the ram can be varied from 7.7 to 96 per minute with eight changes. The length of the stroke can be adjusted without stopping the machine, as can also the positioning of the ram, effected by turning the crank shown just back of the head. The rocker arm is heavy and thoroughly braced, and operated by mechanism so proportioned as to give a nearly uniform rate of speed throughout the entire stroke. A convenient self-locking lever at the rear of the machine throws the back gears in or out. The driving ratio with back gears is 24, 3 to 1, which, with the large cone pulley used, gives great driving power.

The cross-feed, as may be seen, is of the planer type, which does not have to be adjusted in any way when raising or lowering the table. It can be set to give from 0.008 to 0.200 inch when the machine is running, by means of the slotted crank shown. The feed is thrown in or out or reversed by a knurled knob on the large feed gear.



A Back-geared Shaper designed for both Accuracy and Output.

The gears are of coarse pitch and wide face, with pinions cut from bar steel. The bevel gears are planed from solid. All the shafts are of high carbon crucible steel, ground to accurate size. All the points of danger are protected, while easy access is provided to the working parts by a large door on the rear side. Special attention has been given to the matter of lubrication, for the sake of insuring long life and service from the machine. The ram slides are protected and provided with felt wipers, and are oiled from central pockets. The distribution is effected from the wipers, which distribute the lubricant throughout the whole length of the slides, thus doing away with oiling through a multiplicity of holes. Waste oil is received in a pocket at the rear of the column, where it may be drawn out from time to time. A large quantity of oil is stored in a pocket in the arm, which is distributed for the crank-pin and sliding bracket in the rocker arm.

These shapers are made in six sizes, the 15, 16, 18, 21, 25, and 30 inch stroke respectively, all being back-geared with the exception of the 15-inch stroke. The machines are regularly furnished with the heavy vise shown and with all necessary wrenches. At extra cost, the makers will provide a table support, an automatic feed stock for the cross-rail, power down feed, circular attachment, special vise and table

for mold-makers, tilting top for box table, universal table with tilting side, four-speed gear box, and electric motor drive.

CHICAGO BENCH FILING MACHINE.

The bench filing machine shown herewith (built by the Chicago Filing Machine Co., 5-17 West Madison St., Chicago, Ill.) is particularly adapted to small die work. It has a number of advantages in the way of simplicity, improved methods of holding the file, and ease of operation.

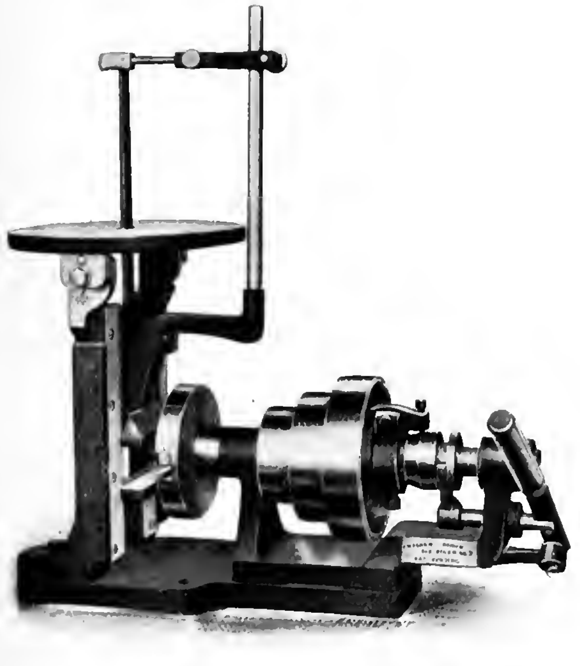


Fig. 1. Bench Filing Machine, suitable for Die Work.

The file holder is shown in Fig. 2. It consists of a tilting base *A*, against which the tang of the file *C* is clamped by two knurled screws *B*. This operation permits the file to be adjusted to bring it to the proper position for the top clamp, without danger of springing it. It will also grasp the outer end of the file as firmly and safely as the tang, so that the machine may be arranged to cut on the down stroke as well as the up stroke, where this is found desirable. It will be seen that the matter of changing the file is one of the greatest simplicity. The upper support may be swung out sideways, to remove the work for inspection without affecting the adjustment of the file.

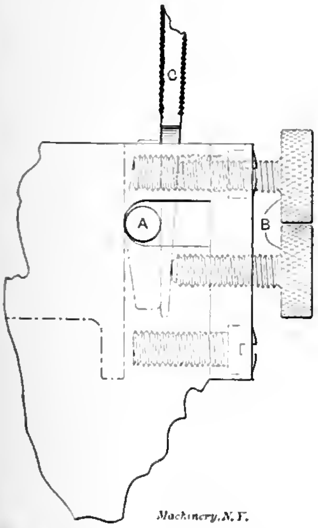

Fig. 2. Clamp for Gripping File.

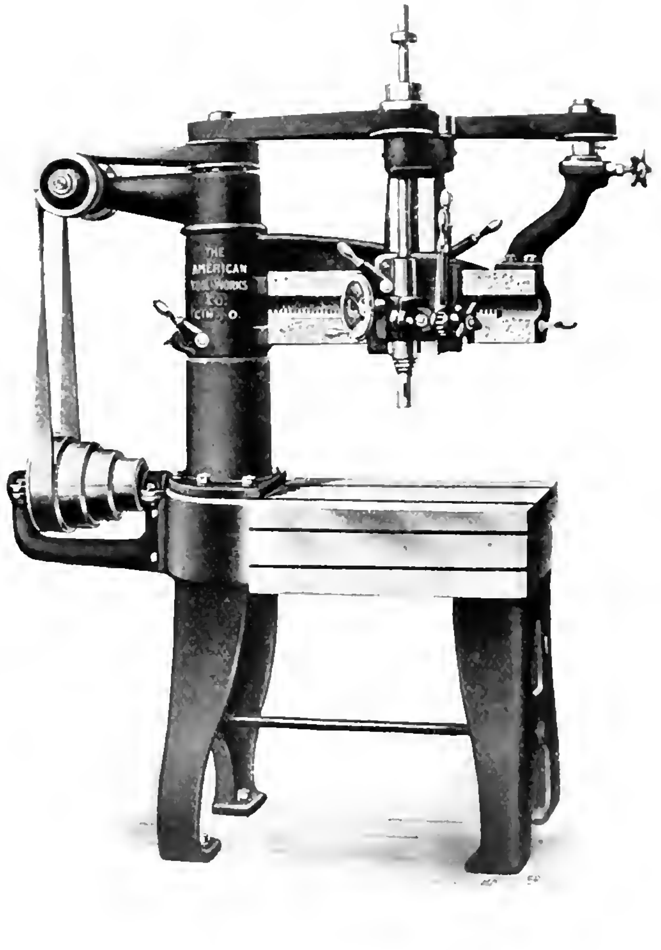
As shown in Fig. 1, the machine is provided with a clutch for quick starting and stopping. The counter-shaft furnished carries a three-step cone and tight and loose pulleys. The file slide has V-bearings, with adjustment for wear. The table is 8½ inches in diameter and tilts 10 degrees either way. The height to the top of the table is 11 inches. The weight of the machine and counter-shaft is 70 pounds.

AMERICAN TOOL WORKS SENSITIVE RADIAL DRILL.

The half-tone illustration shows what we believe to be the first sensitive radial drill, of the standard radial form, made in America. As may be seen, the spindle is carried on a head adjustable in or out on a swinging arm, while the work is supported on a stationary table. This tool is particularly adapted to the use of small size drills up to ¾-inch, on parts of small or moderate size. This includes such work as the drilling of switchboards, automobile chassis, cash registers, harvesting machinery, etc. The machine combines the sensitiveness of the high-speed drill with the convenience and effectiveness of the radial type.

The general design of the machine provides for locating all levers directly at the operator's hand, so that the movement of the head and arm and the feeding of the spindle are quickly and easily accomplished. The arm is of parabolic beam and tube section, to give the proper resistance to bending and torsional strains. It is unnecessary to raise it and lower it, as provision for variable heights is made on the head. This latter consists of a main saddle, sliding on the arm, which carries an auxiliary sliding-head on a vertical dove-tail. The adjustment for the height of work is made by raising and lowering this supplementary head. The adjustment along the arm is effected by a rapid-action rack and spiral pinion. Suitable clamping handles are provided for all adjustments, and full provision is made for taking up wear.

The driving mechanism obviates the use of gears entirely. A double, loose pulley revolving on a vertical stud at the top of the column, is driven from the cone by a belt, and in turn drives the spindle by a flying belt arrangement, giving a constant tension at all positions of the arm. This tension is adjusted by shifting the position of the idler at the extreme right of the arm. The spindle has six changes of speed, ranging from 300 to 900 revolutions per minute in geometrical progression. It is fed by a long hand-lever and a ratchet wheel, whose latch is self-releasing when in the vertical position. An adjustable stop collar is provided which can be used as a depth gage. A convenient star wheel gives a quick return movement. The table is of the height to enable the average operator to conveniently stand to his work. Both top and front sides are fitted with T-slots planed from the solid, and the back end is planed for convenience in squaring up work, etc. The column is of tubular section, internally ribbed, and extends through the arm to the back at the top of the machine. It is firmly bolted to the top of the table.



A Sensitive Drill of Standard Radial Construction.

Experiments with the smaller sizes of this machine have shown that in ordinary shop practice a ¾-inch drill, making

375 revolutions per minute (73.7 feet per minute cutting speed) will feed at 0.028 inch per revolution in cast iron, drilling at the rate of 10½ inches per minute and consuming 3¼ H.P. The drill is made with either a 2-foot or 3-foot arm, having the same general dimensions, except that the latter machine has a longer table, giving a working surface on top of 20 by 40½ inches. The maximum distance from the end of the spindle to the top of the table is 19 inches, while the maximum distance from the spindle to the floor is 54 inches, the table being 35 inches high. The regular equipment includes a 2-speed counter-shaft without the belts. This machine is built by the American Tool Works Co., Cincinnati, Ohio.

REYNOLDS MACHINERY CO.'S GEAR-HOBBING MACHINE.

In the August, 1908, issue of MACHINERY, we illustrated a spur gear hobbing machine made by the Moline Tool Co., which involved the very interesting and valuable principle of a fixed angular position of the work spindle with relation to the cutter spindle. This resulted in an unusually simple design of machine. The rights to this machine have been acquired by the Reynolds Machinery Co., of Moline, Ill., which has redesigned it and taken, it would appear, very full advantage of the possibilities offered by the original principle involved.

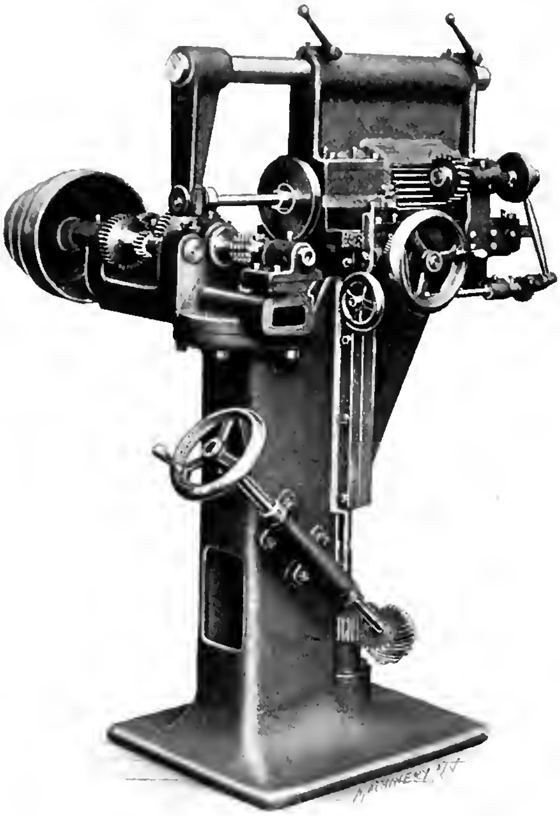


Fig. 1. Gear-hobbing Machine for Hobs of Fixed Helix Angle.

As has been explained in MACHINERY,* in a gear-hobbing machine the cutter spindle has to be set at an angle with the work spindle to agree with the helix angle of the hob, it being necessary for the teeth of the latter to mesh with the straight parallel teeth of the gear to be cut. In this machine this angle is kept constant by varying the pitch diameter of the hob in direct ratio with the circular pitch of the gears being cut, thus making the angle of all the hobs the same. In fine pitches, when this would bring the diameter too small, multiple threaded hobs are used to bring them up to reasonable dimensions. It will readily be seen that the avoiding of the swiveling adjustment of the cutter slide makes possible a simplification which is radical, to say the least.

Figs. 1 and 2 show right- and left-hand views of the machine, respectively, while Fig. 3 gives a top view, indicating the driving and feed connections somewhat more clearly. The work spindle is mounted on a carriage which is fed horizontally along the top of the knee during the cutting action. The knee on which this work-slide travels is vertically adjustable on the column for diameter of work and depth of cut, by the operation of the inclined hand-wheel shaft at the right of the column. The head carrying the hob is fixed in position at the constant cutter angle on top of the column. This makes the problem of bringing the power to the hob as simple as that of driving a milling machine spindle, as there is no need of bevel gears, splined shafts, universal joints or any other similar devices to compensate for the adjustment it is usually necessary to provide. It will thus be seen that the machine is, structurally, of great simplicity.

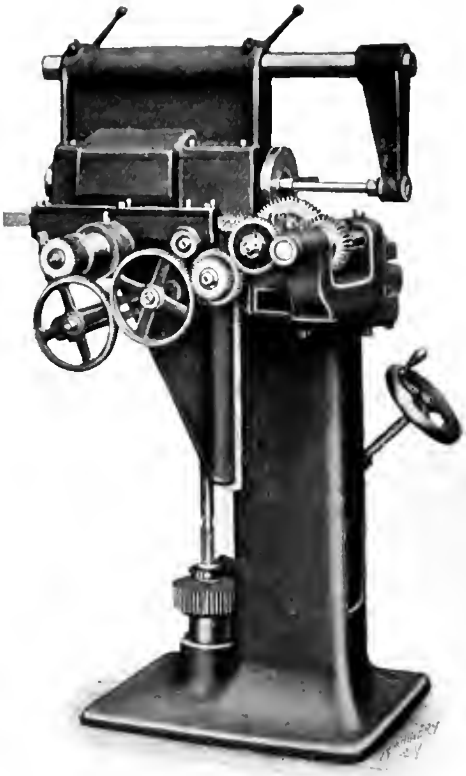

Fig. 2. Left Side of Machine, showing Spindle and Work Drives.

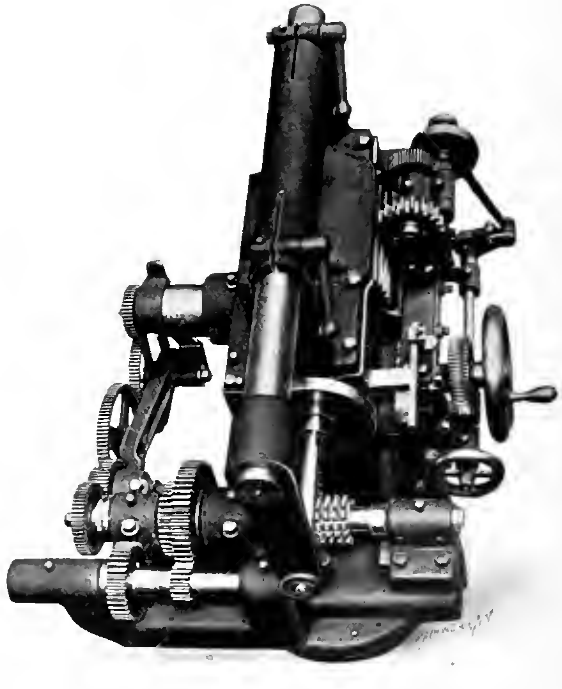

Fig. 3. Top View, showing Back-geared Spindle Drive, Automatic Feed, etc.

That the machine is also simple in its mechanism will be realized by tracing the connection between the hob-spindle and the work, and comparing it with the complication usually

---

* Article on "Gear Cutting Machinery," March, 1908, Engineering Edition.

found necessary for this. The broad face spur gear to which the work-spindle is keyed, is driven by a worm of the same thread angle as the hob. Setting this worm to mesh properly with the parallel teeth of the work-spindle driving gear, brings it into parallelism with the cutter spindle, so that the matter of connecting them to secure the proper rotary speed of the work is as simple as that of gearing the lead-screw of a lathe. The change gearing is mounted on a swinging arm, pivoted to the cutter spindle head at one end, and suspended from the vertical adjustable knee at the other, so that it is possible to adjust the latter for the depth of cut without throwing the gears out of mesh.

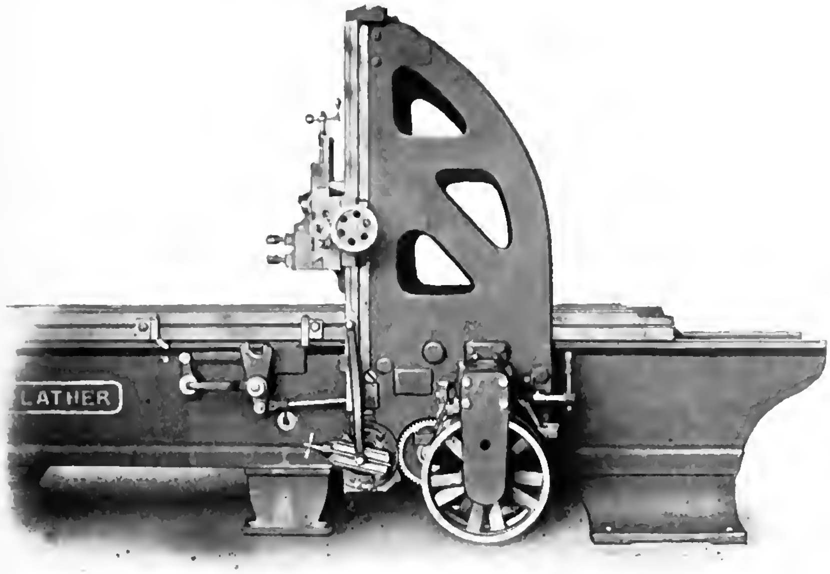

Fig. 1. Thirty-inch Flather Planer, with Two Forward Speeds and Constant Quick Return.

The feed of the work-slide or carriage is effected by two racks on the under side, driven by pinions in a shaft fixed in the knee, and terminating in the hand-wheel shown at the right in Fig. 2. This feed is operated through the worm gearing shown, from a ratchet mechanism, driven by an adjustable slotted crank connected with the work driving gear. An automatic stop is provided for the feed. This, as is plainly shown in Figs. 2 and 3, operates by dropping the feed worm from engagement with the wheel on the pinion shaft. The broad face of the work driving gear permits the full travel of the slide without disturbing its proper mesh with the worm by which it is driven from the hobbing spindle. The racks by which this slide is fed are approximately in line with the thrust of the cut, being a little below on small gears and a little above on large gears. This reduces the wear on the carriage and equalizes what wear there is, so that there is little tendency for the bearings to wear loose in the middle.

The work arbor has a substantial outboard support, as shown, which greatly increases the capacity of the machine and the quality of the work, since it avoids the chattering which often limits the output on work of this kind. The machine is driven by a three-step cone and a 3-inch belt. The hob spindle is back-geared with the driving shaft througn the sliding gear connection shown, giving six changes in geometrical progression. The drive has been proportioned with special reference to high-speed hobs, which it is guaranteed to be capable of driving to their limit. The size shown will cut up to 6 diametral pitch in steel and 5 pitch in iron. The dimension limits are 12 inches pitch diameter and 6-inch face. The machine weighs about 1,400 pounds. It is expected soon to place other sizes on the market.

FLATHER TWO-SPEED PLANER WITH CONSTANT RETURN.

The Mark Flather Planer Co., Nashua, N. H., is building the two-speed planer shown herewith, which is designated as the "Rapid Action" type. In the minds of the builders, there are serious objections to many of the methods which have been tried for increasing the ouput of the planer Some of these designs have been commercially successful, while others have not held their places as factors in the field. Among the new constructions which have been tried are: Accelerating mechanisms for the forward stroke and for the return stroke; and planers with 2-, 4- and 6-speed drives, some mounted in the countershaft, others on top of the housings, and still others in the bed. In bringing out the design, shown in Figs 1 and 2, it has been the aim to avoid some of the objections of the other plans mentioned above. Particular attention has been given to reducing mechanism, too much of an opportunity for wearing, a tendency towards vibration and other similar drawbacks.

It was considered in designing this machine that two speeds for the cutting stroke would practically cover all conditions, since the planer, while requiring a variable cutting speed, does not demand so wide a variation as other machine tools. In practice, it was concluded that a slow speed for roughing and a higher one for finishing, cover the requirements satisfactorily. The planer here shown has been provided with a new shifting mechanism, and has two speed changes in the bed, as shown plainly in the line drawing in Fig. 2.

The usual belts and driving pulleys are retained. *A* and *B* are the loose and tight forward-stroke pulleys, while *C* and *D* are the loose and tight quick-return pulleys, respectively. The loose pulleys are of wider face than the tight pulleys, and unlike the latter, which are made as light as possible, are provided with heavy balance wheel rims. The purpose of this is to assist in the reversing of the machine without throwing the usual destructive strain on the high-speed belting. Light, double 2¾-inch wide belts are used, without slipping or flapping. It will be noted that these belts are wider than the tight pulleys *B* and *D*. This means that they are constantly in contact with the balance wheel pulleys *A* and *C*, so that the effect of these heavy revolving rims is applied directly to reversing the planer table.

Fig. 2. Speed Change Mechanism in Bed.

The gearing connections will be easily understood from a study of Fig. 2. Driving pulley *B* is keyed to the driving

shaft *F*, which carries, inside the bed, pinions *L* and *M*, which mesh with corresponding gears *N* and *O* on intermediate shaft *K*. These latter gears can be shifted so that *O* will be driven by *M*, or so that *N* will be driven by *L*, thus giving the two rates of cutting speed for the forward drive. The reverse is operated by tight pulley *D*, which is keyed to the hub of pinion *H*, meshing with gear *J* on intermediate shaft *K*. The speed of the return is thus constant, irrespective of the position of sliding gears *N* and *O*. The latter are shifted by a block fastened to a rod, which has rack teeth at its outer end engaging a pinion on a rock shaft, operated by the handle shown at the right of the shifting mechanism in Fig. 1.

An ingenious and effective point in the design of this machine relates to the mounting of the four pulleys *A*, *B*, *C* and *D*. The loose pulleys *A* and *C* are each independently mounted on stationary bearings of their own. The forward loose pulley *A* revolves on a stationary journal *E*, which is a part of the heavy overhanging cast iron arm, which contains the shifting mechanism, as shown in Fig. 1. It has no connection whatever with drive shaft *F*, so that the latter is relieved from the belt pull, except when it is itself being driven. Loose pulley *C* is likewise supported by a stationary bearing; in this case, quill *G*, which is seated in a bored hole in the frame as shown. On this quill also revolves pinion *H* and pulley *D*, keyed to it, as previously described. Since the loose pulleys are provided with stationary bearings, excessive wear, heat and friction caused by the customary practice of having pulleys revolved in one direction on shafts rotating in the other, are eliminated. This amounts to a cutting down of the number of revolutions of the loose pulley on its bearing by almost a half a million revolutions per day, and brings, consequently, an appreciable reduction in the friction loss. Bearings of both loose pulleys are of large diameter and are very rigid; they are provided with suitable arrangements for oiling.

Another change incorporated in this design relates to the belt shifting mechanism, which has here been designed to employ the drum type of cam. This has been found to operate more easily and give a quicker action than the plate cams formerly used. The planer herewith shown was arranged for giving cutting speeds of 26 and 45 feet per minute, with a constant return of 120 feet per minute. Its operation has been very satisfactory.

BAIRD FOUR-SLIDE AUTOMATIC WIRE FORMING MACHINE.

The Baird Machine Co., Oakville, Conn., has placed on the market the four-slide automatic wire forming machine illustrated herewith. Machines of this type have become the standard for general work in wire bending, being adapted to the shaping of all except unusually complicated or special forms. This type of machine may be fairly considered as universal in its range, since by means of the various adjustments provided, and by the use of suitable formers, work of great variety may be produced. The makers of the new design shown herewith have had the benefit of long experience in the operation of wire machinery, and have thereby been enabled to include in this design many features that make for increased efficiency. The machine has the advantages of few and simple adjustments, accessible mechanism, easily acting cams, ample bearings and rigid construction.

The general design of the four-slide automatic wire forming machine, as best seen in Fig. 2, provides for a working table with shafts on its four sides, carrying cams operating corresponding slides, which approach the work from four different directions. The left-hand cam-shaft also operates an automatic feeding mechanism, which draws the wire through the straightening rolls, and feeds it so as to be cut off to the proper length to suit the work. The wire straightening rolls shown at *A* are so arranged as to face the front, leaving the wire in plain view of the operator while it is being straightened.

A simplified feed mechanism is used. As plainly shown in Fig. 1, it is operated by a slotted crank whose length of stroke is varied by the knurl-headed screw shown at *B* in Fig. 2. For accurate feeding, positive stops *C* are provided for the feed slide. These stops are quickly and easily set. This mechanism is designed to be an improvement over various geared and slotted lever arrangements previously used, or the friction device sometimes employed. The adjustments for length of feed are operated independently of the feed grip. Neither the latter nor the binding cam requires any adjustment, as the time for gripping and releasing is practically the same for all lengths. The feed throw-out is shown at *L*.

The cut-off is quickly and easily adjusted by the loosening of cam bolt *D*, and the turning of stud pinion *E*, which engages a rack by means of which the proper change is more easily and delicately effected than by the more common method of tapping the bracket in either direction until the right adjustment is reached.

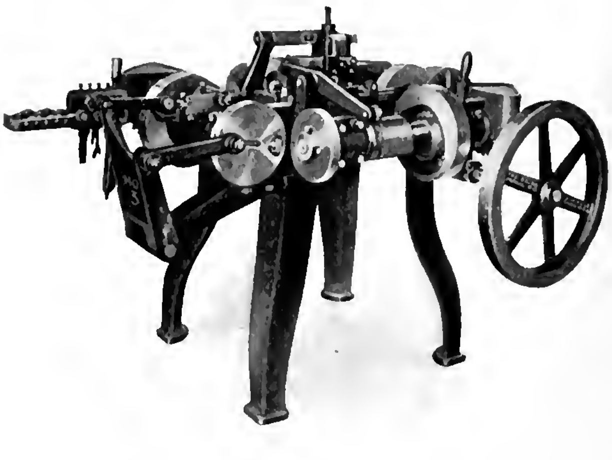

Fig. 1. The Baird Four-slide Automatic Forming Machine for Wire Goods.

Another advantage of the machine is the employment of a swinging former *F*, which permits the use of either a stationary or moving form without change of bracket. The form-holder is suspended from a pivot, and held in line with the wire by a spring; it is carried back by the front tool against the abutment of the heavy, solid bracket. This arrangement permits higher speed and easier movement than is possible when a heavy slide is used in place of the swinging former. The adjustments of the form bracket are shown at *K*.

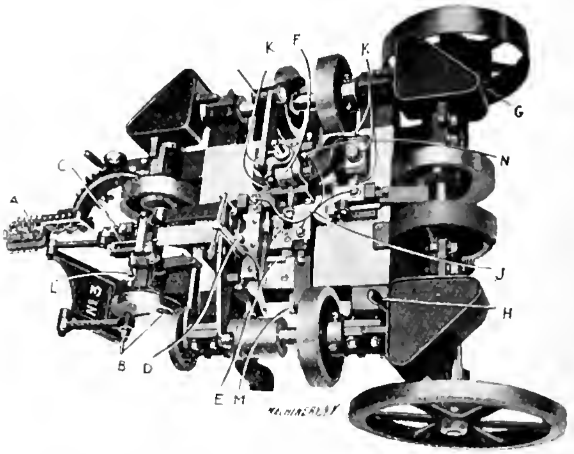

Fig. 2. Top View of Machine, showing Mechanism and Adjustments.

The form holder can be held back by a set-screw when using a stationary form, or it may be taken out and a solid form put in.

The machine is driven by the friction clutch pulley at *G*, controlled by the lever *H*, which is convenient to the operating position. This does away with the necessity for a countershaft, and enables the operator to try the operation slowly and to watch it closely at the same time. The friction can be so set that any undue strain will stop the machine, and prevent the breaking of tools. All the adjustments, as may be plainly seen in Fig. 2, are at the top of the machine and can be reached from the operator's position at the front. Adjustments for the tools are shown at *J*, for the form bracket at *K*, and for the stripper at *N*. These machines are made in six sizes, from No. 0 to No. 5, working wire up to ⅜ inch in diameter and 15 inches long.

PRECISION BORING TOOL.

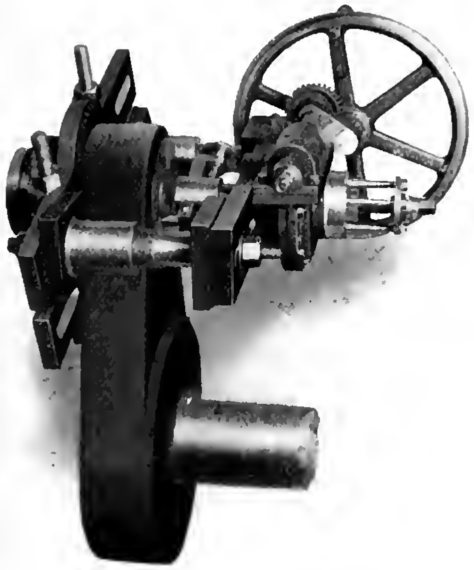
The illustration shows a boring tool adapted to be held in machines with rotating spindles, such as drill presses, milling machines, lathes, etc. It is provided with means for adjusting the diameter of cut made by the rotating tool, so that the workman may know the amount he is removing with each chip. As shown, the main member is a sleeve having a solid shank at right angles to it, by means of which it is held in the spindle of the machine. In this sleeve is carried a tool-holder, adjustable for different diameters by means of a screw having a knurled and graduated head. These graduations read to thousandths of an inch, permitting a high degree of accuracy in operation. The adjustment, when made, is locked by the upper nut shown on the tool-holder shank. The boring tools themselves are held in the split end of the spindle by tightening the lower of the two nuts.

Rotating Boring Tool with Micrometer Adjustment for Diameter.

The body and holder of this tool are made from drop forgings. The cylinder, tool-holder and lock-nut are carbonized to increase their durability. The device will bore holes up to 3 inches in diameter. It is made by the Precision Boring Tool Co., 210 Wetherbee Building, Detroit, Mich.

UNDERWOOD PORTABLE BORING, TURNING AND FACING MACHINE.

The latest addition to the line of portable tools made by H. B. Underwood & Co., 1024 Hamilton St., Philadelphia, Pa., is shown herewith. It was originally designed for the special work of cutting out the countersink for removing riveted crank-pins. This is a laborious and time-consuming operation when done with a hammer and chisel. The mechanism is mounted on a solid cross-head which carries a casing containing a worm-wheel, journaled on large integrally formed hubs.



Machine designed for Cutting out Riveted Crank Pins, but adapted to General Facing, Turning, etc.

The cutting spindle has a sliding movement of 4 inches through the worm-wheel, the feed being operated by hand. The end of the spindle carries a steel slide for the cutting tool. This is adjustable for different diameters by the screw shown, the maximum diameter being about 12 inches.

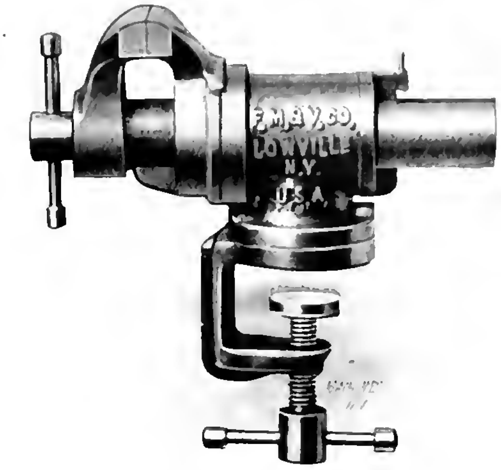
Two clamping plates, with centers cut to a V-shape, which will take a wide range of sizes, clamp the device to the work, being tightened together by 1-inch through bolts. Separate adjustable spacing blocks, or studs threaded to receive each other, may be used for straddling cranks, the spokes of locomotive drivers and other work of varying dimensions. Bolts passing through these blocks clamp the machine proper to the cross-heads. The entire arrangement is very firm and solid, and each piece is light enough to be easily handled by one man. The machine is quickly centered

Three changes of speed, for heavy, medium or light work, are provided. These speeds are obtained by interchanging the gears shown on the driving shaft, or by driving direct without them. The spindle is at right angles to the base or cross-head, and by means of an extra facing attachment can be used for facing off pump or engine valve seats, it being immaterial whether or not the steam chest is solid, or the valve seat several inches below the face of the chest. The machine may be driven by hand or any other suitable power.

As may be seen, the range of usefulness of this device is much greater than the operation of removing riveted crank-pins, for which it was first designed. It may be employed, for instance, in facing up a pipe flange that is out of true. It is practically a universal boring, turning and facing machine for work within its range.

PORTABLE DOUBLE-SWIVEL VISE.

The Fulton Machine & Vise Co. of Lowville, N. Y., builds the universal, vertical and horizontal swivel vise illustrated herewith. It is of a size which is particularly suitable for motor boat and auto equipment, though of course it may be used wherever a small swivel vise is required. A special adaptability to automobile use is given by the universal adjustment, as it is otherwise often impossible when working in a small space, to hold the work with the full length of the jaws. Both swivels are clamped tightly by the gripping of the work, which will slip before the swivels will change position. When the work is gripped, all lost motion is taken up, and the whole tool becomes as rigid as a solid jaw vise. It is claimed by the makers to be stronger than any solid jaw design of the same capacity, having nearly twice the weight.



A Vise adapted to Motor Boat and Automobile Use.

The jaws are steel faced and tempered, the finished parts are nickeled, and other parts are painted with best black enamel. The nut is of malleable iron, and is of the same diameter as the body, having a bearing around the entire outer edge. There are no levers or pivots in the adjusting mechanism to break or wear out. The jaws are two inches wide, and open two inches, and the tool weighs 7½ pounds. It is adapted to be fastened by the clamp shown, to the running board, or any other suitable support.

* * *

In a letter to the Department of Commerce and Labor, Consul-General S. Listoe states that the ancient Dutch windmills are slowly giving way to more modern prime movers, and that gas engines are being introduced in many places, to take the place of the windmills. The reason for abandoning the windmill is the uncertainty of its motive power. At the same time, however, it should be noted that in Denmark, extensive experiments have been made with windmills as motive power for electric machinery, and that plants provided with supplementary gas engines for use when the wind fails, have proved satisfactory. Some small Danish towns have built electric lighting plants operated in this manner.

NEW MACHINERY AND TOOLS NOTES.

Double Stroke Open Die Header. E. J. Manville Machine Co., Waterbury, Conn. This is a new size of the builders' well-known machine design, for the cold heading of parts made from wire up to ½ inch diameter.

Electricians' Screw-Driver. L. S. Starrett Co., Athol, Mass. This tool is similar to the makers' telescopic pocket screw-driver, except that the handle is made of insulating material, fitting it particularly for electricians' use.

Solder File. Hayes File Co., Detroit, Mich. This firm has recently commenced the making of files of a special cut, particularly adapted to work on solder, babbitt and other metals of a similar character, which rapidly fill the teeth of the ordinary file.

Combined Triangle, Scale, Protractor and Erasing Shield. D. J. Kelsey, New Haven, Conn. This drafting instrument is a combination of the various tools mentioned, being an extension of the maker's well-known combination 30, 45 and 60 degree triangle.

Foot Press. La Salle Machine & Tool Co., La Salle, Ill. This foot press is mounted on a table supported on legs, which allow free movement for the operator. It is solidly built and provided with adjustments which maintain its proper action for an indefinite period.

Duplex Die Stock. Borden Co., Warren, O. This tool, which the makers call the No. 6 Beaver die stock, is provided with two sets of chasers, either of which can be used as desired. A single cam changes from one set to the other, and adjusts each set to the proper size.

Pneumatic Chipping Hammer. Pittsburg Pneumatic Co., Canton, O. This is a compact chipping hammer, provided with an air cushion arrangement which reduces vibration to a minimum. It is made in six sizes, weighing from 4½ to 10 pounds, with strokes ranging from ½ to 4 inches.

Radius Gage. L. S. Starrett Co., Athol, Mass. These tools are provided with both concave and convex radius gage surfaces ranging from 1/16 to ½ inch radius for the small size, and from 17/64 to 1 inch for the larger size. They are intended for general use of tool-makers, pattern-makers, etc.

Steel Drafting-Room Table. The Century Mfg. Co., Columbus, O. This is made of angle, flat and round stock throughout, and is so braced as to be very rigid. It can be folded up and adjusted to various positions as may be required. Parallel ruler, and a bracket and tray will be furnished when desired.

Monorail Electric Hoist. Alfred Box & Co., Philadelphia, Pa. These hoists are designed to run on I beams, and are furnished in either the hand- or power-traverse styles, the hoist being operated by an electric motor. Two brakes are furnished, one mechanical and the other electrical, to prevent accident while under load.

Emery Wheel Stand. George H. Calder, Lancaster, Pa. This stand is made in five sizes, for maximum diameter of wheels from 6 up to 15 inches. Special attention has been given to rigid construction; a feature of the design is the placing the table low enough to avoid the danger of breakage, by getting a casting between it and the wheel.

Engineers' Gage. L. S. Starrett Co., Athol, Mass. This gage is of the familiar swinging leaf type employed for various forms of gages. This particular instrument comprises a taper gage reading 64ths per foot, nine feeler gages from 0.002 to 1/16 inch and a wire gage graduated in numbers on one side and decimal measurements on the other.

Tilting Tumbling Barrel. Clark Novelty Co., Rochester, N. Y. This barrel is of the open-end type, provided with a mechanism for setting it at any angle, and thus emptying it and refilling it while in motion. The barrel will be furnished either in cast iron, sheet steel or wood. The machine was developed for use in the shops of the makers.

Tilting Vise For Drill Press, Planer, Shaper, Etc. Blissfield Motor Works, Blissfield, Mich. This tool, called the "Davenport" tilting vise, can be adjusted to any position from the horizontal to the vertical, being supported by diagonal braces at the desired angle. The jaws are 2 inches high and 5 inches wide, and open 6 inches.

Bench Drill Press. Blissfield Motor Works, Blissfield, Mich. The "Davenport" bench drill has the form of the standard drill press on a small scale. It is furnished with a two-step or three-step pulley, as required by the purchaser. It will drive drills up to ¼-inch diameter to the center of a 7½-inch circle.

Combined Forming and Bending Machine. Royal Mfg. Co., Lancaster, Pa. Intended for forming and bending light shapes for general steel work. It will bend small rings or circles of various sections up to the equivalent of ½ inch square stock. A plating and crimping attachment is furnished for ornamental work.

Twelve-Foot Boring Mill With Slotting Attachment. Betts Machine Co., Wilmington, Del. This is a regular boring mill except for the fact that it is provided with a 12-inch boring bar and a slotting attachment, which fit it for the economical finishing of central holes in pulleys, etc., and the splining of the keyways without removing the work from the boring mill table.

Elgin Counter-shaft for Precision Lathes. Elgin Tool Works, Elgin, Ill. This self-contained counter-shaft may be mounted on column supports on the work bench, or on brackets attached to the wall. Convenient provision is made for forward or reverse speeds, and for driving milling attachments, grinding attachments, etc., at any point in the length of the lathe bed.

Centering Device. Patterson, Gottfried & Hunter, New York City. This device consists of a series of blocks, so connected by sliding shafts that they move together simultaneously toward the central bushing, which is thus centered when the blocks are brought down around a piece of square or round stock. The center is then marked by a prick punch, guided by the bushing.

"Perfect" Power Hammer. Macgowan & Finigan Foundry & Machine Co., St. Louis, Mo. This hammer is of the direct action type in which the crank is mounted directly above the ram. It has an adjustable connecting rod and adjustable spring tension. It is made in three sizes, the rams weighing from 30 to 80 pounds. The largest of this line of hammers will work iron up to 3½ inches thick.

Self-Contained Gear Reduction Mechanism. Newark Gear Cutting Machine Co., 66 Union St., Newark, N. J. This device as furnished is formed of an oil-tight casing, containing a train of worm and spur gearing giving four speed changes. It is particularly adapted to direct connection with a motor for driving slow speed machinery, such as annealing and hardening furnaces, etc., at varying rates of speed.

Universal Joint. Michigan Wheel Co., Grand Rapids, Mich. This joint is ordinarily designed for propeller shafts, but can evidently be applied to other purposes. Center blocks, forks and journal pins are of steel, the latter being hollow to serve as a reservoir for oil, supplying enough for an ordinary season's service without refilling. The forks are bronze bushed under hydraulic pressure, and are ground to fit the journal.

Roller Relief Bearings. Pickering Governor Co., Portland, Conn. These bearings are intended for supplementary or emergency use, to relieve the strain on overloaded bearings wherever necessary. Each consists of a roller supported on internal roller bearings, and provided with adjustable mountings for jacking up and supporting the shaft. They are made in sizes to be used for all purposes from light counter-shafts to engines of moderate size.

Ball Thrust Bearing. International Engineering Co., 1779 Broadway, New York City. The "R. B. F." ball bearing has been placed on the market in a style to operate as a double acting thrust bearing. These bearings are self-contained units, and may be handled as one piece. The races are held in spherical seats, which permit change of alignment without disturbing the accuracy of its action, and without disturbing the distribution of the load on the balls.

Combined Steel and Hemp Belting. Massachusetts Belting Co., 207 Congress St., Boston, Mass. This belting consists of interwoven strands of steel wire served with specially prepared hemp marline. The belt thus formed is protected at the edges by solid steel wire to make it proof against wear from belt shifters, etc. The purpose of this construction is to combine the strength of the steel with the durability and high coefficient of friction of the hemp.

Supplementary Turret for Boring Mills. Bullard Machine Tool Co., Bridgeport, Conn. This turret tool-holder fits in the tool-slide in place of the regular tool head, and may be rotated about a vertical axis to bring a succession of cutting tools into action. There are four faces to the device, permitting the holding of four tools in each head. The saving is considerable as compared with the taking out and replacing of tools in manufacturing work with the regular tool head.

Universal Attachment for Milling Machines. Porter-Cable Machine Co., Pearl & Canal Sts., Syracuse, N. Y. This attachment is universally adjustable to fit any commercial milling machine having an overhanging arm. It is intended particularly for high-speed milling. The spindle is driven by bevel gears and belting from the main spindle of the machine, and may be set at any angle about two axes at right angles to each other, thus giving it a full universal adjustment.

Centering Lathe. Climax Co., Hyannis, Mass. This is a specialized form of lathe, having a large hollow spindle, with a chuck at each end for supporting the stock. The centering drill is operated by a second revolving spindle on the tailstock. For accurately centering finish work, a steady rest is provided; in this case only one of the chucks is used—either the one on the inner or the outer end of the hollow spindle, as is required by the work. The drill runs at 600 revolutions per minute, and the chuck at 25 revolutions per minute.

Internal Grinding Machine. Bath Grinder Co., Fitchburg, Mass. This grinding machine is unique in being provided with two spindle heads, and in having the work mounted in a revolving sleeve. This makes it possible to mount the wheel in the middle of a separable spindle, driven at both ends, thus giving a far stiffer support than is usually obtained and resulting in an increased output. The machine is heavily made, to minimize trouble from vibration, and is fully provided with the various adjustments and attachments necessary for the work it is called on to perform.

Automatic Air-Controlled Nut Tapping Machine. Pneumatic Nut Machinery Co., Cleveland, O. In this machine a horizontal six-sided turret is provided, carrying six revolving taps. Automatic magazines and pneumatic feeding mechanisms on each side of the turret feed nuts into the taps as they are successively indexed into position in front of them. An automatic stopping mechanism pulls the tap clear off the chuck and removes the nut from the shank, replacing the tap ready to receive a new nut when it again arrives in front of the feeding mechanism. The machine faces the nuts as well as threads them.

Threaded Adjustment for Micrometers, Drill Spindles, Screw Jacks and Other Uses. F. E. Bocorselski, Supt., Baush Machine Tool Co., 200 Wason Ave., Springfield, Mass. This form of adjustment comprises a nut, threaded to a hollow sleeve, which is provided with a slot through which passes a cross-arm; on this the inner member is supported, so that by the turning of the outside threaded collar or nut the entire member is adjusted longitudinally. This construction has been applied by the inventor to ratchet drills, micrometers, screw jacks, etc., and to the individual adjustment of drills for multiple spindle machines.

Single Crank Power Press. Toledo Machine & Tool Co., Toledo, O. This press is unusually large for its type, and is intended for making stampings from heavy gage metal. It is provided with an automatic releasing clutch for stopping the press at the high point of the stroke, and a hand lever control for stopping and starting the press anywhere at will. The press frame is of the four-piece construction, reinforced by four heavy steel tie-rods. The stroke is 24 inches, and the pressure capacity about 1,250 tons. The friction drive releases instantly when the press is subjected to an overload of 25 per cent greater than this amount.

Multiple Spindle Drilling Machine. Cummings Machine Co., 238 William St., New York City. This drilling machine is of the type in which a multiplicity of spindles are mounted so as to be set to any required layout. A number of new features are provided, not common in machines of this kind. Methods of holding the various spindles and adjusting them to the required position have been carefully worked out, and are unusually convenient. The center-to-center distance has been reduced to a very small dimension, it being possible to drill four 29/32 holes with the centers at the corner of a 1 1/32 inch square. Each drill spindle is driven through a flexible jointed shaft from an independent, self-contained spiral gear drive. These drives may be readily changed to give different speed ratios, thus driving drills of various sizes in a given layout at the various speeds required for effective work.

* * *

THE CLERMONT REPLICA FOR THE HUDSON-FULTON CELEBRATION.

The officers of the Hudson-Fulton Celebration Commission have let the contract for building a replica of Robert Fulton's *Clermont* to the Staten Island Shipbuilding Co. Work has already begun on the copy of the first boat to steam up the Hudson, and the contract calls for its completion by August 1. The boat will be a duplicate of Fulton's first boat, will run under its own steam with a boiler and engine exactly like those which Fulton had built, and will be able to attain the same speed as the *Clermont*—four to six miles an hour! The only differences between Fulton's boat and that which is being built for the celebration next September are those which the steam boat inspection laws make necessary. If the steamboat inspection department had been in existence when Fulton started on his first trip up the river, he probably would not have been allowed to proceed without stopping to put on safety valves, life preservers and other appliances which the present steamboat laws require.

Except for these differences and a slight change in the width of the boat which the steamboat inspection laws require the *Clermont* which is building now will be exactly like that which made the residents along the Hudson in 1807 believe that the earth was coming to an end. She will have the same uncovered side paddle wheels which splashed water on her first passengers, the same little square cabin forward and the same awkward engine and machinery which, however, made practical the navigation of the Hudson without the necessity of waiting for a favorable wind. To be sure, the average speed of the *Clermont* on its first trip was only 4.6 miles against the wind, but this was such an improvement over the average speed of the sailing vessels that it was the cause of great rejoicing.

The search for accurate data on Fulton's first boat by the committee in charge was a long and arduous one. There was plenty of data concerning his subsequent boats, but there appeared to be very little concerning the first boat that steamed up the Hudson. Drawings of her engine were finally found, and from a letter of Hudson's which was unearthed it was learned what the hull of the boat looked like.

The original *Clermont* was 150 feet long and 13 feet wide, with 7 feet depth of hold. She drew 2 feet of water. Her hull (below the deck) had wedge-shaped bow and stern, cut sharp to the angle of sixty degrees. In horizontal plan the sides were parallel and she was almost wall-sided, being a very little wider on deck than on the bottom, which was flat and without a keel. She had two steering-boards or leeboards to prevent drifting sideways. She had two masts, but no bowsprit or figurehead. There were two cabins, one forward and one aft. The tiller was at the back end of the after cabin, so that it was difficult for the helmsman to see what lay ahead. The engine, built in England, was amidship between the two cabins and was uncovered. The boiler was of copper. The paddlewheels, 15 feet in diameter, were uncovered, which resulted in drenching the passengers, and no guards protected the wheels from collision. Later the paddlewheels were covered. To turn the vessel around one paddle-

wheel was disconnected. The flywheels of the engine were outside of the hull forward of the paddlewheels, and revolved the same way. On one occasion, when one of the paddle-wheels was disabled, it is said, paddles were attached to the flywheel and the voyage continued.

The *Clermont*, with the replica of Hudson's *Half Moon*, which is being built in Holland, will be the center of the great naval parade which will start from New York and steam to Newburgh on Friday, October 1. To convoy these two little vessels there will be fleets of American and foreign warships, great river craft and ocean steamships that have evolved from Fulton's awkward little steamboat.

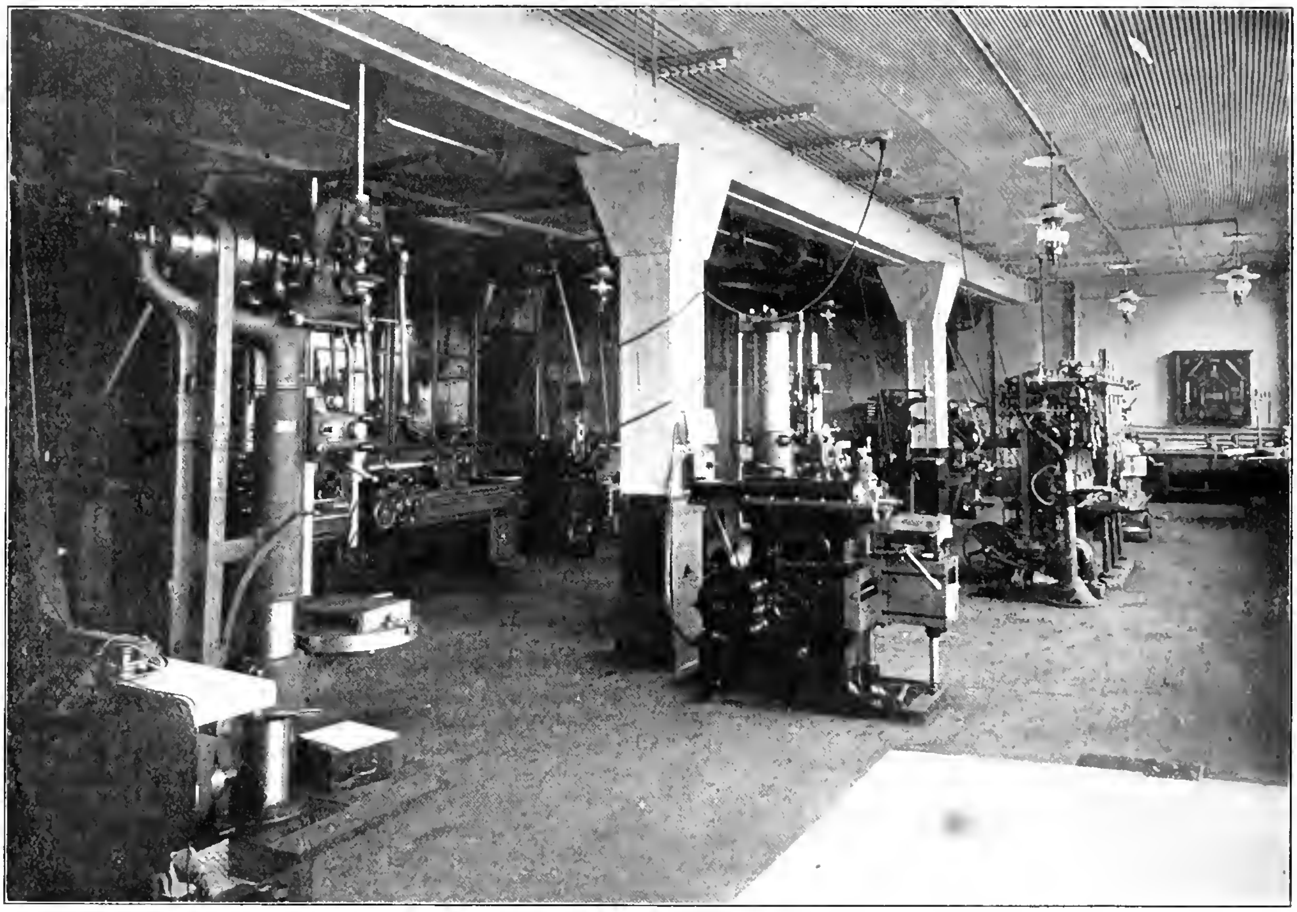
A NEW MACHINE DEMONSTRATING ROOM.

On Saturday evening, February 20, the Marshall & Huschart Machinery Co., of Chicago, opened its new demonstrating room and many men prominent in the machine world were present. The speakers of the evening gave some very interesting and instructive talks, illustrated by practical examples on the machines. Chas. S. Gingrich, of the Cincinnati Milling Machine Co., spoke on "Milling Machines"; S. H. Peck of the Rockford Drilling Machine Co., spoke on "Multiple Drilling"; E. P. Bullard, Jr., of the Bullard Machine Tool Co., talked on "Boring Mill Practice," and J. W. Carrel of the Lodge & Shipley Machine Tool Co., completed the list of speakers with his talk on "Lathe Practice."

The new demonstrating room was fitted up to actually show what the various machines can do. No set pieces are kept in the machines, but they will be set up and tried out on any job that a prospective purchaser calls for, and as the equipment of the room is unusually complete in machines, tools and material, the demonstrations promise to be very valuable to the "man from Missouri." E. V.



New Demonstrating Room of the Marshall & Huschart Machinery Co., Chicago, Ill.

NEW PACKING MATERIAL FOR ANNEALING STEEL.

It is commonly known that steel gains in strength and uniformity of its structure by slow heating to a certain high temperature, followed by slow cooling, but it is only recently that the requisites for successful results have been well understood. Most important among them are the correct ultimate maximum temperature and the very slow and uniform heating and cooling. To secure this latter, some sort of covering must be given to the steel to be so heated, to prevent rapid cooling and oxidation of the surface. Such a protecting packing must be a good heat insulator, that is, allow heat to pass through it but slowly, and also must contain no constituents liable to affect the quality of the steel, either through fusing or oxidation. This requires that the packing shall be infusible at the temperatures used and shall not be capable of absorbing gases.

There are numerous packings which have been used for this purpose with more or less success. Some compositions are secret and highly expensive, others are lacking in uniformity and hence unsatisfactory, while others are satisfactory within certain limits. The Laurentide Mica Company, Ltd., Box 911, Pittsburg, Pa., has just placed on the market a product known as "Micanneal," which has proven itself to be the superior of the packing ordinarily used for this purpose. It is infusible, will not absorb gas and is a remarkably good heat insulator. Therefore it prevents the steel from being heated or cooled too rapidly, and also protects it from oxidation. The specimens come out clean when packed in Micanneal, whereas such combinations as are ordinarily used are scaly. Under the same circumstances specimens packed in Micanneal will require from 25 to 150 per cent longer to heat and to cool than with any other packing, which insures greater uniformity of the steel. Micanneal is prepared in different degrees of fineness from the coarsest to the finest mesh. It is ordinarily sold in lots of approximately 100 pounds.

* * *

An alloy made of 70 per cent nickel and 30 per cent copper, and known as monel metal, has recently been placed on the market by the Orford Copper Co., Bayonne, N. J. According to the *Engineering and Mining Journal*, the tensile strength of the material is about 108,000 pounds per square inch, and the elastic limit of rolled, annealed and cold drawn material is 98,000 pounds per square inch. It is stated that the roof of the new Pennsylvania Railroad station in New York City will be covered with sheets of this alloy.

PERSONAL.

A. J. Dinkel is now the superintendent of the Lisle Mfg. Co., Clarinda, Ia.

Walter B. Snow, Boston, Mass., has been elected a member of the corporation of the Massachusetts Institute of Technology.

John D. Powers, for some years past in charge of the hacksaw department of H. Disston & Son, Inc., Tacony, Pa., severed his connection with that concern on March 31.

James W. Ogden, formerly superintendent of the Bridgeport Foundry & Machine Co., Bridgeport, Conn., is now superintendent of the Wolverine Motor Works, Bridgeport.

George Chase, formerly superintendent of the Pacific Iron Works, Bridgeport, Conn., is now superintendent of the Lake Torpedo Boat Co., Bridgeport.

A. L. Mitchell, for some time round-house foreman for the Wabash R. R. at Decatur, Ill., is now general foreman of the C. P. & St. L. Ry. shops at Springfield, Ill.

W. A. Hopkins, electrical engineer for the Wabash Ry., is now engaged in installing the electrical machinery for the new drop-pit in the Wabash shops at Springfield, Ill.

The successor of Edmund Pennington as vice-president and general manager of the Soo Line, will be John M. Egan, who for several years has been general manager of the Great Western Railroad.

The official photographer of the E. R. Thomas Motor Co., Buffalo, N. Y., is Miss Mimmette Ives Meade, who probably is the only woman in the United States making a specialty of machine shop photography.

H. W. Heidenger, a graduate of Rose Polytechnic Institute, Terre Haute, Ind., has been made mechanical engineer of the Baltimore & Ohio Southwestern Railroad, with headquarters at Washington, Ind.

A. B. Fleming, purchasing agent of the Fairmont Mining Machine Co., Fairmont, W. Va., has resigned his position, and Clarke Evans, secretary of the company, will attend to the purchasing hereafter.

Henry Dreses, president of the Dreses Machine Tool Co., Cincinnati, Ohio, spent a greater part of February and March on a pleasure trip in Cuba, Florida and other Southern parts.

Charles Sterne, mechanical engineer of the Baltimore & Ohio Southwestern Railroad, formerly located at Washington, Ind., has been transferred to Louisville, Ky., to act as round-house foreman.

J. M. Robinson has resigned his position of assistant superintendent of the Chapman Valve Mfg. Co., Springfield, Mass., and has been made assistant manager of the Henry R. Worthington Co., Harrison, N. J.

J. A. Bennett, for ten years with the Pratt & Whitney Co. and later foreign representative for the Niles-Bement-Pond Co., has been made mechanical engineer of the Lodge & Shipley Machine Tool Co., Cincinnati, Ohio.

L. G. Nilson, chief engineer of the Strang Gas Electric Car Co., 15 Wall St., New York, has been elected president of the Nilson-Miller Co., Hoboken, N. J. Mr. Nilson will continue as consulting engineer for the Strang Gas Electric Car Co.

D. O. Ives, chairman of the official classification committee of the Trunk Lines' Association, New York, and former general traffic manager of the Wabash R. R., has been made secretary of the New England Board of Trade and Transportation.

George F. Fenno, for two years past insurance engineer with the Middle States Inspection Bureau, an organization maintained by thirty-six of the leading fire insurance companies, has joined the staff of the George H. Gibson Co., Tribune Building, New York.

Isidor Rauh, for many years president and general manager of the Cincinnati Electrical Tool Co., Cincinnati, Ohio, has resigned his position and has been succeeded by I. W. Becker. Mr. Becker is well and favorably known throughout the Middle West.

Henry Hair, son of John M. Hair, superintendent of motive power of the Baltimore & Ohio Southwestern Railroad, who succeeded Mr. Charles Sterne, formerly mechanical engineer, has been transferred to Seymour, Ind., to act as round house foreman.

Fred J. Miller, vice-president of the A. S. M. E., became on March 1 connected with the Union Typewriter Company of New York, with the title of Assistant to the President. He will devote himself especially to matters connected with the manufacuring department of the company, which has factories at Ilion, Syracuse and Bridgeport.

J. W. Bray, who formerly represented the Bullard Machine Tool Co., Bridgeport, Conn., in New England territory and for the past year was located in Philadelphia, has returned to the Bridgeport headquarters and will travel in New England territory again. Mr. R. H. Snider has taken charge of the Philadelphia office at 1414 South Penn Square.

A. Eugene Michel has opened an advertising office at 1572 Hudson Terminal Buildings, New York. Mr. Michel is a graduate engineer, and has had eleven years advertising and engineering training. He will confine his advertising work principally to steam specialties and apparatus, power transmission appliances, and machine tools.

Prof. Lester P. Breckenridge, head of the mechanical engineering department of the University of Illinois for several years, has been made professor of mechanical engineering at Yale University and a member of the governing board of the Sheffield Scientific School. Prof. Breckenridge succeeds Prof. C. B. Richards, who resigned after twenty-five years service.

E. V. Thompson, for some time assistant superintendent of motive power of the Chicago & Northwestern Railroad Co. at the Chicago shops, has been made superintendent of motive power of the Chicago, St. Paul, Minneapolis & Omaha R. R., with headquarters at St. Paul, Minn. He is succeeded at the Northwestern shops by Mr. E. W. Pratt, who was master mechanic west of the Missouri River.

Price H. M. Brooks, for many years foreman of the Hill shop and Water shop of the United States Armory, Springfield, Mass., has resigned his position. The position has been abolished, and hereafter the Hill shop and Water shop will be under independent foremen. Donald J. Manning has been made foreman of the Hill shop and C. H. Ladd continues as foreman in charge of the Water shop.

Robert Thurston Kent has resigned as engineering editor of the *Iron Trade Review*, Cleveland, Ohio, to become managing editor of *Industrial Engineering*, Pittsburg, Pa., a new paper devoted to mechanical engineering subjects. Mr. Kent has been with the *Iron Trade Review* since 1905, and prior to that time was associate editor of the *Electrical Review*, New York.

George A. Spooner, for some years inspector of tools at the United States Armory, Springfield, Mass., has been made master armorer, a title that has been revived. The master armorer has charge of all the master gages and tools required for absolute interchangeability of the parts of the guns made in the Springfield, Mass., and Rock Island, Ill., armories. There has been no title of master armorer at Springfield for over fifteen years. The revival of the title makes no change in the duties.

Arthur C. Hoefinghoff has been appointed sales manager of the Heald Machine Co., Worcester, Mass., beginning March 1. Mr. Hoefinghoff comes from New Orleans, La., where he was located for some time as manager of the machine tool department of the Fairbanks Co. He is a brother of the late Harry C. Hoefinghoff, who was at the head of the Bickford Machine and Tool Co., and was associated with his brother in the management of that business. Mr. Hoefinghoff has had extensive experience in the building and selling of machine tools and is well fitted for his new work.

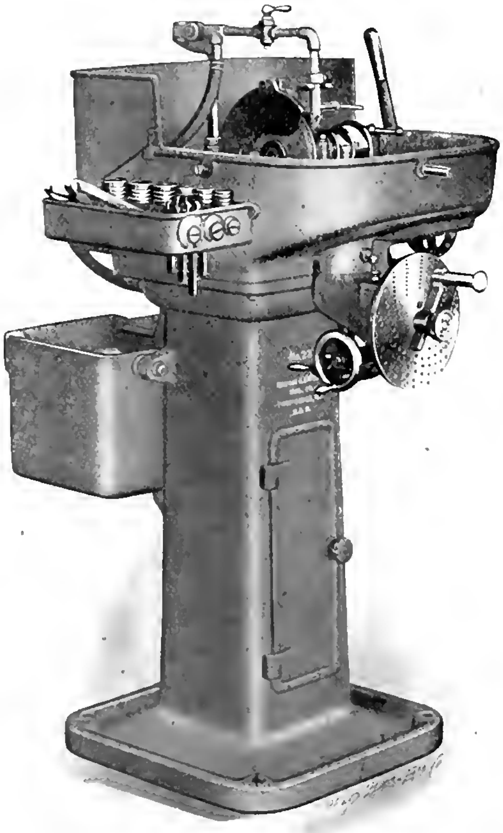
TWO NEW

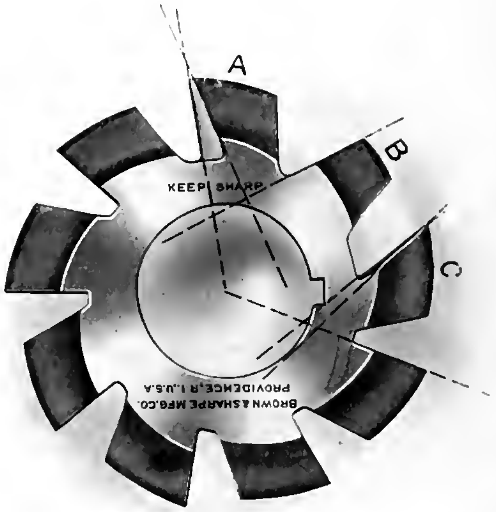
The Gear Cutter Grinding Machine Does Away with the Inaccurate Method of Grinding Gear Cutters by Hand

The form of gear cutter teeth should never be altered or else the accuracy of the cutter is destroyed.

By the aid of an indexing mechanism this machine grinds cutters radially and equidistant, that is without changing their form.

An economical machine to employ where only a few gear cutters are to be ground.





Cut shows how the shape of tooth is lost when ground by hand.

A—Ground on an angle.
B—Ground back of centre.
C—Ground front of centre.

BROWN & SHARPE MFG. CO.

PROVIDENCE, RHODE ISLAND, U. S. A.

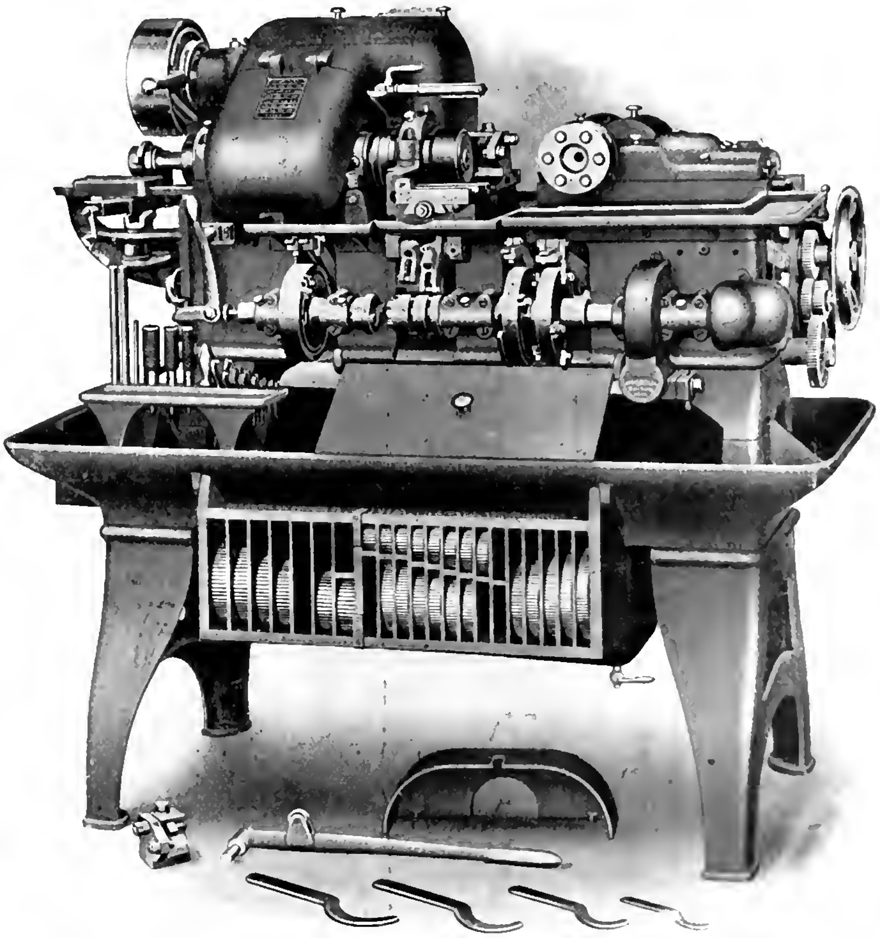
MACHINES

Automatic Screw Machines Of the Constant Speed Drive Type Offer a Distinct Advantage

The complicated overhead works that were formerly necessary are eliminated.

The doing away of the overhead works is an important factor in the development of the automatic screw machine. The care and room necessary to maintain them are dispensed with and all changes of spindle speed, which were formerly made by the awkward shifting of belts are now quickly and conveniently obtained by a system of gearing in the machine, thereby materially increasing its efficiency.

The Constant Speed Drive readily adapts the machine to motor driving.



A special circular describing the machine in detail sent free to any address.

BROWN & SHARPE MFG. CO.
PROVIDENCE, RHODE ISLAND, U. S. A.

Oskar Kylin, formerly designer of special machine tools with the Taylor Iron and Steel Co., High Bridge, N. J., returned on February 26 by the *Adriatic* to New York, after having spent over a year studying the conditions of the machine tool trade and manufacture in various European countries. The main results of his investigations have been published in MACHINERY during the past year in the form of letters and special articles, the latter presenting, with the halftone engravings and concise descriptions, a comprehensive review of the present state of machine tool manufacture in the leading European countries. During his travels, Mr. Kylin went to Germany, Austria, Italy, Switzerland, Belgium, France, England, Denmark and Sweden, visiting the most prominent machine tool manufacturing firms and dealers in these countries.

Einar Morin, formerly in charge of the tool designing department of the Ponds Works of the Niles-Bement Pond Co., Plainfield, N. J., sailed on February 25 by the *La Savoie* for Europe, after a three months' stay in the United States in the interest of his present employers, Stora Kopparbergs Aktiebolag, owners of Domnarfvet's Iron & Steel Works, Borlänge, Sweden. Mr. Morin, who is the author of the series on jigs and fixtures which has been published in MACHINERY during the past year, will spend some time in France and Germany, studying business conditions, and will then return to Sweden, where he will supervise the equipment and take charge of a new manufacturing plant for making machinists' small tools, such as taps, threading dies, cutters, reamers, drills, etc. The series on jigs and fixtures contributed by him to MACHINERY is concluded by the installment in the present issue. We expect, from time to time, to be enabled to publish articles from his pen on interchangeable manufacturing and economical methods of production as developed in his new work.

* * *

OBITUARY.

James Millikin of Decatur, Illinois, president of the Union Iron Works and the Millikin National Bank and founder of the James Millikin University which, with the exception of the State University and the Armour Institute, is the best technical and trade school in the state, died at Orlando, Florida, March 2, aged eighty-two years.

Major Edwin L. G. Zalinski, a retired army officer, an inventor and engineer, died of pneumonia, March 10, in New York, in his sixtieth year. Major Zalinski acquired international fame through his invention of a dynamite gun in which a projectile charged with dynamite was hurled by compressed air. The gun-boat *Vesuvius* was equipped with three of the Zalinski dynamite guns, which threw torpedoes weighing one thousand pounds charged with five hundred pounds of dynamite. The dynamite gun was a practical failure on account of its limited range.

Ervin Saunders, vice-president of D. Saunders' Sons, Yonkers, N. Y., died at the home of his brother in Yonkers, February 17, in his sixty-first year. He was born in Swindon, England, and came to New York with his parents in 1850, and moved to Yonkers in 1854. He entered his father's machine shop at twenty, and after his father's death the firm of D. Saunders' Sons was formed. Mr. Saunders had been in poor health for twenty years and had given more attention to real-estate and his investments than to manufacturing interests. Two brothers, Alexander and Leslie M., survive.

* * *

The enormous number of railway wrecks due to fractured rails has made the need of a higher grade product than the common Bessemer steel rail, very apparent. The open hearth process will in all probability supersede the Bessemer steel process for rail making, but even this steel is not all that could be desired to meet the trying condition of present railway traffic. Heavy engines and high speeds require a rail having physical and chemical characteristics that can be supplied only by some of the alloyed steels. The Bethlehem Steel Co. has, after a long series of experiments, produced a nickel-chrome rail at $51 per ton which, of course, is almost double the present rate for Bessemer steel rails. The standard rail price is $28 per ton for Bessemer steel and $34 for open-hearth steel. It is hardly to be considered that the Americal railways will generally adopt rails that cost $51 except for curves and stretches of track offering particularly difficult conditions.

* * *

COMING EVENTS.

April 27-30.—Annual meeting of the International Master Boiler Makers' Association at Louisville, Ky. H. D. Vought, 95 Liberty St., New York City, secretary.

May 4-7.—Spring meeting at Washington, D. C., of the American Society of Mechanical Engineers. Calvin W. Rice, 29 West 39th St., New York City, secretary.

May 12-14.—Annual meeting of the National Supply and Machinery Dealers' Association, at the Fort Pitt Hotel, Pittsburg, Pa. Secretary-Treasurer A. T. Anderson, 41 Wade Building, Cleveland, Ohio. The association has a membership of 141 manufacturing concerns.

May 18-20.—American Foundrymen's Association convention. Cincinnati, Ohio, Hotel Sinton, headquarters. Richard Moldenke, secretary, Watchung, N. J.

June 1.—Opening of the Alaska-Yukon-Pacific Exposition in Seattle, Washington, which is designed to call the attention of the world to the importance of Seattle as the western gate-way to the United States, and to its rapidly growing commercial importance. The exposition will include many working exhibits, among which are meat packing, watch making, jewelry, silk-making, rope-making, telephoning, printing, etc.

June 1-5.—Annual meeting of the International Railway General Foremen's Association at Chicago, Ill. E. C. Cook, Royal Insurance Building, Chicago, Ill., secretary.

June 7-19.—Cleveland Industrial Exposition, under the auspices of the Cleveland Chamber of Commerce, Cleveland, Ohio. It is estimated that 125,000 different articles are manufactured in Cleveland's 3,500 shops, and it is proposed to display to the world at this exposition the wonderful industrial facilities of the city. The products comprise steel ships, heavy machinery, hardware, twist drills, reamers, milling cutters, wire nails, bolts, nuts, vapor stoves, malleable castings, automobiles, paints and oils, etc. William G. Rose, secretary, Cleveland, Ohio.

June 9-11.—Joint convention of the Southern Hardware Jobbers' Association and the American Hardware Manufacturers' Association at Hotel Shenley, Pittsburg, Pa. F. D. Mitchell, 309 Broadway, New York, secretary and treasurer.

June 16-18.—Annual convention of Railway Master Mechanics' Association on Young's Million-Dollar Pier, Atlantic City, N. J. Joseph W. Taylor, Old Colony Building, Chicago, Ill., secretary.

June 16-23.—An exhibition of machinery, tools and supplies for the railway supply trade will be held under the auspices of the Railway Supply Manufacturers' Association in connection with the railway conventions at Atlantic City, N. J. Membership dues in the association are $25 per year and carry one badge only. Additional badges may be obtained by members for $5 per badge. Contracts have been let for the erection of exhibition structures covering 59,000 square feet, exclusive of aisles. The charge to exhibitors will be 40 cents per square foot, to cover the cost of erection, etc. The association has prohibited the distribution of souvenirs. Application for space should be made immediately to Mr. Earl G. F. Smith, secretary, 345 Old Colony Building, Chicago, Ill.

June 21-23.—Annual convention of the Master Car Builders' Association on Young's Million-Dollar Pier, Atlantic City, N. J. Joseph W. Taylor, Old Colony Building, Chicago, Ill., secretary.

September 25-October 2.—Hudson-Fulton celebration of the three-hundredth anniversary of the discovery of the Hudson River by Hendrick Hudson in 1609, and the one hundredth anniversary of the successful application of steam to the navigation of the Hudson River in 1807. The headquarters of the commission are in the Tribune Building, New York City, General Stewart L. Woodford, president, and Mr. Henry W. Sackett, secretary. The commission solicits the loan of collections of machinery, models, books, etc., having a bearing on the history of early steam navigation in the United States.

SOCIETIES AND COLLEGES.

THE STATE LEAGUE OF SHEET METAL WORKERS at its recent convention held in Springfield, Illinois, selected Quincy as its next meeting place and chose Robert Byron, the retiring president, to represent Illinois at the national convention in Denver next August. At the concluding session the following officers were elected for the ensuing year: W. E. Mosher, Aurora, president; G. R. Wheelock, Decatur, vice-president; F. W. Efert, Alton, recording secretary; August J. Hernsdorfer, Quincy, secretary-treasurer.

THE EVENING MACHINISTS' ASSOCIATION OF PRATT INSTITUTE, Brooklyn, N. Y., gave its annual dinner at the Machinery Club, New York, March 20th. About one hundred and twenty-five were present, including F. B. Pratt, secretary of Pratt Institute G. D. Pratt, treasurer; A. L. Williston, director of science and technical department, and W. J. Kaup, head of machine department, who is known as the "hoss." William Reinicker is president of the alumni association, and John Royals acted as toastmaster of the dinner. The event was a great success, not only as a dinner, but as a manifestation of the strength of the association and the institute's motto: "Help the other fellow."

THE ENGINEERING SOCIETY OF WISCONSIN was organized at the University of Wisconsin, February 24-26. About 150 city engineers, general managers of power and traction companies, construction engineers, superintendents of power and light plants, mechanical and civil engineers, superintendents of highway construction were present and became charter members. Dean F. E. Turneaure, of the College of Engineering, University of Wisconsin, was elected president. The new organization will hold annual meetings for the purpose of bringing together engineers from all parts of the State interested in the solution of problems arising in connection with municipal plants, large construction work, bridge work, water powers, forestry, light and power, etc.

L. C. SMITH COLLEGE OF APPLIED SCIENCES, Syracuse University, has instituted a plan of securing employment for its graduates along the lines of similar plans now in vogue at Cornell and several other technical institutions. An alumni employment committee has been appointed to carry on the work. The committee will keep closely in touch with the graduates and with various engineering interests employing college graduates. A record of the characteristics of the graduates and their work after graduation will enable the committee to recommend men to prospective employers who are likely to fill any reasonable requirement. The advantage of placing graduates through a committee of this character lies in the fact that it has the knowledge and ability to judge a man's capacity even better than the man himself, and fewer failures are likely to result than by employing graduates without the advice of a supervising committee. The work of individuals employed through the committee reflects upon it and tends to make it conservative in all recommendations. It is expected that the result of employment in this way will be very satisfactory to all concerned.

Supplement to MACHINERY, May, 1909

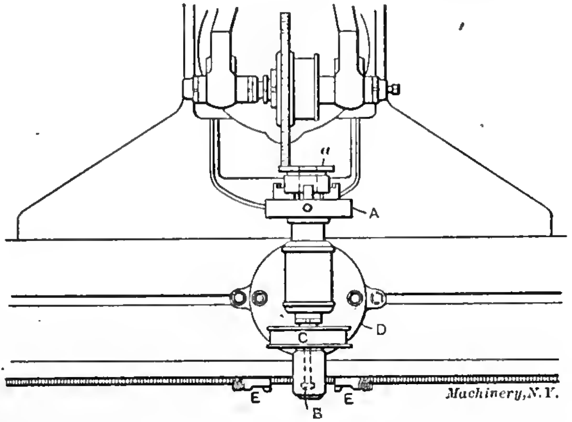
SHOP OPERATION SHEET NO. 97

Paul W. Abbott MACHINERY, May, 1909



Machinery,N.Y.

Grinding a Hardened Steel Bearing—Grinding the Face.

NOTE.—Before using any grinder see that it is well cleaned and oiled. The wheel slide should receive particular attention, as a free movement of this part is essential to accurate work. The grinder illustrated herewith is a Brown & Sharpe universal.

1. Remove the loose pulley which is used for grinding work on dead centers, and screw a three-jawed universal chuck *A* on the spindle. See that the pin *B*, which engages with the pulley *C*, is withdrawn so that the spindle may revolve.

2. Fasten the work in the chuck with the flanged end out, as shown, and set it practically true by using a test indicator which may be attached to a surface gage or base resting on the platen.

3. Select a grinding wheel of about 60 M Norton grading, having a face from ½ to ⅝ inch wide, and place it on the spindle. Arrange for wheel and work speeds of about 5,000 and 35 feet per minute, respectively, the work speed being the peripheral speed of the largest part. Adjust the feed of the table to about ⅛ inch per revolution of the work.

4. Loosen the head-stock and set it, by the graduations on the base *D*, to 90 degrees; also set the platen, which is graduated on the end, to the zero mark.

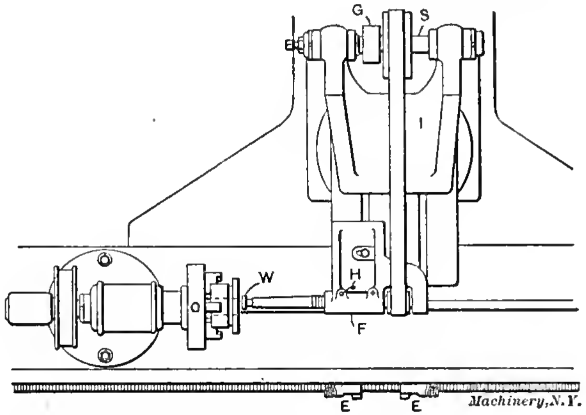
5. Adjust the dogs *E* so that the wheel will grind on the left side of the work as shown in the illustration; then the surface of the work being ground will revolve against or opposite to the rotation of the wheel.

6. Grind on the left-hand side until the surface of the work is trued, and then dress the wheel for finishing. As the surface of the work must be perfectly flat it should be tested, as the graduations on the base *D* are only intended to give an approximate setting. To do this allow the wheel to pass clear across the face *a* and note the density of the sparks. When the sparks show the same at all points the surface is flat.

7. Finish the face by grinding on the left-hand side, being careful to leave sufficient stock for finishing the inner face of the flange.

SHOP OPERATION SHEET NO. 98

Paul W. Abbott MACHINERY, May, 1909



Machinery,N.Y.

Grinding a Hardened Steel Bearing—Grinding the Hole.

1. Turn the head-stock back to the zero position, remove the wheel spindle from its stand *I*, and replace it with the speed spindle *S*.

2. Reverse the position of the stand *I*, as shown, and mount the internal grinding fixture *F* on the wheel slide.

3. Select a wheel *W*, ¾ inch in diameter by ¼ inch wide (assuming that the hole to be ground is 1 inch), with a grain and grade of about 46 *K*.

NOTE.—The driving belt, which runs on the pulley *G*, should be crossed so that the wheel and work will revolve in opposite directions.

4. By changing the overhead belts, adjust the peripheral speeds of the hole in the work and the grinding wheel to about 20 and 4,000 feet per minute, respectively.

5. Set the dogs *E* so that the wheel, at each end of the stroke, will overlap the work about ⅛ inch on each side, and adjust the table travel until the wheel feeds ¼ inch per revolution of the work.

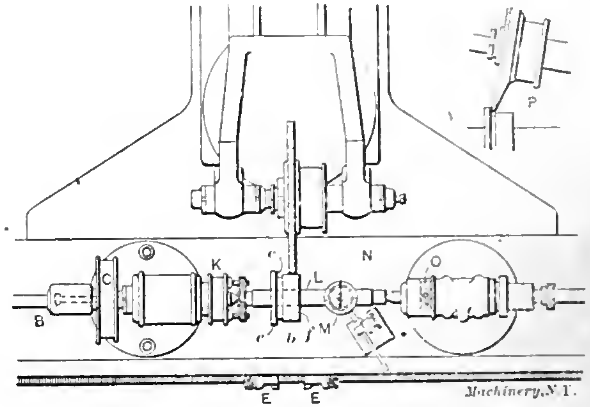
NOTE.—When using the internal grinding attachment, the wheel should not pass clear through the work, as the spring of the spindle will cause the wheel to grind the hole bell-mouthed or large at the ends.

6. Grind sufficient metal from the hole to true it and then dress the emery wheel. Take another light cut and then move the wheel until it is in contact with the opposite side of the hole. As it passes through, note the density of the sparks in order to determine whether the hole is straight or tapering. If the wheel bears heavier as it approaches the back end of the hole, the latter is smaller at that end, but if the density of the sparks becomes less, the hole is smaller in front. When the wheel bears the same on both sides throughout the length of the hole the latter is straight.

7. When the work is properly set, grind nearly to size, taking very light cuts. Cool the work so that the diameter of the hole will be reduced to its natural size; reduce the traverse of the platen to ⅛ inch per revolution of the work, and take the finishing cuts allowing the wheel to pass through the hole several times without feeding it.

SHOP OPERATION SHEET NO. 99

Paul W. Abbott MACHINERY, May, 1909



Machinery,N.Y.

Grinding a Hardened Steel Bearing—Grinding the Body and the Flange.

1. Remove the chuck from the head-stock, and place the loose pulley *K* on the end of the spindle. Insert the cone center and lock the spindle by engaging the pin *B* with a hole in the pulley *C*.

2. Remove the internal grinding attachment and replace the speed spindle used for driving the attachment with the regular wheel and spindle.

3. Select a well-centered arbor *L* of the proper size to fit the hole in the bearing, and place it between the centers. With an indicator *M* test the body of the arbor to see if it runs true. If it is satisfactory, drive the work on lightly.

4. Set the traverse dogs *E* so that the wheel will traverse the body *b*, and grind this part, using a feed for the table of ¼ inch for each revolution of the work, and a peripheral speed for the latter of about 25 feet. Measure the body at each end with a micrometer. If it is not ground perfectly straight swivel the platen *N* slightly, using the fine adjusting screw provided at one end. Continue to rough grind the part *b* and then the flange *c* until these parts are within 0.003 inch of the finish size.

5. True off the periphery of the wheel by traversing a diamond truing tool, held in the foot-stock clamp *O*, across its face. Reduce the table feed to ⅛ inch per revolution of the work, and finish the parts *b* and *c* to size.

NOTE.—After all bearings have been ground as described in the foregoing, they may again be placed on the mandrel and the inner surfaces *e* of the flanges finished in the following manner.

6. Replace the regular wheel with one of a dish shape, swivel the wheel base to an angle of 45 degrees, and dress the periphery of the wheel to that angle; then set the wheel base to an angle of about 10 degrees as shown at *P*.

7. Feed the wheel in and out across the flange by the hand cross feed, taking off about 0.001 inch at each cut until the flange is finished to the required width. Grind the end *f* in the same manner; remove the finished work, and place another bearing on the mandrel.

I.—BORING BARS AND HEADS

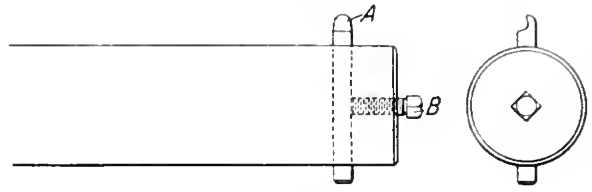


Fig. 1.

Inexpensive type of bar having a square tool A which is a sliding fit in its slot and is held in place by the set-screw B.

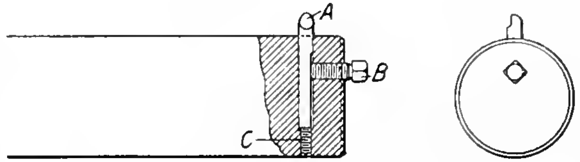

Fig. 2.

Bar equipped with round tool A flattened on one side for the set-screw B which holds it. The tool is adjusted by the screw C.

LOCOMOTIVE REPAIR SHOP PRACTICE

THE CHICAGO & NORTHWESTERN RAILWAY SHOPS AT CHICAGO

ETHAN VIALL*

IN no railroad repair shop in the Middle West is the practice more up-to-date, the amount of work handled greater, or repairs more quickly made, than at the Chicago shops of the Chicago & Northwestern Railway. Altogether there are eighty-one shops in the great cluster of buildings which enclose the thousands of workmen, the clanking machines, the roaring forges and the Gatling-gun-like pneumatic hammers. The average mechanic is apt to look upon a railroad shop as a place where only rough, dirty work is done in an out-of-date manner, but a walk through this works past the huge milling machines, shapers, and high-speed lathes, to say nothing of the drill-presses and boring mills, all of the latest type, would convince anyone that not all or even a larger part of the work is of a rough or dirty class nor done in an antiquated way even if the pieces operated on are as a rule large ones. The milling practice alone of this shop is enough to make the most unobserving "sit up and take notice." Milling cutters with inserted teeth of high-speed steel, plow over rows of castings set in jigs two or three times as long as the ones usually seen on the same class of work. Not only is high-speed steel used in these machines, but also wherever else possible, and beside the big wheel lathes are piles of chips that are not blue but black. The lathe tools are, in many cases, only tipped with high-speed steel, the body of the tool being a cheaper grade of steel to which a small piece of high-speed steel has been welded. This welding is done on the premises and is the first of the kind that I have seen in a railroad shop.

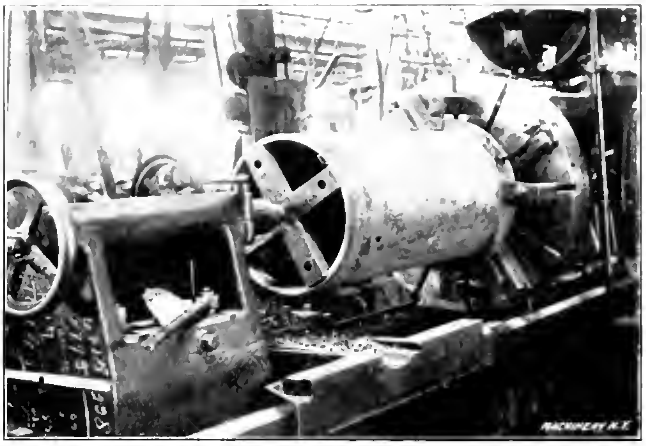

Fig. 2. Turning the Outside of the Piston Ring Casting

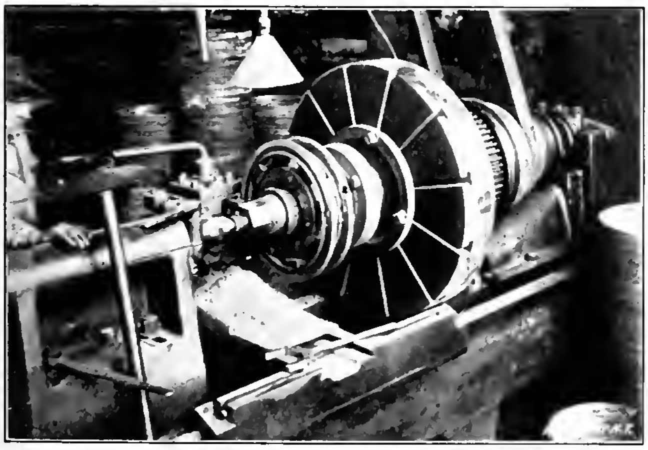

Fig. 3. Finishing Two Piston Rings simultaneously on an Expanding Mandrel

Fig. 4. Drilling Twelve Spring Rings which are held in Place by a Pneumatic Clamping Device

For the handling of materials there are overhead traveling cranes large enough to swing a locomotive, trolley traveling-cranes of the monorail type, swinging cranes, pneumatic hoists, chain hoists and lifting contrivances of every description wherever needed. The power-house is equipped with coal-lifts, automatic stokers, ash-removers and loaders, and everywhere as much manual labor is saved as possible.

While the shop system includes wood-working, painting, car-repairing and numerous other departments that have features of mechanical interest, this article will be confined principally to descriptions of locomotive repair work in its various branches, the machine shop of course coming in for a lion's share of attention. In the beginning I want to express my obligation to Mr. H. D. Kelley, shop demonstrator, who took unusual pains to show me all there was to see and to arrange things for me and assist me in my photographic work. Permission to describe the various methods and processes for the benefit of the readers of MACHINERY, was obtained through Mr. H. T. Bentley, assistant to the Superintendent of Motive Power, Mr. Quayle.

Making Piston Rings

Entering the machine shop from the office one of the first big machines to be noticed is the one shown in Fig. 1, which is at work boring out a piston-ring casting. The way these castings are held while being bored is plainly shown, the jig being very similar to a double steady-rest minus the jaws and in place of which large set-screws are used to center and hold the work. The bored-out castings are taken to the lathe shown in Fig. 2, where they are rough-turned on the

outside and cut into rings. In the engraving the undercut chuck-jaws and auxiliary clamps, as well as the spider used on the tail-stock center, can be seen at a glance. In Fig. 3 is shown the expanding mandrel made to hold two rings which are finished on both sides and to the right diameter, at one cut. The rings are then split and fitted in the usual way.

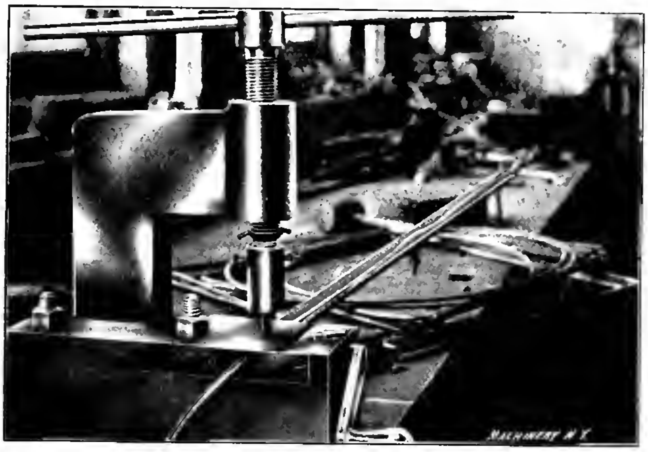

Fig. 16. Press for Cutting Dome and Steam-chest Gasket Wire

Machining Driving Boxes and Brasses

Leaving the piston-ring machines, we are next attracted by the way the driving boxes are machined. The first machine upon which they are placed is the big planer shown in Fig. 13, which is capable of planing twelve driving boxes at once. Both heads are used, and the jig shown is simply a

big iron channel (solidly bolted to the table) to which the boxes are clamped by bolts and cross-bars as illustrated. The boxes are then machined for the brasses on the slotter shown in Figs. 41 and 42 on which three are planed simultaneously.

The brasses are pressed into the boxes with a hydraulic press, as shown in Fig. 14. The truck upon which the box is mounted and run under the piston, is a very convenient one as it can be readily lengthened by loosening two locking-collars, and the axles are supported by springs so that under heavy pressure the springs give, allowing the weight to come on the heavy legs and not on the axles and wheels. The way these driving-box brasses are held between two grooved iron flanges mounted on an arbor, while the outside is turned, is shown in Fig. 12, one of the brasses being clamped in place, while a turned one is resting on the lathe carriage.

Fig. 29. Tool Storage Room equipped with Revolving Racks

When the brasses are being bored in the boring mill. Fig. 15, the box is held in a special universal two-jawed chuck which has a stop at the back, against which the partially finished casting is placed. The jaws are then tightened and the box is brought central without any unnecessary loss of time. This chuck is the only one I have seen used for this purpose, as the other shops I have been in simply clamp the work to the platen with bolts and iron straps.

Milling Eccentrics and Eccentric Straps

The ends of the eccentrics and eccentric straps are tongued and grooved on the slab miller shown in Fig. 5. The jig on the machine will hold two different sizes, and sixteen pieces can be placed in it and milled at one setting. Except for its size, the jig is simplicity itself; the work is easily put in or removed, while if any of the bolts or set-screws break they can be quickly replaced. While drilling the oil and set-screw holes, the eccentric straps are held in an indexing jig, Fig. 6. A similar though smaller jig is shown on the platen. When properly set, these jigs are very handy, for just as soon as one hole is drilled the jig is indexed a notch and the next hole drilled, and so on until finished. An expanding mandrel, Fig. 7, which is of the same general pattern as the one used to hold piston rings, is used to hold eccentric strap brasses while finishing the outside.

Fig. 31. Row of Tool Cupboards

Novel Drilling Jig for Link-block Bushings, Drilling Spring Rings, etc.

At the first glance, there is nothing unusual about the appearance of the drill jig shown in Fig. 18, except that it holds sixteen pieces at one time, but a closer inspection shows that the top of the jig holding the drill-guiding bushings, lifts with the drill spindles, allowing the finished work to be taken out by loosening the set-screws. The jig-top is counterbored under each drill-bushing so that as it is lowered it centers itself over the work. The turnbuckles that hold the top and allow it to be adjusted up or down, can be easily seen in the engraving. The link-block bushings which are drilled out in this machine, were formerly made of heavy tubing, but now the solid stock is drilled out and the final cost of the bushings is far below that of those made of tubing. Close to this drill-press is another multiple-spindle machine, shown in Fig. 4, which is fitted with a pneumatic chuck for holding and drilling twelve cylinder spring-rings at once. This clamping device is worked by an air-cylinder in the center, the piston rod of which is cone shaped on the end, as shown. As this rod is lowered it forces four short plungers outward, clamping the rings against stop blocks. The ends of the four plungers that come in contact with the rings, are fitted with pins backed by springs to allow for any unevenness or variation in the size of the object clamped. The four-spindle drill press shown in Fig. 11 is used to drill cotter-pin holes in several kinds of bolts and pins. The interesting feature of this machine is the pneumatic clamps used for holding the work; nothing more simple or effective could be imagined.

Fig. 30. Box Tools, Expanding Reamer and Strainer Punch and Die

Fig. 32. Lathe equipped for Machining Brass Taper Plugs

Boring and Removing Locomotive Tires

For holding locomotive tires on the boring mill while turning out the inside, some means other than the regular chuck or face-plate jaws must be used on account of the tendency of the tires to spring out of round because of the pressure from the jaws. This difficulty is overcome by the arrangement shown in Fig. 8. As shown in the engraving, the chucking jaws are only used to center the tire and not to clamp it, the clamping being done by hooks projecting over the top of the tire from the outside, which are tightened down

onto it by the driving in of a taper key. Four of these clamping-hooks are used and they make a very quick and effective method of locking the tires in place without danger of springing them out of round. This scheme has attracted considerable attention and has been copied to some extent in other railroad shops. Using this device on the 96-inch boring mill, 54 tires were bored out in 9 hours on a test run, the tires being handled by a pneumatic hoist with an eagle-claw clutch.

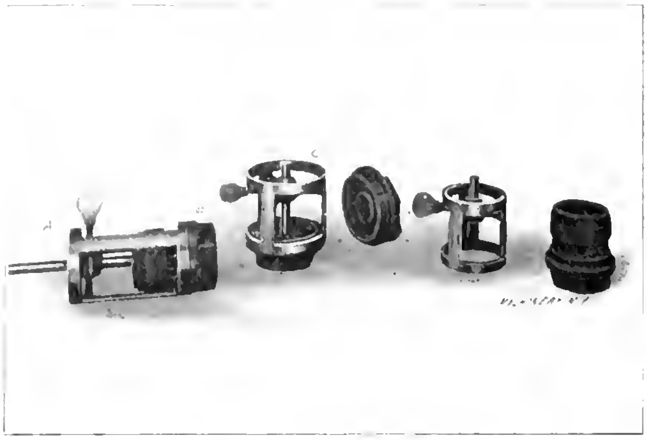

Fig. 33. Gages for Measuring Lift of Air Pump Valves

To remove locomotive tires, the wheels are hoisted onto a horse by the traveling crane and the tires are heated with the gasoline burner shown in Fig. 9, which quickly heats them so that they expand sufficiently to be easily removed from the wheels. The engraving shows one tire already off and the other being heated. The gasoline vapor used in this heater is obtained from the portable tank, Fig. 10, the pressure being supplied by air through a hose connected to the shop pipe line. This tank is very handy and is used to supply several other kinds of burners beside the one shown.

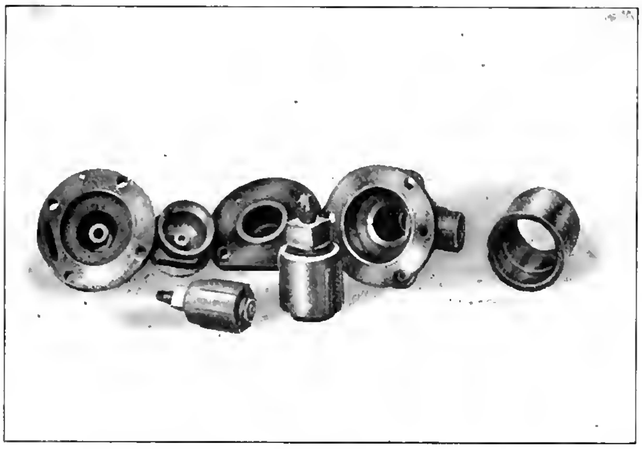

Fig. 34. Types of Reamers used for Air Pump Repairing, and Examples of the Work

Fig. 19 is a crude oil burner, stand and tank, used on some jobs of frame-welding, though the Thermit process is used for most of them. A Thermit repair is shown in Fig. 23, and aside from the method of welding, the job is interesting from the fact that a section of the old frame has been cut out and a new one is being put in. At *A* the end of the section has been welded onto the old frame and is ready to chip, while at *B* the wax core for the next weld is being made. The reason that a new section was put in is that the old frame showed so many defects at this place that it was not thought advisable to risk any repairs on it; so the bad section was cut out and a new one put in as shown. A frame repaired in this way is just as good as an entire new side and far cheaper, as only a few bolts, rivets, and braces have to be removed in comparison with the number connected to the whole side. In the opinion of the foreman in charge the cost of the work on this particular job would not exceed fifty dollars; whether or not this was more than a mere guess, I'll let those familiar with the work decide.

Interesting Tools and Methods in the Boiler Shop

There are very few shops capable of removing fireboxes with radial stay-bolts bodily, as shown in Fig. 20, but this is an everyday occurrence here, and is one of the sights of the shops for visitors. Mr. J. W. Kelley, the foreman of the boiler repair department, is justly proud of his work.

A patented pneumatic stay-bolt clipper, Fig. 24, is used for removing bolt heads on most of the boiler work in this department, and another patented pneumatic device, Fig. 25, is used for cutting out old flues. This tool differs from some similar ones in having a roller cutter (like the one on the familiar hand pipe-cutter) instead of a single blade, and also in having a shrill alarm-whistle which sounds the instant the flue is cut off, thus preventing waste of time whether from carelessness or intention. The shriek of the whistle is ear-splitting and can be heard for half a block above the usual din of the boiler shop.

All old flues are rattled or tumbled in a huge tumbler full of water, and from appearances this seems to be a more effective way than the dry method practiced in some shops, though the results are good either way. The number of flues that are welded here will range from five to nine thousand a month, and one of the best machines for trimming flues to length that I have seen, is shown in Fig. 26. This machine is the usual form of rotary cutting machine to which has been added an air-cylinder for raising and lowering the cutter. In all of those that I have seen elsewhere this is done by means of a hand-wheel, but for ease and speed the air device is much superior to the hand method. The use of an air attachment on the flue cutter brings me around to the old hand-power punch, which has been made over by the addition shown in Fig. 27. In this way a tool that was practically useless for doing a large amount of work, has been made into a productive machine.

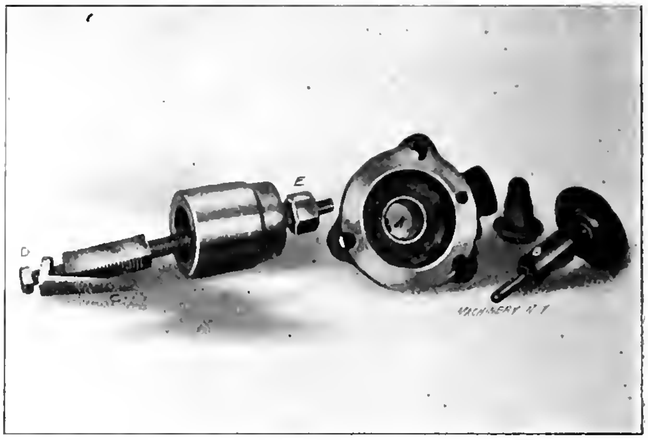

Fig. 35. Triple Valve and Tool for Facing Seat

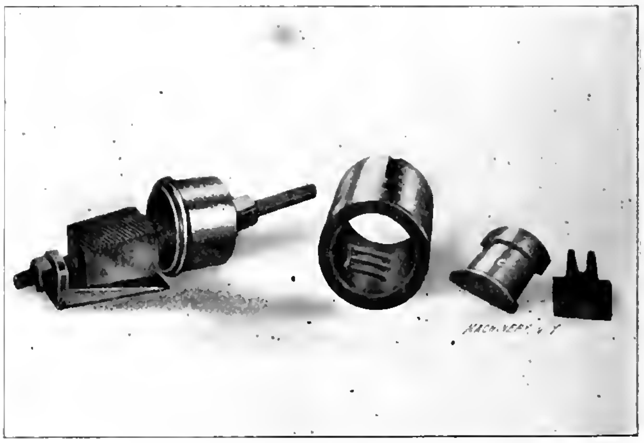

Fig. 36. Main Valve Bushing with Tool and Guide for Facing Valve Seat

Assembling Locomotive Springs

In the blacksmith shop, which is in charge of Mr. John McNally, the new springs used for repair work on all classes of locomotives, are cut, rolled, tempered, assembled, and tested, or new leaves are put in to replace broken ones in old

springs. Fig. 21 shows the special hydraulic press used to clamp the leaves together while a temporary ring is slipped on to hold them while putting on the regular band. After the temporary ring is in place, the spring is removed from the press and set on end in a socket, as shown in Fig. 45. The hot band is then dropped over and driven to place by means of a hand-set and sledge-hammer. As soon as the band is in place, the spring is put in the 100-ton hydraulic press, Fig. 46, which compresses the band around the spring in a box-like die and holds it firmly until it cools and sets. After cooling, the spring is next tested in the big Tinius Olsen testing machine, Fig. 22. The spring shown in the engravings is known as a trailer spring for class D engines, and is tested to 21,560 pounds, while the maximum load it is expected to carry is rated at 17,250 pounds.

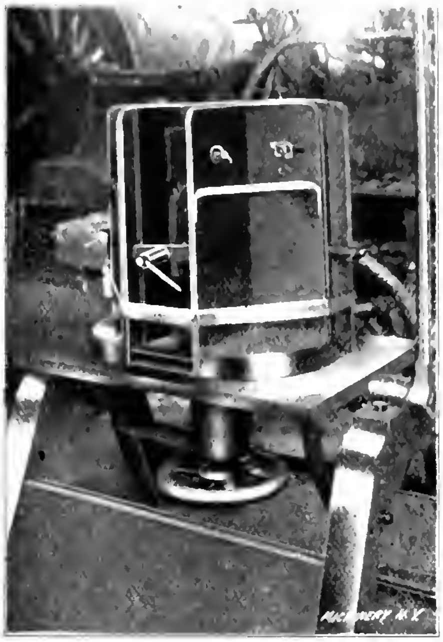

Fig. 38. Mold ready for Babbitting a Four-bar Guide Cross-head

Fig. 39. Cross-head Babbitted in the Mold shown in Fig. 38

The case-hardening furnace used in the blacksmith shop has a pneumatic door-lifter, that saves lots of time and trouble, which is shown in Fig. 28. The arrangement is very simple and could be used to good advantage on almost any large furnace of this type where connection with the air line can be easily had.

Tool Storage, Brass Finishing Department, and the Brass Foundry

The tool-storage room of the main shop is well equipped in every way, the revolving racks, Fig. 29, being especially neat and convenient. Close to the toolroom, which is in charge of Barney Henrickson, is the brass-finishing department in charge of William Water. The box-tools in use in this department are the equal of those used in the finest brass working shops in the country. Two of the wing-type box-tools are shown in Fig. 30, and a special expanding reaming tool is shown at the right, while leaning against the wall is a strainer punch and die of splendid workmanship. The tool cupboards, a few of which are shown open in Fig. 31, are filled with box-tools, forming tools, special taps, dies and the like, which are all made in a way that would reflect credit on any toolroom.

Fig. 32 shows a lathe set up for machining brass taper plugs. The box-tool used is shown swung around, while the self-opening die is just ready to begin to cut the thread on the taper plug held in the two-jawed chuck.

The brass foundry, in charge of Mr. T. Ryan, has two kinds of brass melting furnaces. One is a regular crucible furnace which is used for the finer grade of brass castings, while the other kind is of the box-type, crude-oil-fired furnace shown in Fig. 49. These furnaces are so made that they can be easily tilted by means of a hand-wheel, and in this way all melted brass is easily run out or kept in, as desired. A very refractory black slag forms on top of the brass melted in this way and has to be carefully skimmed off to prevent it mixing in and spoiling the castings.

Fig 43 Babbitting Car Brasses

Fig. 44 Furnace for Melting Babbitt from Old Brasses

A machine that is said to save at least twenty-five dollars a day for the brass foundry is shown in Fig. 48. It is a washer used to wash out all the dirt and save the brass chips and lumps that would otherwise be lost. A pile of several hundred pounds of brass, representing three days washing, showed what a gold mine was being successfully worked.

Air Pump Tools and Gages

There are many ways of obtaining the proper length of plug for the right valve lift in an air-pump, but I have seen nothing better than the gages shown in Fig. 33. The gage *A* is used when fitting the longer plug or cage *B* for the lower air valves (see also Fig. 50) while the shorter gage *C* is for the upper cap *D*. Each gage consists of a brass barrel through the middle of which slides a short rod, which is locked at any point by a thumb-screw. This rod is as much longer than the brass barrel, as the lift of the valve is to be. When fitting the upper plug *D*, the barrel of the gage *C* is set over the plug opening in the pump and the rod is pushed down until it comes into contact with the top of the valve. The thumb-screw is then tightened and the plug is so dressed that when it is inserted in the opposite end of the brass barrel, as shown at *C*, the boss against which the valve strikes, just touches the end of the iron rod. When fitting the lower

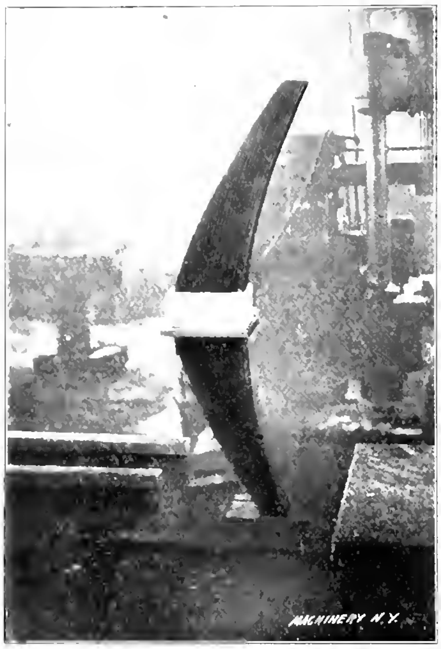

Fig 45. Position of the Spring as the Heated Band is Put in Place

Fig. 47. Grinding an Air Pump Head with Air Motor

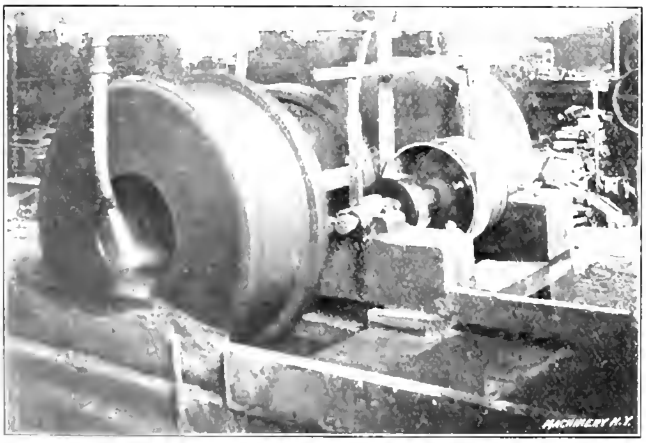

Fig. 48 Washing Machine for Separating Fine Particles of Brass from Foundry and Shop Dirt and Cinders

Fig. 49 Box Type of Brass Melting Furnace, which is fired by Crude Oil

plug the gage *A* is placed over the valve opening as before, and the rod is set against the boss *b* (Fig. 50), against which the lower valve strikes. The plug and valve are then dressed until the latter just touches the opposite end of the gage rod when tested as shown to the left in Fig. 33. Gages for the various valves are kept on hand and there is no excuse for a mistake in getting the right valve lift.

For facing off worn cylinders of triple or brake valves, pump governors, main valve bushings, and cups for air pump heads, the class of expanding reamer shown in Fig. 34 is used. The reamer blades are forced outward by means of the small screw in the middle of the wrench-hold. The tool used for facing off the worn seat of the triple valve at *A*, Fig. 35, to which the part *B*·fits, is something on the plan of a broach. It is set to cut the right amount by means of the wedge *C* and cap-screw *D* and it is drawn through the cut by screwing the nut *E* down on the spindle, which is kept from turning by a box-wrench on the squared end. A similar tool used for facing the seat of the main valve bushing for the 9½-inch air-pump, is shown in Fig. 36. This tool differs from the one just described, in that it has a back *C* to slide on while it is cutting. This cutter hasn't the tendency to turn that the one illustrated in Fig. 35 has, on account of the flat cutting surface, so no wrench is needed to keep the drawing spindle from rotating when the nut is being turned.

Fig. 47 shows how the top-head of a 9½-inch air-pump is ground to a perfect fit, with an air motor to turn it, while emery is used as a grinding medium.

Babbitting Jigs

The jig used while babbitting the crosshead slippers for alligator guides, is shown in Fig. 37, while Fig. 38 shows the jig used when babbitting crossheads for four-bar guides, with a crosshead in place, the side-plates on and all ready for pouring. Fig. 39 shows the crosshead finished and the jig with the side-plates removed. The way the crossheads are heated before they are placed in the jig is shown in Fig. 40.

Car-brasses are babbitted by placing them face down on the special half-mandrels shown in Fig. 43, and the babbitt is poured in through the holes in the brasses. Thousands of these brasses, just as they came from the cars, are shown in the pile in the background. These old brasses are thrown into the furnace, Fig. 44, and heated just enough to melt the babbitt, which runs from a spout into the big kettle shown at the right of the furnace. If the brasses are not too much worn they are re-babbitted, but if they are badly worn they are melted up and re-cast.

Miscellaneous Features of Interest

In Figs. 41 and 42 is shown an unusual way of machining engine cylinders on the slotter. Many advantages are claimed for this method, however, such as quickness and ease in handling and setting, and steadiness under a cut.

All sheet rubber or sheet copper gaskets used for any purpose in these shops are cut in special punch-press dies. The initial cost of the punches and dies is, of course, large, but the aggregate time saved for a year's repair work is enormous. Some cover and steam-chest gaskets are made of heavy copper wire, which is cut to the right length, after which the ends are square-lapped and brazed. The cutting and square-lapping is done at one stroke on the hand-press shown in Fig. 16. An adjustable stop on the bench, in line with the cutting-die, and graduations on the bench for the different sizes of gaskets used, makes it but the work of a moment to cut any size gasket wanted.

As solder is used in immense quantities in the various departments, it is mixed and cast into sticks in the works, the molds being shown in Fig. 17. The nearest molds have been emptied while the white appearance of the rest is caused by the steam of the water used to cool the solder. Close to the window is a set of mandrels for use in casting rocker-arm bearings. These mandrels vary in size by thirty-seconds of an inch, so that a mandrel can be selected from the set that will, by allowing for shrinkage, enable the molder to cast a bearing to fit any rocker-arm that can be used.

Beside their splendid shop practice, these shops have one of the best apprenticeship systems that I have found anywhere, which will be described in detail in another article.

BORING-BARS AND HEADS[*]

LUCIEN L. HAAS[†]

The design of a boring-bar or head is usually somewhat of a problem to most designers, as so much is often required of these tools. There are many important things to be considered in connection with this work, and in the following description of twenty different designs, which are illustrated in the Data Sheet accompanying this issue, I shall endeavor to cover at least the greater part of the questions involved under this head.

Fig. 1 illustrates a temporary boring-bar, which is an old design that is used universally. The end of the bar has a square slot through it into which the square tool *A* is a sliding fit. The tool is clamped in place by the set-screw *B* (which should be of the standard size), and is adjusted by tapping it lightly with a hammer. The bar shown in Fig. 2 is very similar to that of Fig. 1 with the exception that the tool is round instead of square. Set-screw *C* also provides means for a finer adjustment of the cutter than could be obtained for the one shown in Fig. 1. The set-screw *B* which bears against a flattened side on the cutter, clamps the latter in place. If this flattened surface is not provided on the tool it is liable to turn when taking a cut and serious damage may be the result. The bar illustrated in Fig. 3 is so designed that the cutting edge of the tool *A* is slightly in advance of the end of the bar. This tool is held by the screw *B* and adjusted by the screw *C*. Of course, it is necessary to remove the tool when making adjustments. This bar is adapted to boring blind holes, or for working close to shoulders, etc. The cutting tool should be set at an angle of about 60 degrees with the axis of the bar. Fig. 4 is a design of boring-head with two cutting tools. This head, after it has been hardened, is ground on the exterior *D* so that it can be used to guide the tools. It is fastened to the bar by the threaded shank shown. The cutting tools, which are set at an angle of 45 degrees, are made of round stock, and are held in place by set-screws *B*. When the tools are to be adjusted, they are removed and the adjustments are made by the screws *C*. Fig. 5 illustrates a bar with a cutter which is adjusted by means of a nut *C*. The tool is only threaded at one end and is a sliding fit in the bar. When properly adjusted it is held by the set-screw *B* which bears against a flattened surface. That part of the bar which is in contact with the nut *C* is also flattened. While all boring-bars will work with good results for a short time with soft centers, it is always advisable when accurate work is to be done to insert hardened centers *D* in the ends of the bar. These are easily made, and often much time has been wasted and much work lost simply because this point has been overlooked.

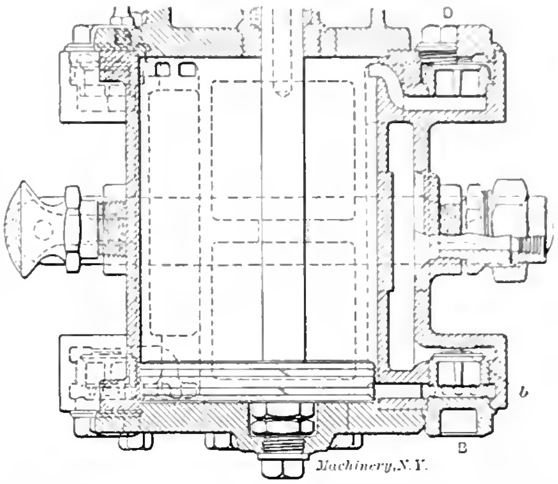

Fig. 50. Section of Air Cylinder of 9 1-2 inch Westinghouse Pump—The Valves are given the Correct Lift by the use of the Gages shown in Fig 33

The types shown in Figs. 6 and 7 are very much alike with the exception that the cutting tools are held differently. With the design of Fig. 6 the cutter can be placed in the

---

[*] With Data Sheet Supplement.

[†] Address: 341 Landon St., Buffalo, N. Y.

center of the boring-bar as well as at the end; but with the method of fastening shown in Fig. 7, the tool must be located at the end. In one case, as will be seen by referring to the illustrations, the cutter is held in place by a wedge, while a set-screw is used in the other. The tools in both cases should be made to hook over flats on the bars, thus centering them. The cutting edges are backed off similar to the teeth of a milling cutter. Both these designs are very good for heavy boring or cutting. Two designs which are also very similar are shown in Figs. 8 and 9. As will be seen, the ends of the bars are slotted, and the tools fit into these slots centered by fittings on either side, as in Figs. 6 and 7. Bars of this type are designed to face as well as bore, and they are admirably adapted to roughing out heavy work. The cutter in Fig. 8 is held in place by the conical-pointed screw which bears against a slot milled to an angle of 30 degrees in the cutter. As *C* is screwed inward the cutter is forced against the bottom of its slot. The cutting tool in Fig. 9 is held by means of a hardened bushing *D*—the flattened side of which is forced against the cutter by the screw *B*—which, as shown, is placed at an angle of 6 degrees with the side of the cutter. This method of fastening the tools is more expensive than that shown in Fig. 8, and does not give any better results. Fig. 10 shows a single-step tool with means of adjustment, which I have used in automatic turret machines for boring out steel, with excellent results. It has been found advisable, through experience, to equip a bar carrying such a tool with a pilot as shown in the illustration. The bar can be made of ordinary machine steel, but the pilot should be carbonized and ground to fit whatever sized bushing is used in the head of the machine. The cutting tool is beveled on the bottom at an angle of 30 degrees, and is adjusted by means of a hardened headless screw *C*, which has a corresponding taper. The tool is held in place by the two screws *B*.

The bars shown in Figs. 11 and 12 were designed for light boring, in such metals as aluminum, etc., and give the very best results for this class of work. Slots are cut on either side of the bar into which the cutters *A* are fitted. Hardened bushings *D* and screws *B* hold the cutters as in Fig. 9. The design illustrated in Fig. 13 works very successfully where there is facing as well as boring required, when it is absolutely necessary to have the cutters adjustable, and, as often happens, when it is also necessary that the cutters be held in place by some simple means accessible at the back instead of at the face or side of the head. The bar is slotted across the end to receive the two tools which are also slotted, as shown at *D*, sufficiently to allow one side of the round heads of the clamping bolts *B* to enter. This arrangement makes it possible to clamp the cutters by simply tightening the nuts on the bolts *B*. The tools are adjusted by the conical-pointed screw *C*, the end of which bears against the inner ends of the cutters, which are also tapered. The design shown in Fig. 14 is excellent when a boring-head for finishing cuts is wanted. It acts similarly to a reamer, and the tools *A* are very easily adjusted as they fit in tapering slots, and adjustments are obtained by varying their position. The clamps *D* and the screws *B* hold them in place. The bar shown in Fig. 15 is one that has been used for years as a roughing tool for cast iron cylinders.. The small cutting tools *A* which are held in place by the screws *B*, fit tightly in the slots provided for them. This design is defective, however, in that when adjustment is required it is necessary to insert new cutting tools.

Fig. 16 illustrates a design which is preferable to the one shown in Fig. 15, as the tools are provided with adjustment and, in addition, are rigidly held so that they will withstand a great strain. The bar is especially adapted to the boring of cast iron cylinders and gives excellent results when made up in sets for roughing and finishing. The bar has a slot across the end in which the boring cutters *A* fit. These cutters are notched, as shown, to allow the partial entrance of the heads on screws *C* which give the necessary adjustment. When the cutters are set they are held in place by the hardened set-screws *B*. The inserted-tool boring head shown in Fig. 17, is one of the strongest made. It is intended for boring steel, and will stand up under the most severe tests. The head should be made of steel and the cutting tools, should be made of the very best high-speed square steel and a sliding fit in their slots. The end of the head should be bored out first for the ring *D* and then slotted for the cutters and tapped for the set-screws *B*. Ring *D*, which contains the adjusting screws *C*, may then be driven in place. Fig. 18 illustrates a boring-bar or head with two inserted blades, which is an excellent tool for finishing brass or aluminum and may also be used for steel as well. The head is attached to the bar by means of a threaded shank. The cutting tools are tapered on the bottom and fit in slots having a corresponding taper, thus providing means of adjustment. They are clamped in place by driving in the taper pins *B*. Fig. 19 shows another design of boring-bar head, for finishing, which is attached to the bar in the same manner as the one shown in Fig. 18. The blades are also held in practically the same manner, but instead of using taper pins which often work loose, specially designed hardened screws *B* with heads tapered to about 8 degrees included angle, are used to clamp the cutters. Fig. 20 illustrates an excellent design for small cylindrical boring. The bar is threaded to fit the hardened collar *D* and the lock-nut *C*. The ring *B* should be a sliding fit on the bar and is kept from turning by the key *E*. This ring is slotted to suit the cutting tools, which should be made of square stock and which are adjusted by screwing back the collar *D* and tightening the lock-nut *C*. Three cutting tools are shown, but this number can be varied according to the size of the head.

GREAT POSSIBLE INCREASE OF BOILER CAPACITY

A preliminary report on the work of the Technologic Branch, United States Geological Survey, relating to experiments on steam boilers, has recently been issued. These experiments have been undertaken to ascertain the possibilities of increasing the capacity of boiler plants. It is stated in the report that the experiments so far made indicate that it is possible to double or triple the capacity of the plant without making any radical changes in furnace and boilers. This increase would require that a correspondingly increased amount of air be put through the grates; to do this, it would be necessary to apply increased pressure to the air, in order to force it through the grates. An equipment of fans designed to supply three or four times as much air under several times the pressure would be required. The results, however, appear as yet to be only tentative. The forcing of air under high pressure through the grates would require considerable power, and the proper ratio between this increased power, and the increased efficiency, must be established. It should not be attempted to force more air through existing grates by running fans a great deal faster, because the power required for this increases in too rapid a ratio. New fans would have to be installed of sufficiently larger size to supply the larger quantities of air at higher pressure. It is likely that new designs of grates, stokers, furnaces and boilers would be required in order to obtain the highest efficiency; but while the designs be improved, it is understood that no radical changes would be necessary. The United States Geological Survey will, in the near future, issue a bulletin on "The Significance of Drafts in Steam Boiler Practice" and another bulletin entitled "Drafts." They will deal in detail with the question of the influence of increased draft on the capacity of steam boilers.

* * *

An army officer whose duties require him to frequently visit three large cities which are so situated that a straight line drawn from one to the other forms a perfect triangle is soon to be court-martialed for adding a fourth side to the triangle.—*New York Times.*

This description of an equilateral triangle as a "perfect triangle" is on par with a "round circle." The addition of a fourth side would stagger Euclid himself. A caustic contemporary remarks: "That unique triangle ought to be put in a museum and kept there for the everlasting delectation of mathematical amateurs."

VERTICAL SAW-TOOTH ROOF CONSTRUCTION

In the accompanying illustrations is shown a type of vertical-sash saw-tooth for roof lighting, developed by F. W. Dean, mill engineer and architect, Boston, Mass. It, of course, is commonly known that in order to exclude direct sunlight from a skylight which faces toward the north the angle of inclination of the sash varies with the latitude. In general practice the face is inclined at an angle of between 60 and 80 degrees with the horizontal. The angle of 60 degrees which has been adopted by some as a standard in the average latitude of the principal manufacturing industries in the United States admits some direct rays when the sun is in the zenith. For the mean latitude of the United States it may be shown that the angle of the face should approximate 73 or 74 degrees.

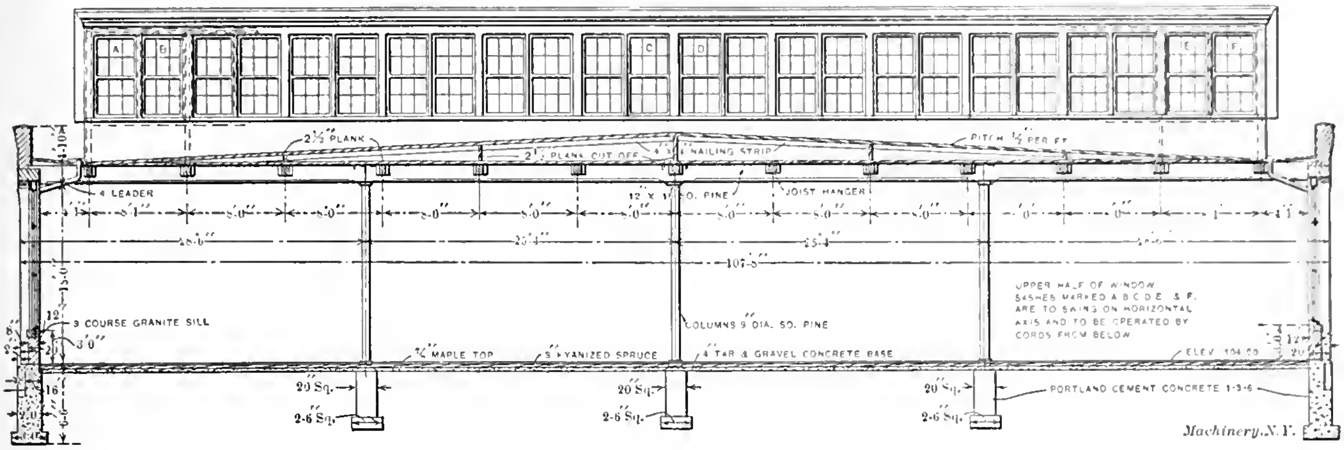

Fig. 1. Section through Building having Vertical Saw-tooth Roof

Study of the angles concerned shows that it makes but little difference in the lighting whether the face be vertical or not, but it is manifest that in features of construction and maintenance the vertical face avoids certain somewhat objectionable features of the inclined surface. Not only is the roof of the skylight more easily and simply supported in this design, but ordinary window sash may be used in place of the somewhat elaborate form of rigid metal sash with special provisions against leakage which is required when the glass is inclined.

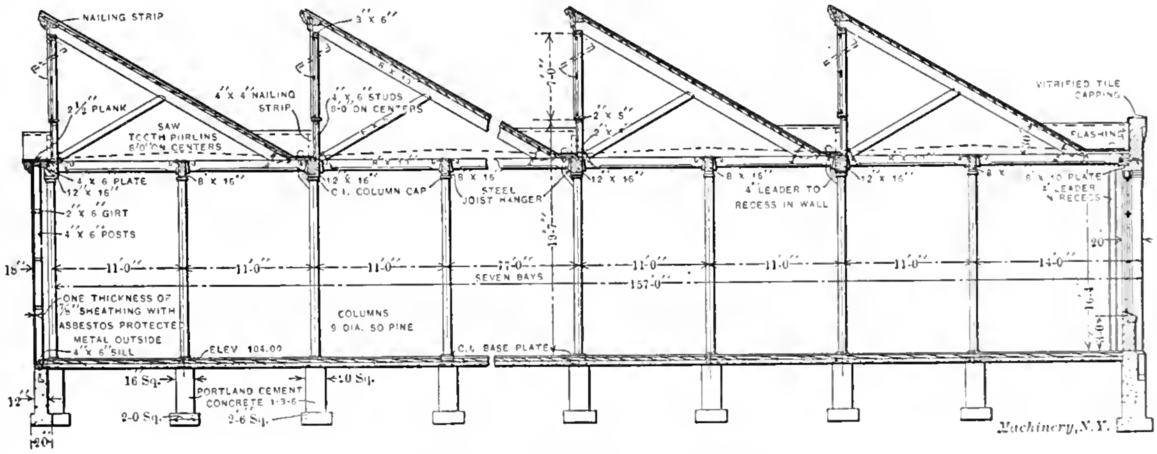

Fig. 2. Section showing Saw-tooth Roof Construction

In Mr. Dean's design regular window sash are used. The saving thus effected is practically balanced by the increased expense due to the longer rafters which are required, but it is not necessary to provide independent ventilators, for the upper sash are hung on a horizontal central axis and arranged to be operated by cord from below. By this arrangement the ventilation can be regulated to suit the exact requirements, either by opening some of the windows, or opening all a portion of the way. Condensation on the glass is positively caught by the zinc trays at the stools. The skylight roof, which is inclined at an angle of 30 degrees to the horizontal, consists of 2½-inch plank carried on 8 by 10-inch rafters, spaced 8 feet on centers and braced by 6 and 6-inch struts. The roof is covered with plastic slate, which is extended up the front of the skylights to act as flashing. The skylight windows are about 3½ feet wide by 6½ feet high.

This style of roof was used on the machine shop recently designed by Mr. Dean for the Canadian Rand Co., Ltd., of Sherbrooke, P. Q. It has also been employed to advantage in textile and similar mills.

TRAINING OF GERMAN ENGINEERS

An interesting reference to German methods in the practical training of engineers is given by Mr. Franz zur Nedden in the *Engineering Magazine* for April, 1909. The practical training of a German engineer is briefly as follows: The boys usually leave the high-school at an age of eighteen years. All German technical colleges require that candidates for admission must have passed through a year of practical work in a machine shop or factory. During this year the students are called volunteers and not apprentices, the name indicating that their aims are different from those of the latter class. This year of practical work is followed by four years of study in the technical college. Each year there is a three months' vacation, during which additional practical training is acquired. There are no shops for special training in the colleges, although from year to year the mechanical laboratories are becoming more important in the whole plan of instruction. It is evident that the training of a one-year "volunteer" is not always a very profitable undertaking to the firm where a student obtains his practical experience, and therefore a number of prominent German machine firms required a payment by the student of from $75 to $125 a year for giving special training to prospective engineers. Some firms, among which may be mentioned the Ludwig Loewe & Co., have instituted a high-grade educational course for their regular apprentices which was mentioned in the September, 1908, issue of MACHINERY, and their volunteers attend this course also.

FORMULAS FOR CRANE BEAMS OR GIRDERS

C. R. WHITTIER*

In a former article (March, 1909) it has been shown that for I-beams of the minimum sections, which are commonly used, with a fiber stress not exceeding 16,000 pounds per square inch, and properly braced sideways at distances not exceeding twenty times the width of the flange, the depth of a beam, h, is closely determined by the formula $h = \sqrt{1.2\,l\,W} + 1$, where l is the span in feet and W the center load in tons. And approximately for center loads for the standard plate girders tabulated in the Carnegie hand-book, with a fiber stress not exceeding 15,000 pounds per square inch, $h = \sqrt{l\,W}$. But for the ordinary crane beam, and similar uses which do not admit of side supports, the above formulas require modification.

They become with center loads: For beams, $h = \sqrt{1.2\,l\,W} + 1 + 0.004\,l^2$; for girders, $h = \sqrt{l\,W} + 0.004\,l^2$.

Of course these are based on the supposition that the beams are sufficiently long not to fail by crippling of the web—a case which almost never occurs in practice.

These formulas give a ready means for determining the size required for a given load and span without the use of tables and the usual trial-and-error methods; they are especially useful in the field, and for preliminary work. Up to the point where the length of the beam does not exceed seventy times the flange width, they will be found sufficiently accurate. Above this point the error slowly increases, but always on the safe side.

As with the original formulas, the correction given is not purely empirical, but is deduced from accepted laws. The result is surprisingly simple when the long road required to reach it is considered. The method may be of interest.

The manner of determining the proper coefficient for reducing the usual load to prevent undue strains in the compression flange when the beam is considered as a column, is well known; and different authorities give slightly varying figures. The Carnegie table is as follows:

When the length of a beam does not exceed 20 times the flange width, the coefficient for safe load = 1.
When the ratio does not exceed 30, coefficient = 0.9.
When the ratio does not exceed 40, coefficient = 0.8.
When the ratio does not exceed 50, coefficient = 0.7.
When the ratio does not exceed 60, coefficient = 0.6.
When the ratio does not exceed 70, coefficient = 0.5.

Changing the length to feet, and keeping the width in inches, this is equivalent to the following:

When the ratio, l in feet, w in inches = 1.7, coefficient = 1.
When the ratio, l in feet, w in inches = 2.5, coefficient = 0.9.
When the ratio, l in feet, w in inches = 3.3, coefficient = 0.8.
When the ratio, l in feet, w in inches = 4.2, coefficient = 0.7.
When the ratio, l in feet, w in inches = 5.0, coefficient = 0.6.
When the ratio, l in feet, w in inches = 5.8, coefficient = 0.5.

We now wish to substitute for w its equivalent value in terms of h. By plotting, and deducing an approximate formula for the curve, we find that $w = 1.4\sqrt{h}$ very nearly, this being a simple parabolic curve which closely averages the plotted points.

Substituting in the above, we have, for the first case,

$$\frac{l}{1.4\sqrt{h}} = 1.7. \quad \text{Reducing } \frac{l}{\sqrt{h}} = 2.4, \text{ and}$$

$$\frac{l^2}{h} = 5.7.$$

Applying this method to the other ratios, as well, we have:

When ratio $l^2/h = 5.7$, coefficient of load = 1.
When ratio $l^2/h = 12.2$, coefficient of load = 0.9.
When ratio $l^2/h = 21.2$, coefficient of load = 0.8.
When ratio $l^2/h = 34.7$, coefficient of load = 0.7.
When ratio $l^2/h = 49.0$, coefficient of load = 0.6.
When ratio $l^2/h = 67.0$, coefficient of load = 0.5.

Plotting the above, it will be found that the straight line formula, coefficient = 1 — 0.008 ratio, gives practically the same coefficients. Therefore, coefficient for safe load, $C = 1 - \frac{0.008\,l^2}{h}$.

$$C = \frac{h - 0.008\,l^2}{h}$$

Now let W_1 represent the load in our original formula for plate girders, *i. e.*, $h = \sqrt{l\,W_1}$

Applying our coefficient for correction we have approximately, $W_1 = \frac{W}{C}$, and $h = \sqrt{\frac{l\,W}{C}}$. Squaring, and clearing of fractions, $h^2\,C = lW$. Substituting the value of C determined above:

$$\frac{h^2\,(h - 0.008\,l^2)}{h} = lW, \text{ and } h^2 - 0.008\,l^2h = lW.$$

Completing the square, and solving for h:

$$h - 0.004\,l^2 = \sqrt{l\,W + (0.004\,l^2)^2}\ .$$

The quantity $(0.004l^2)^2$ is so small in comparison with lW as to be negligible, and we have finally, $h = \sqrt{lW} + 0.004\,l^2$, as first given.

By a similar process for I-beams, we have approximately:

$$h = \sqrt{1.2\,l\,W} + 1 + 0.004\,l^2$$

It is easy to point out discrepancies in the extreme cases of this method of averaging by simple curves, but the final tests show that the errors of the approximations are relatively small. The resulting formula is so simple that it can be solved mentally, and is close enough for all but construction work. A few comparative examples with extreme lengths are appended, to show their accuracy; shorter lengths give even more accurate determinations.

For this purpose, a size of beam and span are assumed, the safe loads taken from the tables and corrected for center load, and the usual correction applied for no lateral support, giving the net load for this condition. Then for comparison with this usual method, assuming this same net load and span to be given, the process is reversed, and the size of beam determined by the formula.

From the tables, reduced to center load:
24-inch I-beam, 36 feet span, 12.9 tons load.
$w = 7$ inches,
$36 \times 12 \div 7 = 62$,
$C = 0.6$,
$12.9 \times 0.6 = 7.7$ tons net safe load.
By formula:
$h = \sqrt{1.2 \times 36 \times 7.7} + 1 + (0.004 \times 36^2) = 18.3 + 1 + 5.2 = 24.5$ inches, required height of beam.

Similar extreme examples for smaller beams give the following results:

Beam =	18 inches	12 inches	6 inches	4 inches
$W =$	6.5 tons	3.3 tons	1.0 ton	0.4 ton
$l =$	36 feet	20 feet	30 feet	20 feet
$w =$	6 inches	5 inches	3 inches	2.66 inches
$\frac{12\,l}{w} =$	72	72	80	90
$C =$	0.5	0.5	0.4	0.3
$WC =$	3.3 tons	1.6 ton	0.4 ton	0.12 ton

Calculated by the formula the required heights of the beams, in inches, are the sums of the following:

12	7.6	3.1	1.5
1	1	1	1
5.2	3.6	1.6	1.6
18.2	12.2	5.7	4.1

In practical solutions, all decimals of feet and tons may be disregarded, using the nearest whole number, and the results obtained mentally will give the same beam. A few decimals were retained in the examples for the purpose of showing how closely the formula applies.

* * *

A 2,000-kilowatt steam turbine installed in Rugby, England, has been placed on a rubber foundation and it is expected in this way to avoid objectionable vibration. The turbine is bolted to a concrete base 2 feet thick, which in turn, rests on several circular rubber stools, standing on a regular concrete foundation. Each rubber stool is a cylinder about four inches in diameter and three inches high when compressed by the weight of the turbine set. The idea of mounting turbines in this way is not new, but it is stated by *Engineering* that it has never before been tried with so large a turbine unit.

DESIGN AND CONSTRUCTION OF ELECTRIC OVERHEAD CRANES—5

GIRDERS

R. B. BROWN

The primary consideration when designing an overhead crane lies in selecting the correct type of main girders, since not only the general efficiency of the crane is affected by this question, but, as the girders usually represent the bulk of the machines, the subsequent success in competition largely depends upon the selection of an economical type. Coincident with the question of type is that of the factor of safety, or the working stress. Practically all crane girders are now built of steel sections made by the open hearth acid process, and usually specified to possess a tensile strength of from 28 to 32 tons per square inch.

A great variation of opinion exists on the question of working stress; while many cranes are made having girders stressed to only four tons per square inch and even less, others, will be found having above seven tons stress. Taking into consideration the fact that a general factor of safety of five seems to be usual and most desirable in crane work, it is necessary to limit the stress to one-fifth of the maximum breaking strength of the steel, which gives approximately 5½ tons per square inch.

There are four types of girders commonly used, *viz.*, box-plate girders, single web-plate girders, braced girders, and rolled beam girders. Each will be considered independently.

The simplest form of girder for spans up to about 40 feet is the rolled steel joist, and for light loads it is undoubtedly the cheapest type. The effective range of span and load for beam girders will be seen from Table IX which has been compiled to show the type of girder generally considered suitable for a given span and load.

For cranes up to 15 tons with spans too great for joists but not more than 65 feet, the best form of girder is the single web type. Up to 40 feet span, providing the traveling speed is not very high, these girders can be made to carry themselves and a light platform, if the flanges are moderately wide, but above 40 feet span these girders will be found weak laterally, and a subsidiary braced platform girder of light construction should be added, the same being braced horizontally to the main girder, as shown in Fig. 17. Although this type has been found somewhat costly, there is no doubt it is stiffer laterally than a box girder, and the single web girder always possesses the advantage of permitting inspection and painting, thereby avoiding deterioration from corrosion, such as occasionally takes place in box girders. For cranes above 15 tons and for spans up to 65 feet, however, the box girder is considered the best and cheapest type that can be used. The sections and proportions required by such loads generally ensure the girder being stiff enough to carry the platforms and cross-shaft without causing any lateral distortion.

For cranes up to and including 4 tons, above 40 feet span and for all cranes from above 65 or 70 feet span, braced girders are the most economical. They are cheaper to make, and the reduced weight of the crane effects a saving in the power required for traveling, and may possibly reduce the scantlings of the runway girders. The most important question concerning braced girders lies in the adoption of the correct system of bracing, of which there are three designs in use, *viz.*, the Warren, the Linville and the latticed, as shown in Figs. 18, 19 and 20, respectively.

In point of cost, weight, and general convenience, the Warren type is the most suitable for the ordinary form of traveler. It has fewer joints and members, and gives satisfactory results in all respects. When the rolling load is large in proportion to the structural load, as is invariably

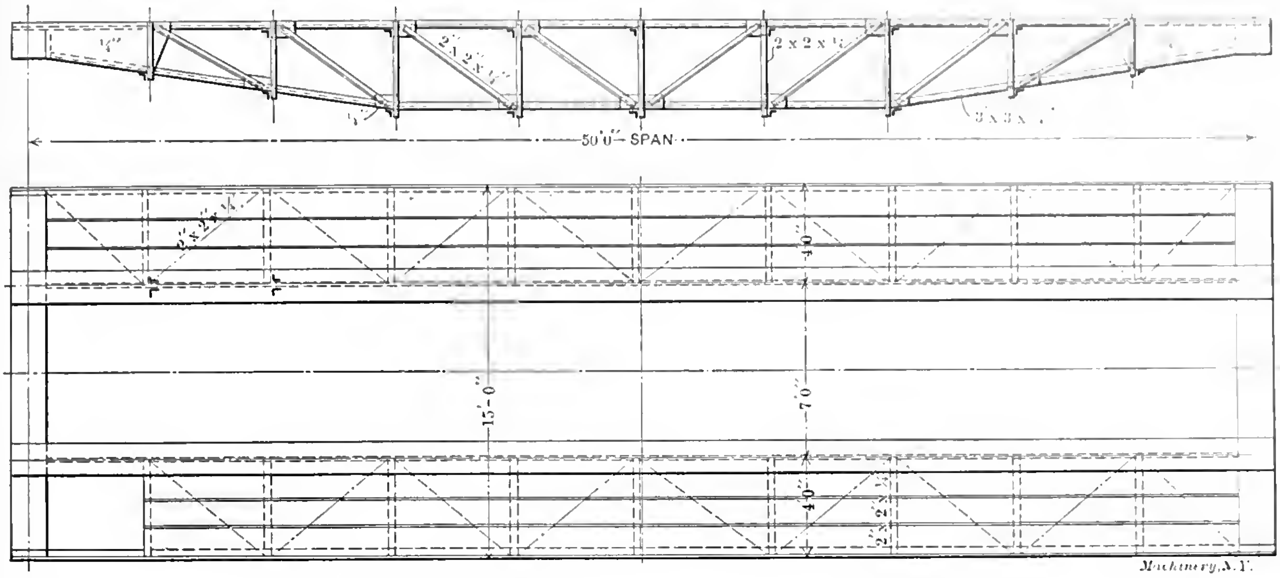

Fig. 17. Web-plate Girder with Braced Platform Girder, added to insure Sufficient Strength for Wide Spans

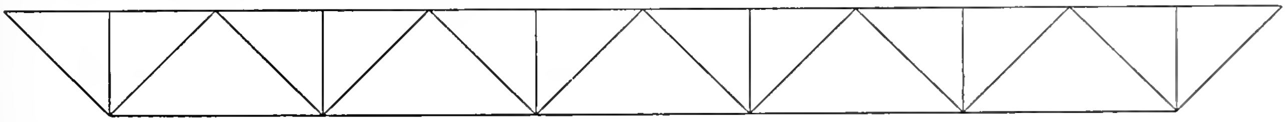

Fig.18

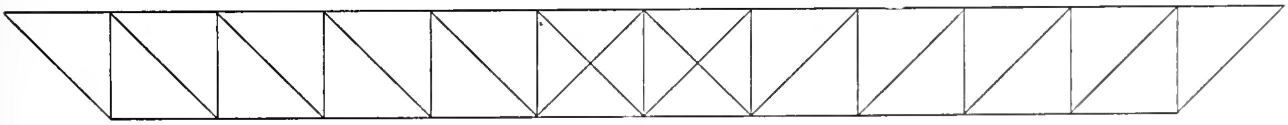

Fig.19

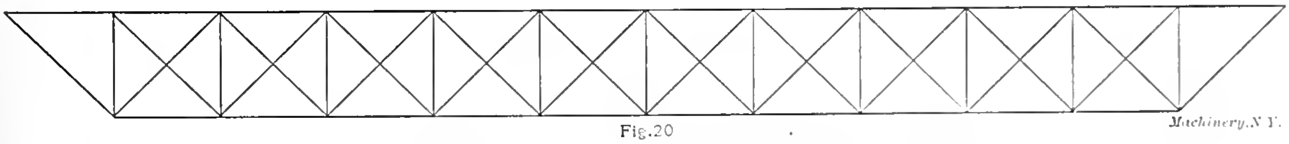

Fig.20

Figs. 18 to 20. Warren, Linville and Latticed Girders

the case with cranes, the Linville type requires so much counterbracing in the center, that it practically results in a latticed girder pure and simple, which, although frequently adopted, is heavier and more costly than the Warren type.

In order to treat the subject completely, it is proposed to consider the details of each type of girder, *i. e.*, solid, web, and latticed, independently, and although some parts may be a repetition, the arrangement will be more convenient to the designer.

Single Web, Box and Beam Girders

The preliminary calculation concerning the strength of girders of the above type is principally that of finding the bending moment in the ordinary way. This quantity should include the forces due to the rolling load of the weight and crab combined, the structural load due to the weight of the girder itself and the platform and cross shaft; and, if the driving motor is in the center, allowance must be made for this also.

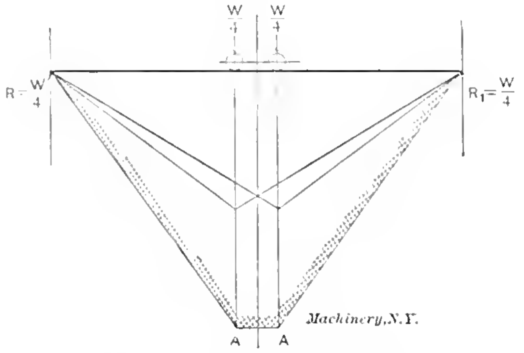

Fig. 21. Bending Moment Diagram, showing how the Effective Span of Girder is shortened by the Center Distance of the Crab Wheels

The practice of making some allowance for impact forces is neglected by the majority of crane builders, while, on the other hand, when work of this nature is undertaken by bridge builders, one finds as much as 50 per cent being added to the actual rolling loads to cover supposed impact forces.

TABLE IX. TYPE OF GIRDERS USED FOR DIFFERENT LOADS AND SPANS

R S B = beam section.
S W P = single web girder with lateral bracing girders.
B G = ordinary box girders.
L G = lattice girders, preferably Warren type.

Load in Tons.	Span in Feet.					
	30	40	50	60	70	80
5	R S B	R S B	S W P	S W P	L G	L G
10	R S B	S W P	S W P	S W P	L G	L G
15	R S B	S W P	S W P	S W P	L G	L G
20	R S B	S W P	S W P	S W P	L G	L G
25	B G	B G	B G	B G	L G	L G
30	B G	B G	B G	B G	L G	L G
40	B G	B G	B G	B G	L G	L G
50	B G	B G	B G	B G	L G	L G
60	B G	B G	B G	B G	L G	L G
75	B G	B G	B G	B G	L G	L G
100	B G	B G	B G	B G	L G	L G

That some allowance should be made appears quite consistent, particularly in high speed cranes, but there seems to be no definite rule for this. Generally speaking, the working stresses of crane girders, say 5 to 6 tons per square inch, provide a margin for small additional impact forces. No allowance will be made in the following calculations for impact stress, but such allowance could easily be added if considered necessary in any particular case.

If the crab is symmetrically built, the rolling load may be considered to be divided equally over the four wheels. By making this allowance it will be seen, as far as the rolling load is concerned, that the effective span of the girder is shortened by a distance equal to the center distance of the crab wheels. This can better be seen by reference to the bending moment diagram in Fig. 21, where it will be seen that the maximum bending moment from the rolling load occurs at *A A*, and is equal to the reaction at either support multiplied by the distance from that support to the center of the crab wheel. This quantity is also the bending moment at the center. To find the bending moment due to the structural load, it is usual to treat the latter as an evenly distributed load, where $M_b = \frac{WL}{8}$; similarly a traveling motor in the center of the span must be considered as a concentrated load, where $M_b = \frac{WL}{4}$.

A bending moment diagram might be drawn combining the whole of the above forces, but the same result can be found more quickly directly by figures, as shown in the following example.

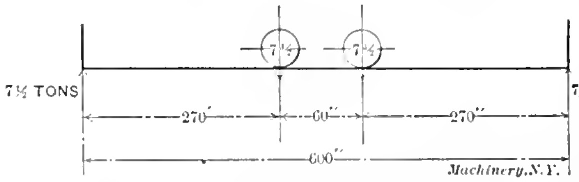

Fig. 22. Example for Calculating Bending Moment in Crane Girder

Find the total bending moment of a 25-ton crane, 50-foot span, weight of crab 5 tons, centers of wheels 5 feet. Approximate weight of one girder and platform, etc., 5 tons. Traveling motor in the center: weight ¾ ton. (See Fig. 22.)

$$\text{Bending moment, rolling load} = 270 \times 7\tfrac{1}{2} = 2025 \text{ inch-tons}$$

$$\text{Bending moment, structural load} = \frac{5 \times 600}{8} = 375 \text{ inch-tons}$$

$$\text{Bending moment, traveling motor} = \frac{3 \times 600}{4 \times 4} = 112.5 \text{ inch-tons}$$

$$\text{Total,} \quad = 2512.5 \text{ inch-tons}$$

When the maximum bending moment has been found, the depth of the girder must be considered. Modern practice generally makes this quantity the nearest even dimension equal to 1/15 or 1/16 of the span. In the case of heavy cranes, however, it is more economical to increase the depth of the girders than to make the flanges abnormally heavy, so that in the case of 100-ton overhead cranes of moderate span, the best proportion is about 1/12 of the span. An exception to the above rules occurs in the case of all short span cranes, where the depth becomes a matter of convenience.

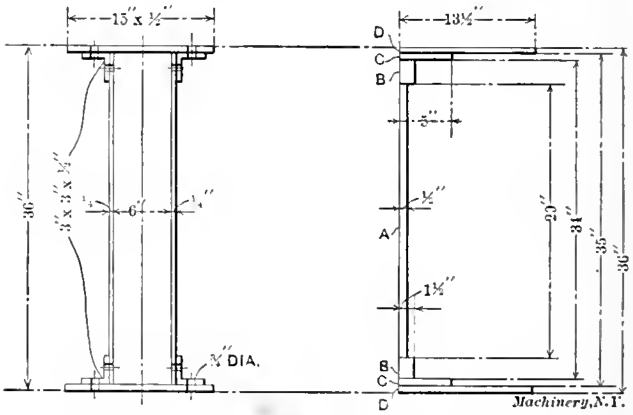

Fig. 23. Proposed Section of Girder, drawn to convenience its Calculation

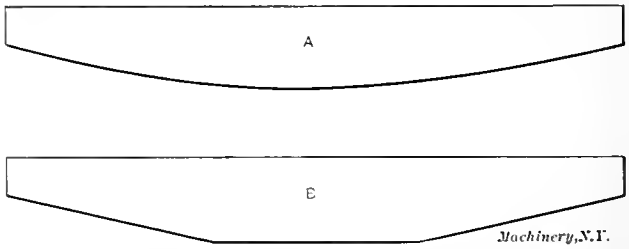

Fig. 24. Types of Fish-bellied Girders in Use

In determining the section of the girder it has, until quite recently, been common practice to totally ignore the value of the webs to resist bending, the flange area alone being

taken into consideration. This practice is open to some question; it seems that if the webs are stiffened in the usual way, they are of such value as to allow the whole section of the girder being taken into account, but in any case, the webs do not add much to the modulus. In order to calculate the strength, the moment of resistance or modulus of the section must be found; and this must be equal the bending moment divided by the working stress F in the girder:

$$\frac{M_b}{F} = Z$$

When finding a required modulus, the section has to be assumed, preferably by comparison, after the depth has been fixed. Allowance should be made for the rivet holes in the flanges to be ⅛ larger than the size of rivet. It is generally found convenient to draw the proposed section as shown in Fig. 23.

Before the modulus itself can be found, the moment of inertia of the section must be calculated. This quantity, for rectangular symmetrical sections taken about the neutral axis, is equal to 1/12 $b h^3$, when b = breadth and h = height of rectangle.

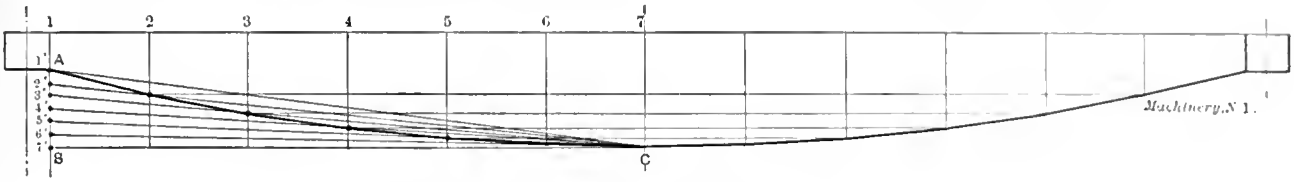

Fig. 25. Laying out a Girder of the A Type, Fig. 24

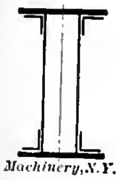

TABLE X. GENERAL DIMENSIONS OF BOX GIRDERS FOR ELECTRIC OVERHEAD CRANES, AND MODULUS OF GIRDER SECTION

Depth.	Flange, Inches.	Angles, Inches.	Webs, Inches.	Modulus.
2'-3"	12 x ⅜	3 x 3 x ⅜	¼	230
2-3	12 x ½	3 x 3 x ½	¼	292
2-6	12 x ⅜	3 x 3 x ⅜	¼	273
2-6	12 x ½	3 x 3 x ½	¼	308
2-9	12 x ⅜	3 x 3 x ⅜	¼	314
2-9	12 x ½	3 x 3 x ½	¼	380
3-0	15 x ⅜	3 x 3 x ⅜	¼	378
3-0	15 x ½	3½ x 3½ x ½	5/16	530
3-6	15 x ⅜	3½ x 3½ x ⅜	¼	500
3-6	15 x ½	3½ x 3½ x ½	5/16	653
4-0	18 x ½	3½ x 3½ x ⅜	5/16	797
4-0	18 x ⅝	3½ x 3½ x ½	5/16	940
4-6	18 x ½	3½ x 3½ x ½	5/16	998
4-6	18 x ⅝	4 x 4 x ½	5/16	1118
5-0	21 x ¾	4½ x 4½ x ¾	⅜	1809
5-0	21 x 1	4½ x 4½ x ¾	⅜	2057

Referring to Fig. 23, it will be understood that, owing to its irregular shape, each rectangle A, B, C, and D must be treated independently.

The total moment of inertia of the section can, therefore, be stated as follows:

$$I = \frac{(36^3-35^3)\times 13\frac{1}{2} + (35^3-34^3)\times 5 + (34^3-29^3)\times 1\frac{1}{2} + 29^3\times\frac{1}{2}}{12}$$

= 8,600 approximately.

It is well known that the modulus of moment of resistance of a symmetrical section is equal to the moment of inertia divided by the distance from the neutral axis to the extreme outer edge of the section; consequently the modulus Z of the section $= \frac{8600}{18} = 478$.

Tables X and XI give approximate values of various box and single web sections suitable for crane work.

Although box girders have been made with 3/16-inch web plates, it cannot be considered good practice to use plates less than ¼ inch thick, owing to the small margin allowed for deterioration from rust. For box girders on cranes up to and including 20 tons, ¼-inch webs have been repeatedly used and show no signs of buckling with the ordinary arrangement of stiffeners. The same applies to 5/16-inch webs for 30- to 50-ton cranes, above this size ⅜-inch plates are recommended.

In the case of single web girders, ¼-inch plates have been used for cranes up to 7 tons, increasing to 5/16 inch up to 20 tons, and ⅜ inch or more, above, as required. When the stiffeners are placed outside, T sections are generally used, but for cranes up to 10 tons, 2½- to 3-inch angles are amply strong enough, and also convenient for fastening the brackets. The various formulas for pitch of stiffeners used in bridge practice do not seem to agree with the results found in crane girders, since they usually give the centers of stiffeners unnecessarily close. The average practice is to place the stiffeners about 5 feet apart, but it is better to reduce this dimension to 4 feet 6 inches for girders up to 2 feet 6 inches deep. The practice of placing channels or Z-bars inside, instead of using outside T-stiffeners, generally necessitates some hand riveting; otherwise this is a neat and strong type.

As shown in Fig. 24, there are two forms of fish bellied girders in use. The lower boom in both cases is polygonal, that in A having a side or flat for each division made by the stiffeners, while that in B has three straight cuts only, and is, therefore, cheaper; the general opinion is that both look equally well when erected. To find the varying depths in girder A, it is best to draw a parabola in the usual way, as shown in Fig. 25. The divisions 1 to 7 represent the centers of the stiffeners, and the distance AB must be divided into the same number of equal divisions on each side of the center line of the girder. Drop verticals from 2, 3, and 4, etc., and join $C2'$, $C3'$, $C4'$, etc. The point of intersection between these two lines gives the depth of the girder at that point. Although the above method gives a well-shaped girder, it is not theoretically correct, since the parabola should be set off from the top flange. When this is done, however, the ends of the girder have to be parallel for a certain distance and this causes extra trouble in planing the webs, without any economy in material. In the case of type B, the correct parabola should be laid out, and the flats laid off to suit.

For girders up to 40 feet span which are going to be shipped in one piece, it is possible and preferable to have

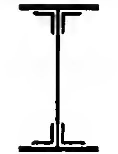

TABLE XI. GENERAL DIMENSIONS OF SINGLE WEB GIRDERS FOR ELECTRIC OVERHEAD CRANES, AND MODULUS OF GIRDER SECTION

Depth	Flange, Inches.	Angles, Inches.	Webs, Inches.	Modulus
2'-3"	12 x ⅜	3 x 3 x ⅜	¼	202
2-3	12 x ½	3 x 3 x ½	5/16	271
2-6	12 x ⅜	3 x 3 x ⅜	¼	238
2-6	12 x ½	3 x 3 x ½	5/16	282
2-9	12 x ⅜	3 x 3 x ⅜	¼	272
2-9	12 x ½	3 x 3 x ½	5/16	315
3-0	15 x ⅜	3 x 3 x ⅜	5/16	340
3-0	15 x ½	3½ x 3½ x ½	5/16	467
3-6	15 x ⅜	3½ x 3½ x ⅜	5/16	448
3-6	15 x ½	3½ x 3½ x ½	⅜	583
4-0	18 x ½	3½ x 3½ x ⅜	⅜	705
4-0	18 x ⅝	3½ x 3½ x ½	⅜	849
4-6	18 x ½	3½ x 3½ x ½	⅜	881
4-6	18 x ⅝	4 x 4 x ½	⅜	1002
5-0	21 x ¾	4½ x 4½ x ¾	7/16	1631
5-0	21 x 1	4½ x 4½ x ¾	½	1917

the flange plates and angles in one length, and thereby avoid the joints. When, however, joints are necessary in the flanges, it is the practice of some makers to allow 25 per cent extra section for the rivets, and the flange joint plates and angles should be of the same section as the flanges themselves, at least.

For cranes traveling at a moderately high speed, that is, anything over 200 feet per minute, the lateral stresses due to suddenly stopping the load require consideration. If, for example, the 25-ton crane previously referred to travels at 300 feet per minute (5 feet per second) under full load, the momentum of the load and crab at full speed will be $\frac{W v^2}{2 g}$

$$\text{or } \frac{30 \times 5^2}{64.4} = 11.6 \text{ foot-tons.}$$

It is difficult to assume what would be the least distance that the crane would travel before coming to rest after the current had been shut off and the brake had been applied, but a minimum of five feet has been found satisfactory, and under this condition the average horizontal force on the two girders would be $\frac{11.6}{5} = 2.3$ tons, or 1.15 ton per girder. This would be the concentrated effort, but there is also the distributed effort due to the girder itself, which will be found by the above formulas to be about 0.95 ton per girder.

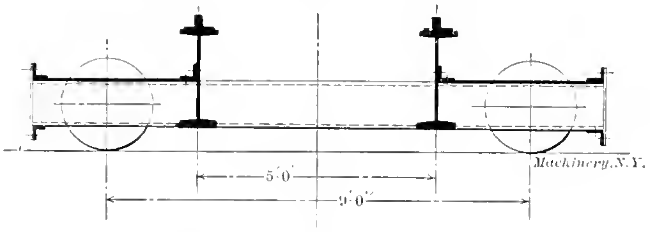

Fig. 26. Method of Stiffening Steel Joist Girders

In order to avoid possible distortion from the concentrated load, one must assume that it is carried by the upper part of the girder only, that is, the flange plate, angles and about 18 inches of the webs. The bending moment from the concentrated load, in the above example, allowing for the spacing of the crab wheels, is $0.57 \times 270 = 154$ inch-tons.

The modulus of the upper flange taken horizontally is 45.7, therefore, the stress is $\frac{154}{45.7} = 3.4$ tons per square inch.

The distributed load is carried by the full depth of the girder, and, allowing for the horizontal modulus of the whole of the section, gives a stress equal to about 0.7 ton per square inch, bringing the total lateral stress up to $3.4 + 0.7 = 4.1$ tons per square inch.

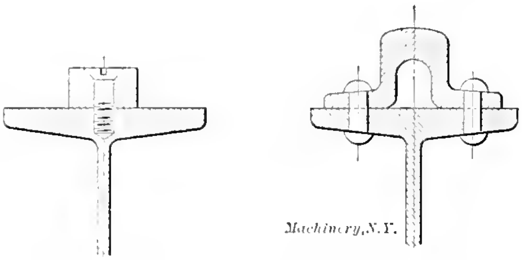

Fig. 27. Methods of Attaching the Rail to the Beam Girder

The total lateral stress should not exceed four tons per square inch under the above conditions, since the ratio between flange width and span, which is usually about 1 to 40, is large, and the girder is, therefore, more easily deflected.

By referring to Table IX it will be seen that rolled steel beams can be used for cranes of varying capacity, up to 40 feet span. The most economical and only really practicable method of using steel beams for moderate-speed and high-speed cranes is to attach a steel chequer-plate platform to both girders in such a manner as to provide the necessary lateral stiffness. Fig. 26 shows a typical form of this arrangement.

There are two common methods of fixing the rails on the beams, either by riveting on a bridge section rail, or screwing on a flat bar, as shown in Fig. 27. Both methods are equally satisfactory.

[In the fourth installment of this series, published in the April issue, two errors occurred in the numerical calculations. At the top of page 578 the calculation of the weight required for mechanical brakes should have been, theoretically, 127 pounds, instead of 12.5 pounds, and the weight with the extra allowance about 150 pounds, instead of 15 pounds, for the conditions given. The numerical example for a brake of the friction disk type also contains an initial error which makes the subsequent results erroneous. The formula given, however, is correct. Those who file these articles should, therefore, make note of this in the places referred to, so that confusion may be avoided when the matter is referred to in the future.—Editor.]

* * *

ANTI-FRICTION ALLOYS FOR BEARINGS*

The load at which rubbing begins is generally greater, the harder the metals in contact; the coefficient of friction on the other hand is generally smaller, the harder the metal. In order to reduce friction as well as to avoid cutting, hard substances should be used for bearing surfaces—hence the use of phosphor bronze.

The use of hard substances, however, corrects only the effects of defective lubrication, and assumes that the surfaces in contact are regular, so that the load is uniformly distributed and not concentrated in certain points. If the metal is hard and unyielding, the pressure on these points becomes considerable and leads to heating and cutting. Hence the bearing metal must have a certain plasticity so as to mold itself around the shaft and increase the surface of contact. But the bearing itself is constantly wearing away irregularly, and the plasticity of the metal must be such as to constantly restore its contact with the shaft.

We are led, therefore, to seek in alloys for bearings subjected to friction, two apparently contradictory characteristics, namely, hardness and plasticity. We may combine them, however, in using metals composed of hard grains embedded in a plastic matrix, and this is the main principle aimed at in anti-friction alloys.

The constitution of bronzes is the reverse of that of white alloys. Instead of hard grains in a plastic eutectic, we have soft grains in a hard eutectic for the same degree of plasticity. The behavior of bronze and white metals is not identical, and the bronze has a greater tendency to cut than the white alloys.

If the weight borne by the bearing of a uniformly-rotating shaft be gradually increased, when a certain load is reached the oil is driven from the space between the shaft and the bearing, and the metal becomes heated. In the case of white metal the wear is then considerable, and if the load continues to increase, the alloy may be partially fused. In the case of bronze, the portions rich in copper adhere to the shaft, forming a rough surface and increasing the friction.

Bronzes are then inferior to white metals because they are less plastic and do not mold themselves as well around the axle; their greater strength does not permit a heavier load, for then the lubrication is interfered with, and they tend to become heated. Bronzes, on account of their constitution, have a greater tendency to cut than white alloys, and thus produce a deterioration of the axle.

An anti-friction alloy should have hard grains in a plastic matrix; then the load is carried by the hard grains which have a low coefficient of friction, and the cutting can only take place with difficulty. The plasticity of the cement makes it possible for the bearing to adjust itself around the shaft, thus avoiding local pressures, which are the chief cause of accidents. Such properties may be obtained in binary alloys with such metals as antimony, tin, and copper, which form chemical compounds. The requisite properties are better obtained in ternary alloys, which give a good plastic matrix (eutectic). To test an anti-friction alloy, compression and the microscope are invaluable aids.

SPECIAL AUTOMOBILE FACTORY TOOLS AND DEVICES[*]

ETHAN VIALL[†]

The things that impress a visitor most as he goes through the great automobile factory of the Geo. N. Pierce Co., Buffalo, N. Y., are the splendid buildings, the magnificent lighting and the immense floor spaces. An idea of the size of the plant may be obtained from the following dimensions of the various buildings that make up the group. The office building is 250 by 67 feet and consists of two stories and a basement, the first floor being used for offices, the second as a dining hall, smoking and club room, while the basement contains closets, individual lockers, bicycle racks and long rows of white enameled wash bowls. Next is the manufacturing building, 401 by 205 feet; the assembly building, 410 by 122 feet; the brazing building, 377 by 55 feet; the power house, 194 by 55 feet; the garage, 139 by 55 feet; and the motor testing building, 91 by 43 feet. All of these, except the office building, are of the one-story saw-tooth roof type. Then there is the three-story body building, where the automobile bodies are set up and finished, the north wing of which is 327 by 60 feet; south wing, 401 by 60 feet, and the east wing, 50 by 40 feet. The floor space represents over 360,000 square feet, and the plant is as nearly fireproof as it is possible to make it, being almost entirely concrete with no more wood anywhere than is absolutely necessary.

Fig. 1. Milling the Ends of the Bearings of Aluminum Crank Casings for Pierce Automobiles

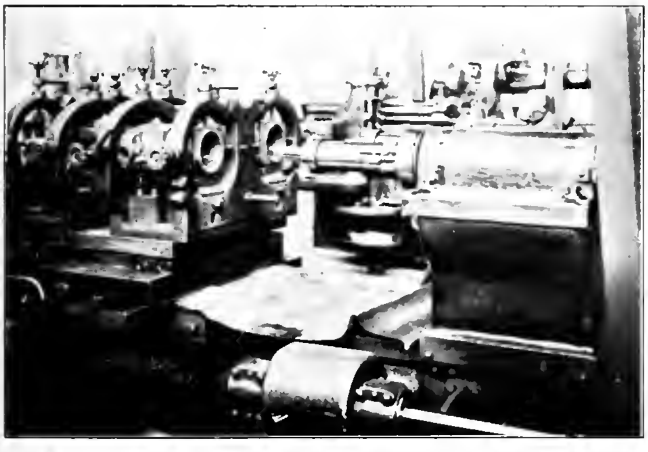

Fig. 3. Lathe Fixture for Holding Four Cylinders while They are being Rough Bored

There are in the factory many very interesting features, viewed from an engineering standpoint, but as this article is to deal principally with special tools and devices, other features not coming under this classification will merely have passing mention.

In the construction of the Pierce Great Arrow car, aluminum is very extensively used; bodies, crank-cases and many other parts being made of this metal. The method of milling the ends of the crank-bearings in the aluminum crank-cases is shown in Fig. 1. A finished crank-case is shown leaning against the machine, while another is clamped to the angle-plate ready to be milled. The lubricant used is a soap-water mixture. Fig. 2 shows the machine that bores out the crank and cam-shaft bearings in one operation, using three boring-bars. In connection with the finishing of these crank-cases, the arrangement shown in Fig. 6 is very useful. It consists of an air-drill to which has been fitted a bracket and taper mill as illustrated, and it is used for trimming off the bosses in order to save chipping and filing. The machine produces a smooth finish quickly and it is easily operated.

Machining the Cylinders

The fixture used to hold the cast-iron cylinders while rough boring, is shown in Fig. 3. After "seasoning," the cylinders are ground on the machine shown in Fig. 4. In this machine the cylinder remains stationary and the emery wheel is rotated around the bore as it grinds. The loose emery and metallic dust is removed through the hose which is coupled to the cylinder, and which is connected with the piping of a powerful suction fan system. A jig for holding cylinders while drilling, reaming or tapping the various holes, is shown in Fig. 7, and a complete set of valve-hole finishing tools is shown in Fig. 5.

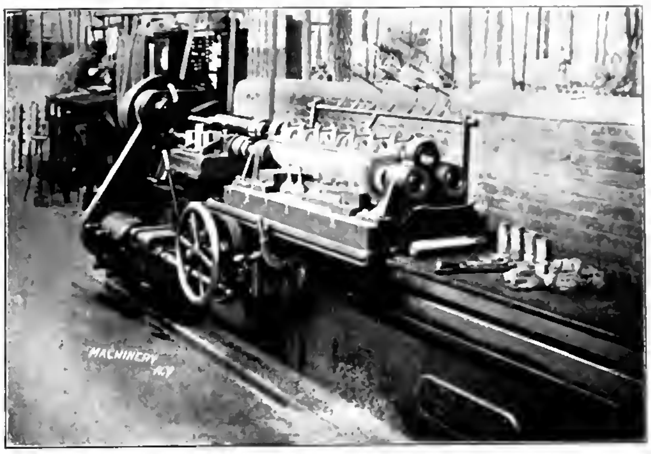

Fig. 2. Machine for Boring the Crank and Cam-shaft Bearings at the Same Time

Fig. 4. Grinding the Cylinders—The Hose to the Right is for Carrying away the Dust

Roughing Out Piston Rings

The piston-rings used in this shop are roughed out in a different way from any the writer has seen elsewhere, though they are finished on the grinder in the usual manner. A view of the specially fitted machine used, is shown in Fig. 8. This view was taken from above, back of the turret and looking toward the chuck. The inside of the ring casting is bored by means of a boring-bar in the turret, guided by a bushing in the spindle, which is the general practice. The outside is also turned eccentric at the same time by means of a sliding tool-carriage and an eccentric cam-ring *A*, acting on the guide *B* which causes the carriage and turning tool to feed in and out as the spindle rotates with the work. The small cam *C*, placed on the outside of the cam-ring *A*, is used to operate a special mechanism for notching the rings at their thinnest point in order to facilitate the splitting operation,

---

[*] For previous articles on this subject, see Drop Forge Work in an Automobile Shop, September, 1908; Organization and Equipment of an Automobile Factory, March, 1909; Special Tools and Devices for Automobile Factories, April, 1909, and Autogenous Welding as a Means of Repairing Cylinders, April, 1909.

[†] Associate Editor of MACHINERY.

which is done on a milling machine. As the cam-ring turns, cam C comes into contact with the part D which is pushed outward pulling with it the part E, which causes a little tool at F to notch or mark the casting at its thinnest point, as if it had been struck with the edge of a sharp chisel. Before this notching device was put on the machine, the rings were notched in the tool shown in Fig. 9, which has an indicator needle at the bottom to indicate the thickest part of the ring, thus locating the thinnest place at the top where it is to be split by a saw. The ring is clamped by means of an eccentric lever which pushes up the block *K*. Of course the testing of each separate ring to find the thinnest part took a great deal more time than is required when the rings are automatically marked at the proper place before being cut off from the original casting by the gang tool.

Machining Small Cams, and Balls for Ball-and-Socket Joints, Construction and Use of Special Fixtures, etc.

Small cams used for valve lifting are turned by being keyed in place on a mandrel having a master-cam which operates a sliding carriage holding the cutting tool, as shown in Fig. 10. The carriage guide is held up to the master-cam by a weighted chain running over a pulley as shown.

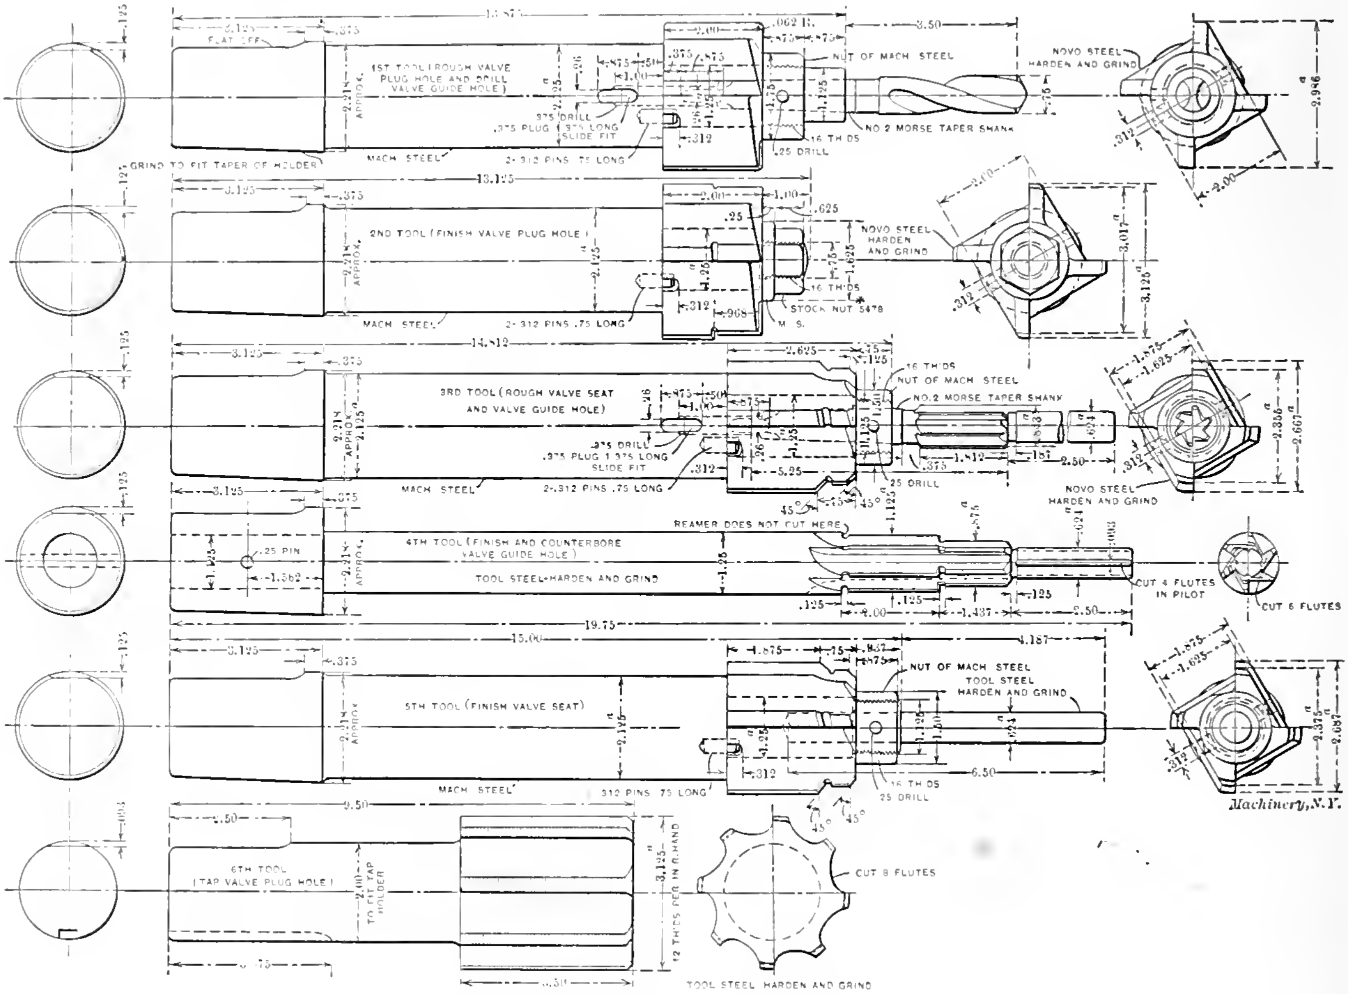

Fig. 5. Complete Set of Tools for Finishing Valve Holes.

The balls on the ends of levers used in ball-and-socket joints and for other purposes, are turned in a lathe by using the device shown in Fig. 12. The height or radius of the cutting tool and, consequently, the size of the ball turned, is regulated by the screw *A*. The tool is swung around in an arc by turning the handle *B* which is fastened to a worm meshing with an enclosed worm-gear.

The pin holes for the front-axle steering-knuckles are drilled and reamed in the jig, Fig. 13, while the differential gear cases on the rear axle, are held as shown in Fig. 11, when the holes for the clamping bolts are drilled.

Many of the cap-screws used are too large, so to avoid trouble in the assembling room, the threads are resized in the device shown in Fig. 14. This is a hand-machine, the spindle of which has a chuck at the lower end, and into this is placed a socket-wrench fitting the heads of the cap-screws to be re-cut. Clamped to an angle-plate below the spindle, is a die and holder as illustrated. A boy can accurately size a large number of screws in a day at a very small expense. For slotted-head screws, a screw-driver is used in the chuck in place of a socket wrench. Undersize nuts are also retapped in this machine by putting a tap in the chuck and using a special socket to hold the nuts.

Bevel gears are hardened and the rough hole is then trued up and ground to size on the machine shown in Fig. 15, the chuck being shown in detail in the line engraving Fig. 28. As will be seen from this illustration, the gear is centered in the chuck by a sliding cup which is pushed forward by a long bolt (not shown) which passes through the hollow spindle of the machine. As this bolt is screwed in, it moves the sliding cup (with the bevel gear in it) forward until the large end of the gear comes in contact with the removable front plate; then only a slight turn is needed to lock it firmly and centrally in place. An end view of another chuck used for holding a number of different sizes of spur-gears while grinding the hole, is shown in Fig. 16.

A special milling fixture used for backing off the teeth of three-toothed claw-clutches, is shown in Fig. 17, and in detail in Fig. 29. In using this device, the milling cutter and clutch blank are placed in the proper relation to each other, and the pin *A* is placed against the stop-pin *B*. The hand lever *C* is then slowly pushed forward in the direction indicated by the arrow. This movement is transmitted, through clutch *D*, to the screw *E* the lead of which determines the angularity of the face *F* of the clutch tooth. When the pin *G* strikes the stop-pin *B*, one cut is completed. The lever *C* and the screw *E* (against which the clutch *D* is pressed by the springs shown) is then turned back, the screw moving 120 degrees or until pin *A* strikes *B*, and the lever and the work moving 240 degrees or until clutch *D* turns in relation to screw *E* 120 degrees after the movement of the latter has been arrested by the pins *A* and *B*. Clutch *D* is

then again forced into engagement with the screw by the springs shown, and in this way the work is indexed for the next cut.

Except for the working of the lever for each cut, the device is automatic in action, as the teeth are cut exactly alike and an equal distance apart, and as the hand lever is drawn back to index, the clutch blank is also drawn away from the cutter and placed in position for the next tooth.

Fig. 6. Air Drill with Taper Mill used for Trimming the Crank-case Bosses

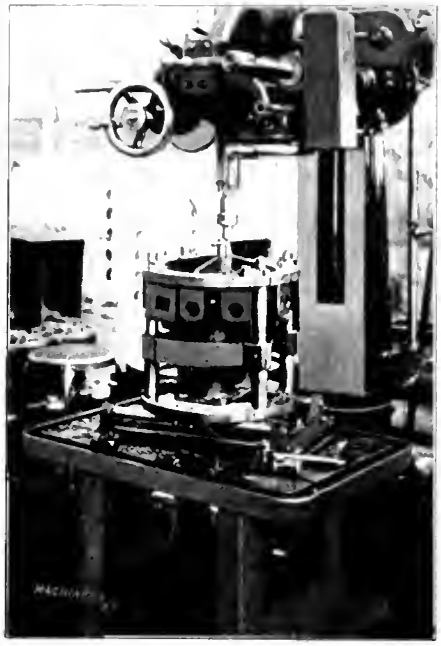

Fig. 7. Jig for Holding Cylinders while Drilling, Reaming or Tapping the Various Holes

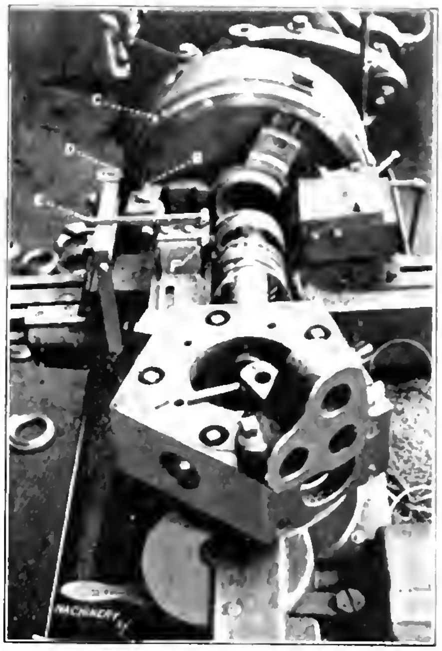

Fig. 8. Machine for Boring the Inside and Outside of Eccentric Rings simultaneously

A fixture used while slotting the quadrants for the change gear lever, is shown in Fig. 18 with a finished quadrant in place. As the bushed pin holes in the side of the device show, the quadrant can be placed in four different positions, corresponding to the several slot ends, without removing it from the fixture.

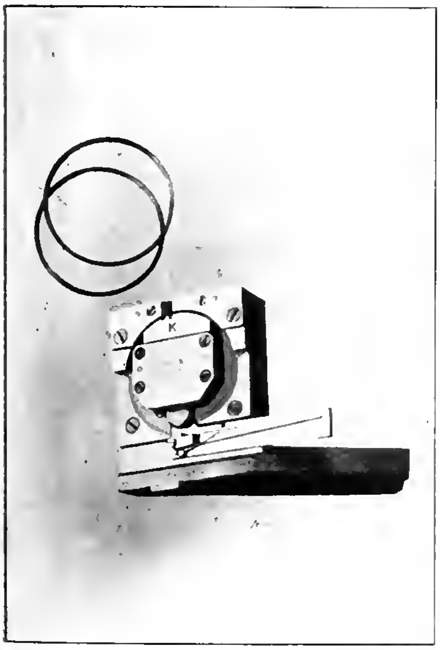

Fig. 9. Tool formerly used for Locating the Thinnest Part of the Rings prior to Splitting

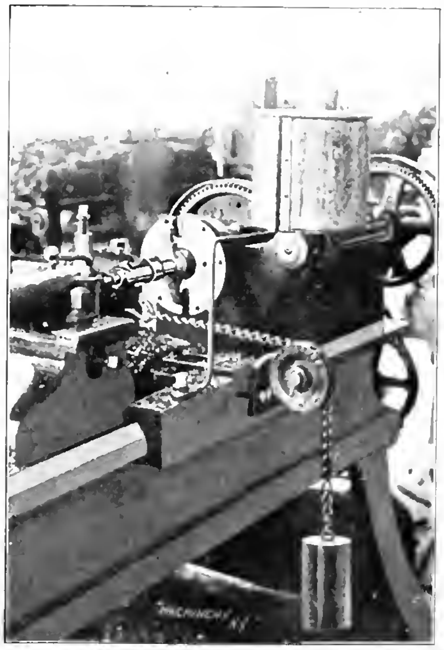

Fig. 10. Machine arranged for Turning Valve Cams

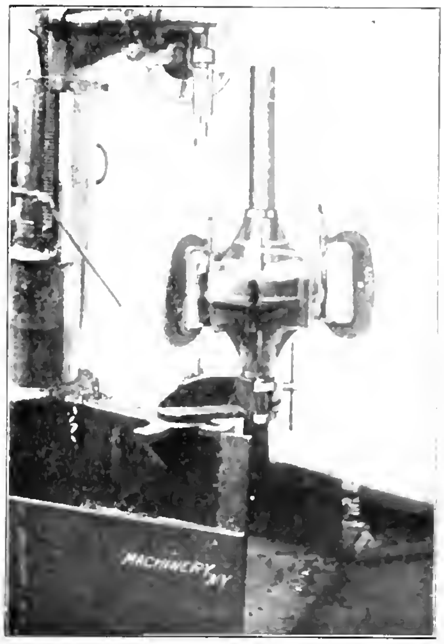

Fig 11. Drilling Bolt Holes in the Differential Gear Case

In Fig. 19 are shown two expanding arbors, and in Fig. 20, three forms of drilling jigs with different locking devices on each.

Brass bushings used in some of the bearings are lined with babbitt in the type of jigs shown at *A* Fig. 21. The bushings are first heated on a flat iron plate *B* and then tinned on the inside with acid and common wire solder. This tinning is done so that the babbitt will adhere firmly to the brass, as it would otherwise have a tendency to peel off. After being tinned the bushings are clamped as shown at *A* and placed as at *D*. The space between the bushing and the half-mandrel is then filled with babbitt from the kettle *C*. An immense amount of brazing of all kinds is done in this factory, and the form of brazing-torch and stand used is shown in Fig. 22.

The Inspecting Department

The department where the machined parts are inspected is in charge of Mr. W. C. Wenk, and it is one of the most important in the factory, for upon it depends, to a great extent, the reputation of the output. Many of the inspecting tools and gages used here have been designed especially for the work by Mr. A. F. Wisner, the chief-draftsman, who has also, in conjunction with Chief Engineer Ferguson, designed a large part of the special tools which have been already shown. The inspection methods of Mr. Wenk and his men are very thorough and no chances are taken on poor workmanship or castings that "might do." All work is taken to the inspecting room after each complete operation, and O. K.'d or rejected before it has a chance to go onto another machine. In this way, a piece that has been spoiled is scrapped before any more useless work has been put on it. As soon as a piece of work has been found that does not come up to the standard requirements, a "Scrap Material" tag like the one shown in Fig. 30, but fully filled out, is attached to it. Three

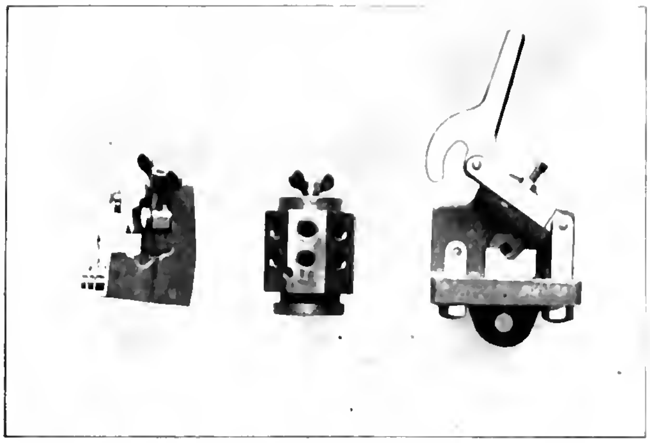

Fig. 20. Three Types of Drill Jigs, each of which is equipped with Different Locking Devices

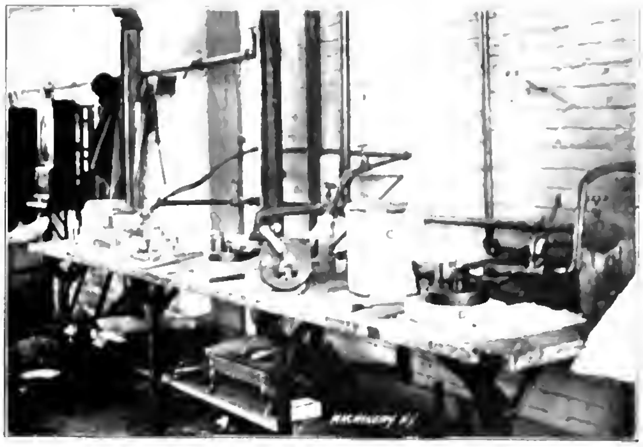

Fig. 21 Bench where Brass Bushings used in some of the Bearings are lined with Babbitt

Fig. 22. A Simple and Inexpensive Form of Burner and the Stand which are used for Brazing

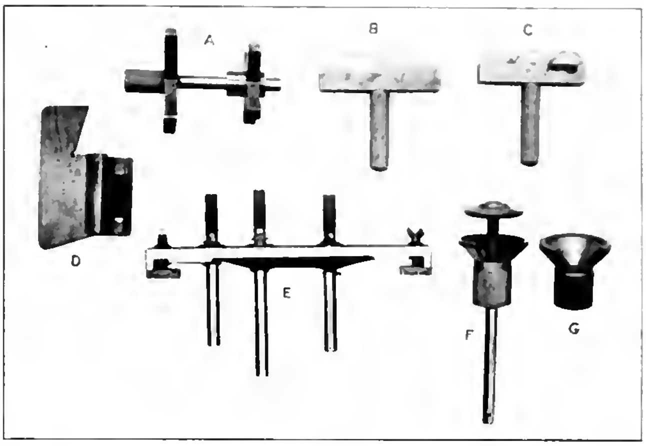

Fig. 23. Some of the Gages used in the Inspecting Department for Testing the Accuracy of Keyseats, Valves, Bevel Gears, etc.

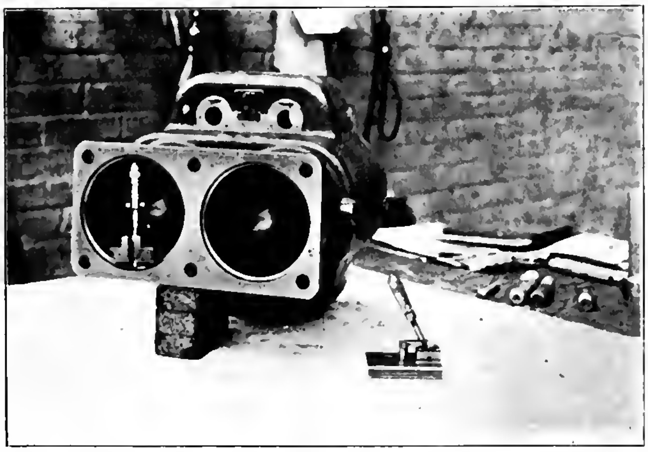

Fig. 24. Micrometer Gage for Testing the Size, Roundness and Parallelism of the Cylinder Bores

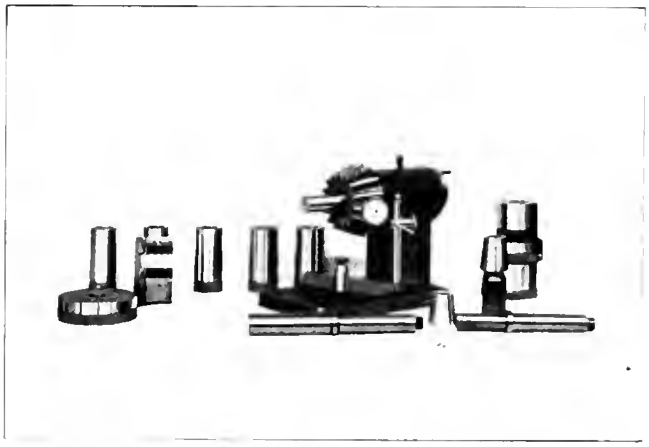

Fig. 25. Starrett Indicator and Stand used for Testing the Accuracy of Gears of Various Kinds and Sizes

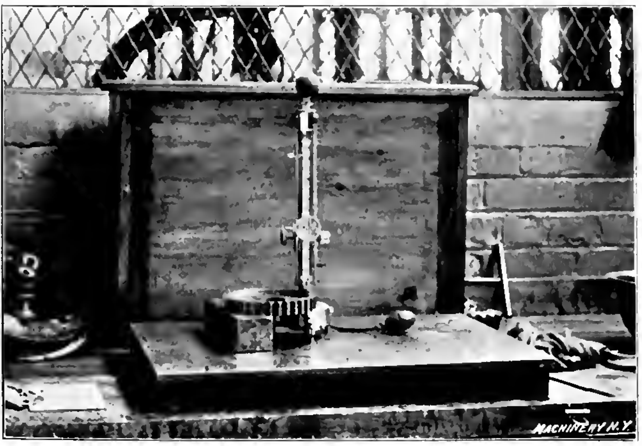

Fig. 26. Testing the Hardness of a Gear with a Scleroscope

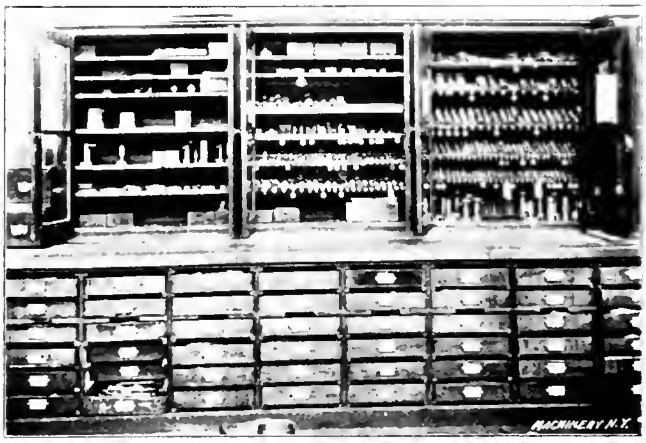

Fig. 27. One of the Gage Cases in the Inspecting Room

duplicate report slips like those shown in Fig. 31 are then made out and one copy filed in the inspecting room, one sent to the general foreman and the other to the cost department. In this way a complete record is kept of all work and the man at fault easily traced. The work of handling the small parts is greatly facilitated by placing them in large, oblong, pressed-steel pans, and wheeling them from place to place on low four-wheeled trucks.

Fig. 23 shows some of the gages used; A is a double "star" gage for testing the size and alignment of the opposite ends of a hub; *B* and *C* are Woodruff key-seat gages for testing the size, depth and alignment of two and three key-seats, respectively; *G* is a valve bevel, size and stem gage which is used as shown at *F*; *E* is a gage for testing the size, distance, depth, straightness and alignment of three holes; and *D* is for testing a bevel gear and its shaft position. Fig. 24 shows an inside micrometer caliper fitted to a special base, which is used for testing the bore of cylinders for size, roundness and parallelism. As the one on the bench shows, the micrometer head can be laid flat or placed upright when it is held in place by spring clips. The special base makes it easy to detect small hollows or other faults that might otherwise escape notice. Fig. 25 shows a stand and a Starrett indicator, used to test gears of various kinds and sizes. The plug or spindle on which the gear is placed, acts as a gage for the hole, while the indicator shows how much the outside of the teeth are out. Gages and bushings for other sizes of gears are also shown in this illustration. Fig. 26 shows the sclerescope used to test the hardness of all gears and other hardened parts. A view of one of the gage cupboards is shown in Fig. 27.

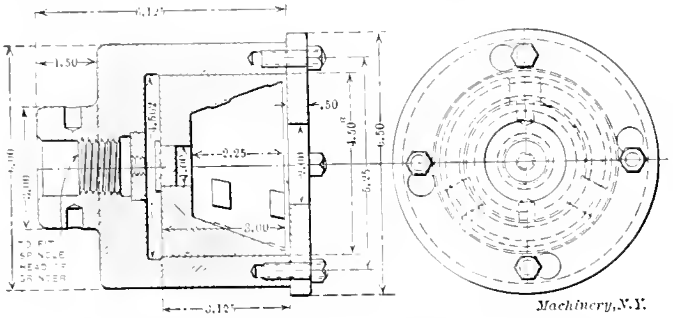

Fig 28. Detail of the Chuck used for Holding Bevel Gears when Grinding them, as illustrated in Fig. 15

Testing the Motors

The motor testing department is in a building by itself some distance from the main group. Here all engines are required to run a large fan, as shown in Fig. 32, at a certain speed for seventy hours, before being allowed to go into an automobile. This method of testing is probably the most satisfactory way of getting at the real power of a motor. The differential and transmission gears are also tested by the fan method, as shown in Fig. 33, the mechanism being driven by an electric motor of measured rating; any friction beyond an allowed amount is at once detected.

Fig. 34 shows the neat way that small parts are stored in metal boxes in the stock room. Everything is plainly labeled and easily found.

A partial view of the big dining room where luncheon is served to the men, is shown in Fig. 35. In this room eight hundred workmen can be seated at once. The lunch is served family style; that is, everything is placed on the table in large dishes or platters and the men help themselves to all they want, at a straight charge of fifteen cents each. The necessary waiters are provided by having the men in the inspection department quit work at 11:30, eat their dinner, and then serve the rest. A glance at the engraving will show that the dining room compares favorably with many of the higher-class restaurants in its fittings, and as to the quantity and quality of the food, the writer can say from personal experience that it is first class in every way.

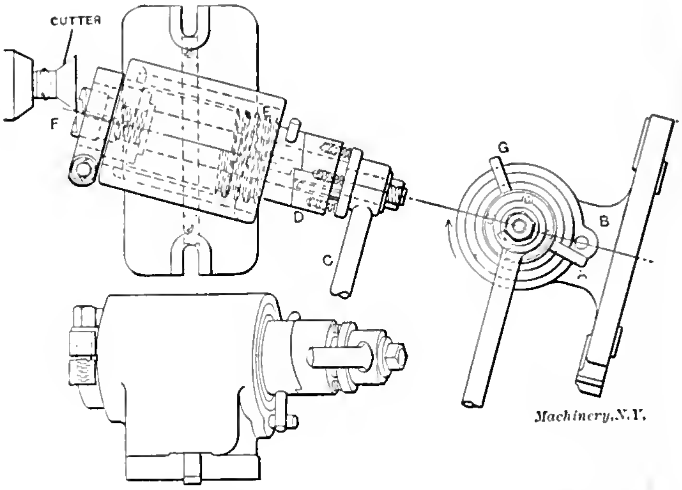

Fig. 29. Plan and Elevations of the Clutch Milling Fixture shown in Fig. 17

* * *

The Comptroller-General of Patents of Great Britain has ordered a patent owned by the British Westinghouse Electric & Mfg. Co., relating to electric-arc lamps, to be revoked on the ground of inadequate working of the patent in the United Kingdom. It appears that the company manufactured about 1,300 lamps in England, but that a license had been granted a German concern to import the patented article in Great Britain, for which privilege the German company paid the British Westinghouse Co. a considerable royalty. As the number of lamps imported under this agreement was several times greater than the number manufactured in the United Kingdom, it was considered by the authorities that the patented article was not manufactured to an adequate extent, and the patent has been revoked and the patentee ordered to pay the applicant for the revocation $375 for costs. Thus, it seems, that manufacturers of patented articles outside of Great Britain run a risk of having their patents revoked if they do not manufacture practically the whole supply for the British demand in that country.

PROPER DESIGNING OF MILLING AND DRILLING FIXTURES AND JIGS*

R. B. LITTLE†

In the designing of milling and drilling fixtures and jigs, I find from experience that there is always a chance of the designer overlooking some important point that is vital to the proper working of the jig or fixture. After observing these points for a long time and noting each one carefully, I have compiled them into a set of sheets carefully arranged, and we find them one of our greatest helps in this work. Each member of our drafting department is given a set of the sheets and is required to answer in his own mind each question given as he proceeds with the design of the fixture.

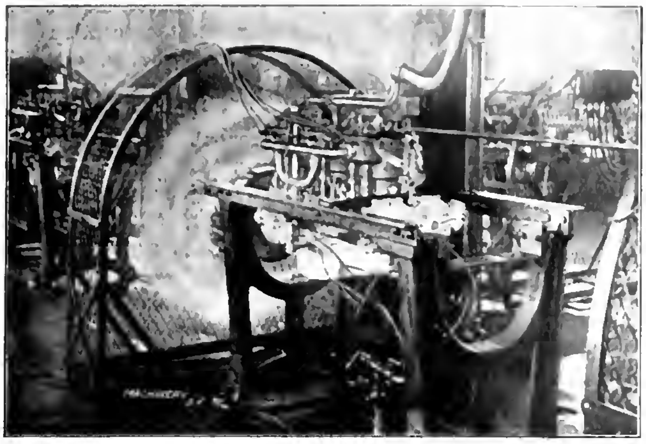

Fig. 32. Motor-testing Department—Each Engine is directly connected to a Fan which it drives for a period of 70 hours

Accompanying the catechism on the design of jigs and fixtures is one for checking drawings which we believe is especially good. It is believed that every point is touched on in proper order. These helps will be found particularly valuable to the chief of the tool-designing department. It will relieve him of much of the checking of drawings and the small details of work, allowing him to put forth more and better efforts in a more profitable direction.

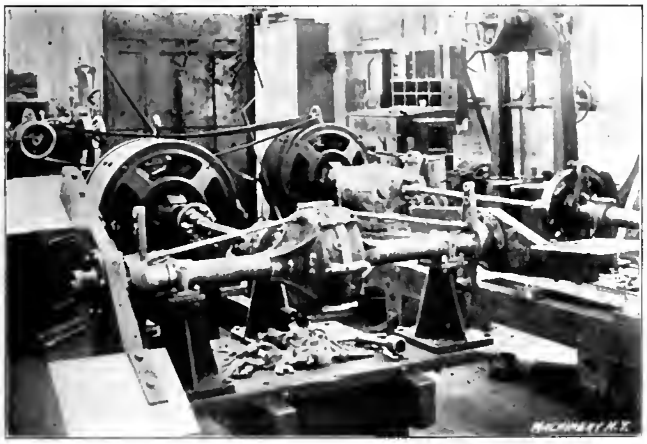

Fig. 33. Testing the Differential and Transmission Gears

Things to be Considered before Designing

1.—Does the part you are working on need a special fixture?

2.—What degree of accuracy is required in the work? Is it necessary that the drilled or milled pieces be intechangeable?

3.—Are there enough pieces to be machined, and will the accuracy of the work or the time gained warrant making the fixture?

4.—If it takes longer to mill or drill the part with a fixture than without it, will the accuracy of the work when done with the fixture compensate for the loss of time?

5.—Will any time be saved if the fixture is designed so as to do a number of pieces at each setting?

6.—Can the fixture be designed so that the operator can be replacing parts already done while others are being done?

7.—In drill jigs, if the holes to be drilled differ greatly in size, will it pay to make two jigs rather than put two largely different sized holes in the one? Have you range of speed or capacity varying enough to drill the two largely different sized holes on any one drill press?

After Designing Milling or Drilling Fixtures

1.—Considering the job, is the fixture too expensive to build?

2.—Will the fixture be a money-saver? Can you do more pieces and do them better with the fixture than without it?

3.—Will the expense of building the fixture be greater or less than that of the employes' extra time required to do the work without the fixture, and do it as well?

4.—What arrangement for holding the part in place in the fixture? Is it the simplest and quickest to operate, both in putting in the part and removing it, of anything you can design without sacrificing effectiveness?

Fig. 34. View of the Stock-room, showing the Neat Arrangement of the Metal Boxes which hold Small Parts

5.—What arrangement for taking care of milling and drilling chips? Can the chips be easily and quickly cleaned away?

6.—Has the fixture any bad places to collect grease and dirt? Any non-get-at-able places that will require cleaning?

7.—Has the fixture any weak points that may be strengthened? Are any of the parts a great deal stronger or heavier than necessary?

8.—Is the fixture too heavy and awkward to handle?

9.—Is there anything to hinder getting oil or compound on the work?

10.—If a pattern is to be made, are there fillets in all sharp corners where it is possible to put them? What arrangement for draft? Can the pattern be made so that it will come out of the sand? Are there any sharp corners to hold the sand in the pattern, or to break away in pouring?

Fig. 35. The Dining Room at the Works, which will accommodate 800 Workmen

11.—Is there anything about the make-up or operating of the fixture to endanger life or limb of the employe?

12.—Is the base of the fixture broad enough so that it has no tendency to tip over while the work is being done? Does the pressure of the work fall within the base?

13.—If the fixture will require oiling at any point, have you provided an oil hole?

---

* For additional information on this subject, see Jigs and Fixtures (first installment), April, 1908, and articles there referred to.

† Address: Oscar Lear Auto Co., Springfield, Ohio.

Drill Jigs

1.—How is the part located in the jig with regard to drill bushings? Is it located from the rough or from some previous operation?

2.—Does the jig need fastening down to the drill press bed? If so, what arrangement for same?

3.—If the jig is a small one and not to be fastened down, is there a handy place to hold it from turning with the drill?

4.—What takes the thrust of the drill?

5.—Does the point of drilling at any place fall outside the base of the jig?

6.—If the jig registers from hole to hole, what method of registering is used? Is it quick and simple to operate and is it positive and accurate?

7.—If any of the holes are to be tapped or reamed outside the jig, have you allowed for this in the sizes of the bushings?

8.—Are the bushings as close to the work as you can get them, and are they long enough to guide the drill through the hole?

9.—If the bushings are necessarily long are they relieved at top end to prevent chips from clogging around the drill?

10.—Is there a chance for the drill to run out without drilling a hole in the bed of the drill press?

Milling Fixtures

1.—Can the part be held more securely or the work done more accurately with a special milling fixture?

2.—Will the fixture save any time in doing the work?

3.—What takes the thrust of the cutter? Is it strong enough to take the thrust of the heaviest cut liable to be made?

4.—What arrangement for clamping the fixture to the platen of the milling machine?

5.—What arrangement for locating the part in the fixture in proper relation to the milling cutter? Located from the rough or from some previous operation?

6.—Is there a tongue on the bottom of the fixture for lining it up in the T-slot, and is it the proper width to fit the size of machine to be used on the job?

7.—If the fixture is a long one, is it strong enough to prevent buckling after the mill has passed over?

8.—Are there any projections which will bank the milling chips up in the way of the cutters?

9.—If the fixture has a dividing head or registering arrangement, what method is used? Is it accurate and positive?

10.—If the work is close to the arbor, have you allowed room for the arbor collars to pass over or by it?

11.—If you intend using a facing cutter, is the part supported at the proper places opposite the cutter so as to avoid the tendency of the work to spring away from the cutter?

12.—If formed or outline cutters are to be used, can they be ground without changing their forms?

To Check Your Own Drawing

1.—Have you given all dimensions necessary for the pattern-maker, the forge man, and the tool-maker?

2.—Drawing number on each sheet?

3.—Pattern symbol for each part that requires a pattern?

4.—The material and number required of each detailed part?

5.—The shop number of the fixture to be built or the order number under which it is built?

6.—The name of the fixture?

7.—The symbol of the part to be machined?

8.—The date?

9.—The proper note for every hole, whether drilled, tapped, reamed, bored, cored, or counterbored?

10.—Dimensions for the location of every hole and its depth and size?

11.—On all studs, pins, arbors, etc., the kind of fit required; whether sliding, running, wringing, loose, tight, tapping, drive or press?

12.—Over-all height, length, width, etc., of all parts? Will all sets of dimensions add up and produce the over-all dimensions given?

13.—The diameter and length or thickness of all round parts?

14.—All required finish marks?

15.—The kind and number of threads for all special taps or threaded pieces

16.—Will all the parts fit together as you intend them to, if the tool-maker follows your figures?

17.—Are all your threads shown long enough so that all nuts will come down to place?

18.—Notes for all parts you wish hardened, ground, etc.?

19.—Does your layout show plainly how to assemble the fixture you are building?

20.—Have you given finished faces for the tool-maker to lay out his work from, and have you given the location of all important holes, slots, bosses, tongues, grooves, etc., from these finished faces?

21.—Have you given all the views necessary for each part to make its every detail plain and readable to the maker?

22.—Have you given all necessary notes such as knurl, flat, rough-finish, finish all over, and your authority for all gages quoted, whether B. & S., Stubbs, U. S. Std., etc.?

23.—In laying out circles of holes, have you given the chord from hole to hole?

24.—Notes for all coil springs including size, and whether compressed or extended?

25.—Have you figured your tapers accurately?

26.—Can you do anything to your drawing to improve its appearance?

27.—Is there any way you can show your idea more plainly to the shop man? Can you make your drawing more readable?

28.—Will the fixture you have designed work as well when made as it appears to work on paper.

* * *

THE VALUE OF AN EFFICIENT ACCOUNTING SYSTEM

In an address, "Changing Industrial Conditions," delivered by James Logan, mayor of Worcester, Mass., at the Commencement of the Worcester Polytechnic Institute, June 11th, 1908, strong emphasis was put on the need for efficient accounting systems in manufacturing enterprises. He said that an accounting system is as real an invention and that it marks an advance in industry as great as many mechanical inventions. It was his opinion that cost analysis in some lines of industry has done as much to reduce the cost of production during the past five years as have the mechanical inventions made during the same period. Yet there are manufacturers who spend money lavishly, whose scrap heap for old machinery represents not one, but several fortunes, who are conducting their accounting by as crude methods as those which were in vogue when the stage coach represented rapid transit. These manufacturers have thrown into the scrap heap millions of dollars' worth of machinery which was not worn out and which still had in it years of efficiency, but because they were without definite knowledge of what it cost to operate the old machines, they had been persuaded to throw them into the scrap heap, taking estimated costs of the operation of new machines—estimates which are always stated in minimum figures, and which are almost never correct. As an example in point, Mr. Logan further said:

"I have in mind a series of envelope machines, which with the patents cost approximately $40,000, which could make and print envelopes at one operation for practically nothing if you simply figured the wages of the girl who sat before the machine. But no allowance was made for the fact that, in actual operation of these complicated machines, high-priced mechanics had to stand over them all the time with a monkey-wrench and screw-driver to keep them running. When this cost as well as repairs and interest on the extra investment were considered, the older machine, which made less waste, required less supervision, and stood a smaller interest charge, distanced in the race the new, improved, automatic, fast-running machine, and it has gone to the junk heap and the machines running before this machine was invented and installed in the same factory are still doing good work and at a lower cost (when all the costs were figured in) than the new machine ever did. The point I want to make is this: if there had been a knowledge of the actual costs of operation of the old machines, a comparison of those costs would have developed the fact that the new machine was not a good investment and its purchase would never have been considered."

ANVILS AND FORGES[*]

JAMES CRAN[†]

The anvil and the forge are the two most important appliances of the blacksmith shop. Anvils are made in various shapes to suit different classes of work, but for all around work, and particularly for machine blacksmithing, no anvil gives better service than the standard pattern of solid wrought iron provided with steel face. This class of anvil is practically the only appliance used by the blacksmith that has been standardized. In general, it may be said that the anvil appears to have been developed along intelligent lines, and standard anvils are generally satisfactory with the exception that the square hole for the tool shanks is seldom straight or of exactly the same size in any two anvils of the same make and weight. This difficulty might be overcome by broaching the hole before the face is hardened. With this improvement, tools made to fit one anvil could be used elsewhere without danger of breaking the shank.

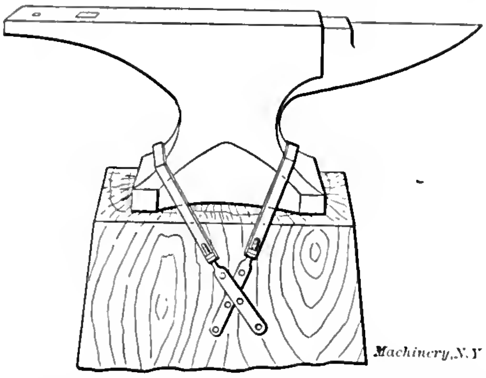

Fig. 1. Objectionable Manner of Holding an Anvil in Position

The quality of an anvil can generally be judged by its "ring," a good anvil giving out a sharp, clear sound when struck with a hammer; if soft or not free from flaws, the sound will be dull. A good anvil mounted on a block in such a manner that it gives out its full volume of sound is easier to work upon than one where the ring is deadened. There is a great deal of difference of opinion as to how anvils should be mounted, the general idea apparently being that it should be strapped fast to the block on which it is placed. If this were necessary, it is likely that the makers of anvils would have provided them with lugs or slots suitable for fastening them to the support.

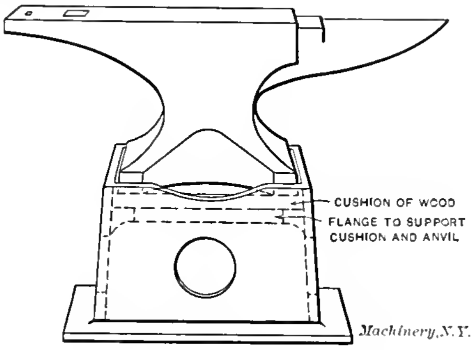

Fig. 2. Correct Form of Anvil Block, and Proper Method of Mounting Anvil.

When a wooden block is used under the anvil, it is necessary to use a few spikes to keep the anvil in place, but these should be placed around the base in such a way that they do not bear directly upon it or pinch the corners. A common but poor way of holding an anvil in position is shown in Fig. 1. This method checks the vibration which tends to keep the face free from scales, and it renders a high-grade wrought iron anvil little better than if it were made from cast iron.

A mistake often made is the selecting of anvils too light for the work to be done. This may be done from a mistaken idea of economy, but light anvils do not give as good service or last as long as heavier ones. The 300-pound anvil is suitable for nearly any kind of machine blacksmithing, and if of this weight or heavier it will not move around when used, or need to be strapped to its block.

Wooden blocks must be sunk to a certain depth in the floor in order to keep them in place, and their height may have to be adjusted from time to time to suit a short or tall blacksmith. Cast iron mounting blocks are therefore preferable. An anvil mounted upon a block by a proper method is shown in Fig. 2. The block is made of cast iron, hollow in the center, with a flange $1\frac{1}{2}$ inch wide by $1\frac{1}{4}$ inch thick, having a heavy fillet on the lower side where it joins the body of the block. On the inside, $2\frac{1}{2}$ inches from the top, a piece of wood about $1\frac{1}{2}$ inch thick and of the same size as the top of the block inside, is placed. This forms a cushion for the anvil to rest on. The top edges of the block in the back and front are made lower in the center than at the ends, permitting the scale and dirt from the work to find its way to the floor instead of getting under the anvil. A flange 3 inches wide all around the outside forms the base of the block and gives it a solid bearing on the floor. The location of an anvil mounted on this type of block can be changed at any time, and its height can be adjusted without much trouble. The wooden cushion gives a block of this kind all the advantages and none of the disadvantages of a wooden block.

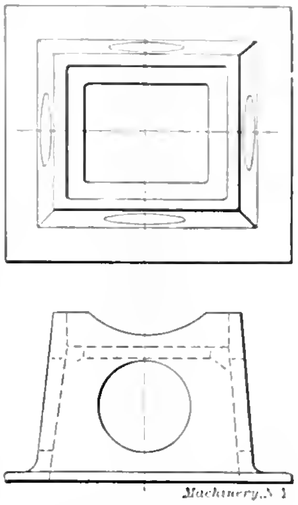

Fig. 3. Cast Iron Anvil Block

In Fig. 3 the cast iron anvil block is shown in detail. It should be so adjusted when an anvil is placed upon it that the face of the anvil will be inclined at an angle of about 3 degrees towards the front. This not only makes the work easier for the blacksmith, but gives the scales a tendency to leave the face of the anvil on the side furthest from him.

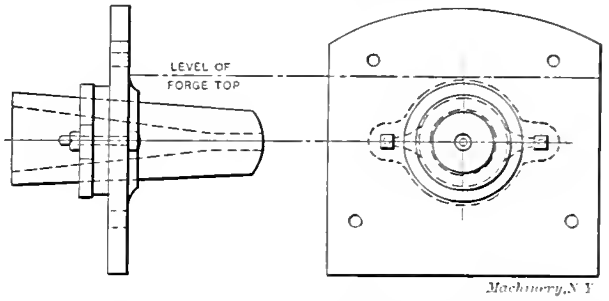

Fig. 4. Solid Tuyere for Side Blast for Light Work

Large pieces of hot metal should never be left on an anvil longer than absolutely necessary, and in no case should hot work be left on the face of the anvil when the blacksmith leaves his work. If this is done, it will affect the temper and soften the face.

The Forge

The forge has been developed along somewhat less successful lines than the anvil. Different makers have turned out various types, if not a little better, at least a little different from their competitor's. There is scarcely a forge on the market which does not have the opening or openings of the tuyere at the lowest point of the fire pan, which is the place where clinkers and slag collect, and the opening of the tuyere gets filled up if not constantly cleaned out. To overcome this evil, some forges have a shaker, which in turn has brought about the enlarging of the opening of the tuyere to accommodate the shaker. This not only has a tendency to spread the fire, making it almost impossible to take short heats, but clinkers and slag are worked through the tuyere into the air chamber or wind box until the blast is obstructed. The aim of the practical blacksmith is to have the forge and fire in such

---

[†] Address: 916 West Third St., Plainfield, N. J.

condition that he can concentrate the heat at some given point of his work when required. The lack of a suitable forge for this purpose on the market accounts for so many forges of the home-made variety being used. The home-made forge is usually very crude looking, but it serves its purpose. The material used for the top of the forge may be either stone, brick or a piece of the shell of an old steam boiler or tank, or even a wooden frame forge with sand up to the level of the tuyere. The writer has seen a very serviceable forge made from one-half of a large barrel. This was used for heating work up to five inches in diameter. This, of course, does not mean that wooden forges are recommended.

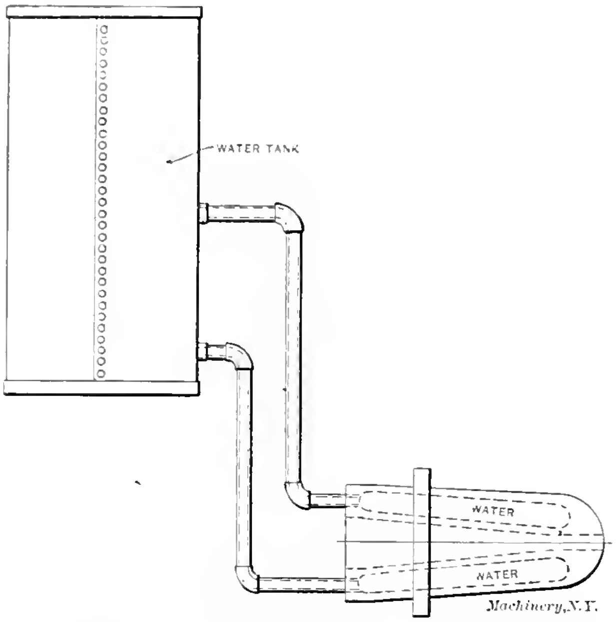

Fig. 5. Water-cooled Side Blast Tuyere for Medium and Heavy Work

The most important features on a forge are the method of conducting the blast from the blower to the fire and a simple and effective means of getting rid of the smoke. In conducting the blast to the fire it must pass through the tuyere. There are two distinct types of tuyere, one with side, and one with bottom blast, either of which will give good service if properly constructed. The side tuyere, although little used in this country, is extensively used throughout Europe, and is preferable to the bottom tuyere for some classes of work, particularly when heating to an even temperature on all sides when the shape of the work does not permit it to be turned in the fire. The work is then placed in the fire on the level of the opening of the tuyere and the fire is so arranged that the blast circulates freely over and under the work. A solid side tuyere with breast-plate is shown in Fig. 4. The shape is circular and slightly tapered, with a collar at about one-third of the entire length from the large end. The inside is hollow and tapers as shown. When placed in position in the breast-plate, the tuyere is forced as far through as the collar will permit, and is held in position by a yoke placed behind the collar. Two bolts connect the yoke with the breast-plate, which in turn is attached to the left-hand side of the forge by bolts. This tuyere is used for light forging.

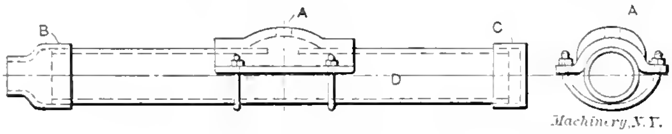

Fig. 6. Air Chamber and Tuyere for Bottom Blast

For medium and heavy work a tuyere as shown in Fig. 5 is generally used. The principle of construction is the same as in Fig. 4, but it consists of an outer and inner shell, the space between which is filled with water to keep the metal from being overheated. The water is supplied from a tank, to which it returns after it has passed through the tuyere. Sometimes tuyeres of this style are directly connected with a water tank without the use of pipes.

A simple and inexpensive but very efficient form of air chamber and tuyere for bottom blast is shown in Fig. 6. The air chamber *D* is made from a piece of wrought-iron pipe at least 4 inches inside diameter. On the end projecting through the left-hand side of the forge a reducing coupling *B* is placed so that a pipe of $2\frac{1}{2}$ to 3 inches in diameter can be used to connect it with the air supply. On the other end, which projects on the right-hand side of the forge, a metal cap *C* is used, which closes this end. This cap can be unscrewed at any time for cleaning the air chamber. The tuyere *A* can either be made of cast iron or forged from wrought-iron and is held in position by two U-shaped bolts. Some fire clay or asbestos soaked in water placed between the tuyere and the air chamber provides an air-tight joint when the bolts are tightened. When making a tuyere of this kind it is important that it be spherical or conical in the center and that the blast opening be at the highest point. Clinkers and slag will then collect at the base instead of directly over the opening. With a tuyere made in this way no shaker or other device is required to keep the opening clear. The air chamber is made larger than the pipe supplying the blast in order that a full air supply may pass through even when a small quantity of clinkers or slag have accumulated under the tuyere.

An air chamber and tuyere of somewhat improved design is shown in Fig. 7. The air chamber is cylindrical with a circular opening at the top into which the tuyere fits. A small opening at the left near the top of the air chamber provides an inlet for the blast, and a larger pipe to the right provides means for cleaning. No bolts or other appliances are necessary to keep the tuyere in place, fire clay or asbestos placed under the flange making it air-tight and holding it in position.

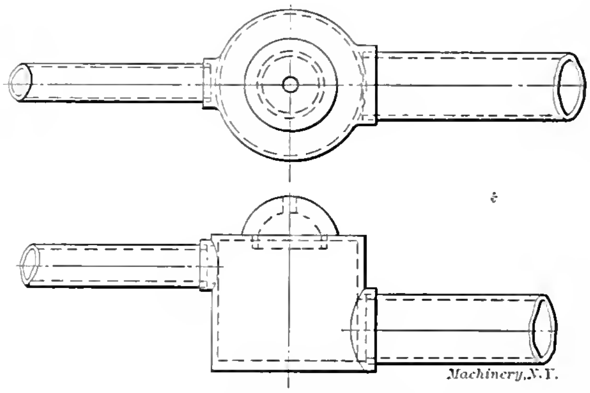

Fig. 7. Improved Design of Air Chamber and Tuyere for Bottom Blast

In shops where the range of work is large and the number of forges is limited, tuyeres with different sizes of openings can be used in the same forges for different classes of work when made as outlined. For heavy work, a low tuyere with a large opening should be used, and enough fuel should be kept between the blast and the work to consume the oxygen before it reaches the work. For light work a high tuyere with a small opening is used, because it saves fuel and tends to keep the fire in a small space.

For machine blacksmithing forges should be from 36 to 42 inches in diameter and from 26 to 30 inches high, the top of the tuyere being from $4\frac{1}{2}$ to 7 inches lower than the top of the forge. As there are no standards or definite data for guidance in determining the size of the opening for tuyeres or the depth at which they should be placed below the level of the hearth, the accompanying table gives what the writer considers to be proper dimensions for work varying from $\frac{1}{4}$ inch to 10 inches diameter, when the blast is delivered

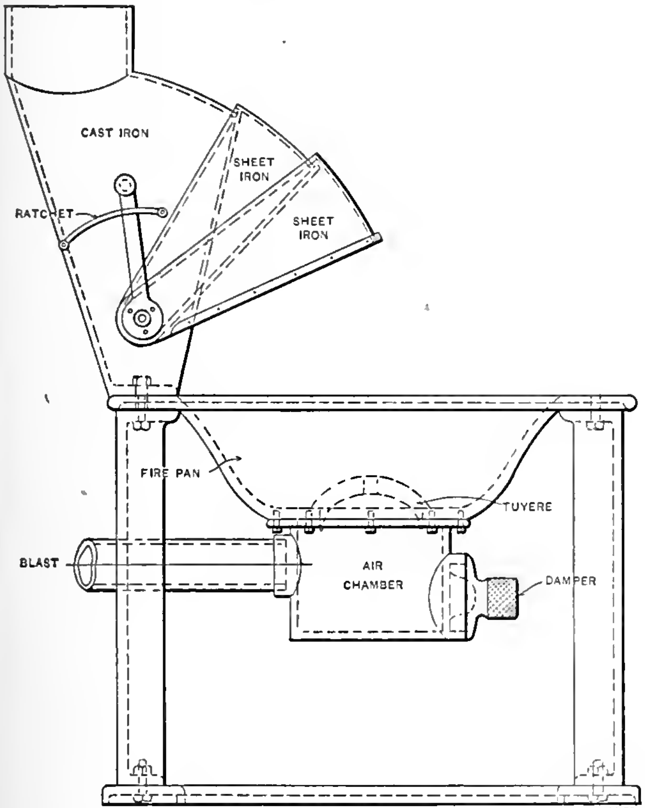
TABLE OF SIZES AND ARRANGEMENTS OF TUYERES

	Inch.	Inch.	Inch.	Inch.	Inch.
Size of opening in tuyere	$\frac{3}{4}$	1	$1\frac{3}{8}$	$1\frac{3}{4}$	2
Distance between top of tuyere and top of forge	4	5	6	7	8
Size of supply pipe.	$1\frac{3}{4}$	2	$2\frac{1}{2}$	3	$3\frac{1}{2}$
Size of work to be done	$\frac{1}{4}$ to 1	1 to 2	2 to 4	4 to 7	7 to 10

at a pressure of eight ounces per square inch or over. Work over 10 inches in diameter can be more uniformly and economically heated in a furnace.

Carrying off the Smoke from the Forge

The smoke is generally carried off with more or less success by means of a bell-shaped hood suspended over the forge and connected with the chimney. Without exception the bell hood is the worst form to use, as more smoke and gas is admitted at its base than the chimney is capable of carrying off, and the smoke spreads through the shop and escapes by doors or windows after having made conditions uncomfortable for the blacksmiths. Forges without hoods are preferable to the bell hood, provided there are means for ventilation in the roof of the shop, as then the gases can rise freely and escape. Another objection to the bell hood is that it prevents a crane from being used to any advantage over the forge. In order to overcome the drawbacks mentioned some concerns have installed the down draft system in their blacksmith shop. This system has its advantages; no overhead pipes, smoke or gas have to be contended with and the equipment is ideal for training schools and similar places, but for the practical blacksmith shop, where the cost is an item of first importance, it presents disadvantages; it is designed to work in direct opposition to the laws of gravity, and the smount of power necessary to create enough suction to draw the smoke and gases down is too great.



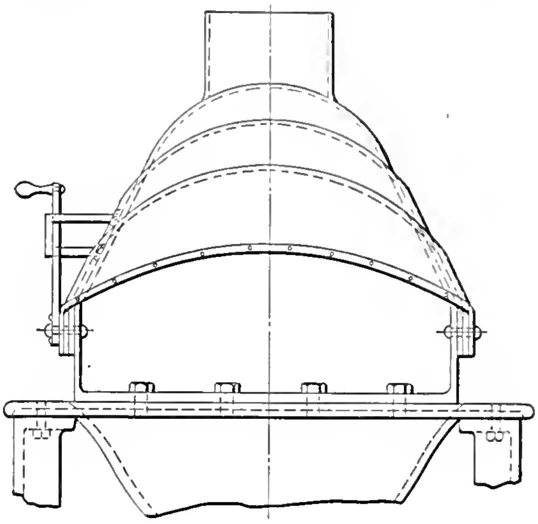


Fig. 8. Skeleton Forge with Cast Iron Hood Frame and Adjustable Sheet Iron Folding Hood

A forge and hood, which give good service both for heating work and for carrying off the smoke when individual chimneys are used for each forge, or when connected with a draft system, is shown in Fig. 8. The body of the forge is of cast iron and constructed on the skeleton plan. This allows of tools or other appliances too large for the tool bench to be kept under the forge. The tuyere and air chamber are practically the same as shown in Fig. 7. The main part of the hood is of cast iron and is placed on the left-hand side of the forge where it is held in position by bolts. The chimney is placed to the left as shown and out of line with the top of the forge, and therefore permits of a crane being brought directly over the fire and the work. The adjustable parts of the hood are made of sheet metal, reinforced at the edges with band iron and joined near the base so that they can be let down close to the forge when a new fire is being built, or folded back to the base of the chimney, leaving the whole top of the forge clear when required. The chimney should never be less than 8 inches inside diameter. The forge here shown was designed several years ago and has been in use continually and has given satisfaction on all kinds of machine blacksmithing from $\frac{1}{4}$ inch to 10 inches in diameter.

* * *

An amusing instance of the peculiar foolishness cherished by some manufacturers in regard to so called "trade secrets" came to our attention a few months ago. A demonstrator and trouble-man, working for a prominent Western machine tool builder, some years ago visited a small concern in the East which had developed a new process of making—well, let us say gimlets, as that is about as near as we can approach the name without telling what the product really is. The process and gimlet were patented and the inventor had no hesitation in showing the process in its entirety to the interested mechanic. In the course of a year or so the gimlet and process were sold to a competing concern noted for its conservatism and fear that any process carried on within its walls would become known to the prying world outside. Our friend having business with the concern in connection with the machines he represented asked the privilege of inspecting its methods of making gimlets and was turned down flat for the reason (?) that a new process had recently been produced which was a valuable trade secret and under no circumstances could he or any other outsider be permitted to see it. A few questions elicited the fact that the secret process was the one our friend had seen in its entirety a year or so before.

It will be noted that we said our friend asked the *privilege* of seeing the methods of manufacture. It is indeed a great privilege we enjoy generally in the United States of being admitted into manufacturing plants and seeing the principal manufacturing methods in which we are legitimately interested. If a manufacturer does not care to grant this privilege to every one he is entirely within his rights. The time and trouble of escorting visitors through a large plant is often a serious tax on the time of men capable of explaining the processes intelligently, and if the advertising that results is not appreciated or desired, the manufacturer is under no obligation to follow the general custom, but if he does not care to follow it he should not take refuge in the threadbare excuse that the privilege is denied because of the existence of trade secrets. This plea brands him as unprogressive and out-of-date, when as a matter of fact, he may be neither.

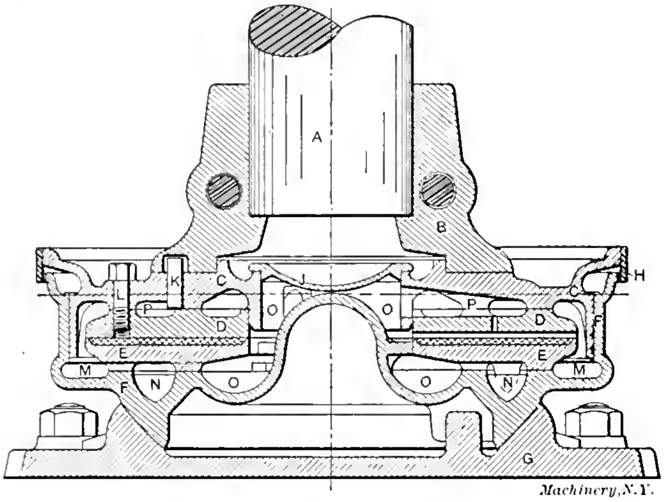
* * *

It is stated in the *Mechanical Engineer* that a British firm, the Hadfield's Steel Foundry Co., has for a long time been experimenting in order to ascertain whether it be possible to cast armor plates. The experiments appear to have been successful, and the company now supplies some parts of armor made by a casting process.

EXAMPLE OF STEP BEARING DESIGN

The thrust or step bearing is a difficult proposition at its best. When heavy service is required of it, the engineer meets with three inherent difficulties in design. These difficulties are: first, insufficient bearing surface; second, difficulty of lubrication; and third, uneven wear of thrust surfaces. In the case of important bearings, such as those for taking the thrust of the propeller on a steamship, multiple thrust collars are used, which obviate the first difficulty; forms of forced lubrication are employed, to avoid trouble from the second cause; and the bearing collars are made comparatively narrow, and enough of them used to give the required area, to avoid the trouble from uneven wear. This, of course, necessitates careful adjustment of the different bearings, so that each has its proper share of the load.

For installations which do not work under quite such severe strain, and on which there is not so much depending as in steamship service, it is common to provide the thrust bearing with a number of washers between the revolving shoulder of the shaft and the seat of the bearing. This does not add to the effective bearing area but does decrease the troubles arising from insufficient lubrication and uneven wear, as a multiplicity of bearing surfaces are provided, one of which automatically goes into action when another commences to run hard from any cause. The surfaces thus take turns with each other as need arises. The question of lubrication is generally settled by causing the rings to revolve in a bath of oil. If the grooves are properly placed, this is sufficient for ordinary purposes.



Machinery,N.Y.

A Submerged Step Bearing for Heavy Service.

The bearing shown in section herewith works under particularly difficult conditions in that it is heavily loaded, runs in an atmosphere charged with gritty dust, and is liable to neglect. The service for which it is used is too rough for the first method of design described above, and too heavy for the second. It is used for supporting the heavy revolving grinding pans, which are used to crush and temper the raw material in clay working industries. The grinder wheels of these pans weigh 5 or 6 tons, not to mention the weight of the clay and the pan itself. There is the further strain of the shock resulting when the heavy grinder wheels roll over large lumps of clay and fall back to the pan again. This constant jar requires a bearing of the simplest construction, without delicate adjustments. The design shown herewith has been in use for a number of years under these severe conditions and has given excellent satisfaction.

As may be seen, a single set of surfaces is used, the bearing taking place between plates *D* and *E*. The upper plate, which is the revolving member, is of close-grained cast iron. It rests on seats formed in the plug *C*, and is caused to revolve with it by means of screws *L* and dowels *K*. The lower plate is a cast iron shell with its wearing surface filled with "Fahrig metal." It rests on finished seats in the bowl *F*, where it is held in a central position and prevented from rotating by lugs which interlock with others on the bowl. This latter member rests in a spherical seat in the base-plate, *G*, so that any irregularities in the alignment of the foundation and shaft are overcome, and any changes of position which may occur are automatically taken care of without springing of the working parts. Interlocking lugs on both the base-plate and the bowl prevent the latter from revolving.

The bowl *F* is, as its name indicates, a receptacle for the lubricant, which rises to the level of the dotted line shown. The plug *C* is finished on its periphery, where it forms a bearing surface with the bowl, while it carries a rim *H*, which extends upward and outward over the bowl, forming an apron which prevents access of dust to the lubricant through the only possible entrance. The circulation of oil is effected by staggered channels in the wearing face of *E*, in combination with circulation grooves in face of the upper plate *D*. When the bearing starts to revolve, the construction of these grooves draws the oil through from inner reservoir *O* to the outer or supply chamber *P*. This movement is assisted by centrifugal force in the upper chambers *O*, which force the oil to pass down through the holes in the plug *C* into the grooves in the plate. This movement of the oil results in an increased head or pressure in the outer chamber *P*, and a corresponding decrease of head in the inner chamber *O*. Since the lower part of the oil body in the outer section is at rest, it is not under the influence of centrifugal force, though under the excess of pressure caused by that part of the oil that is in motion, a return movement is set up toward the central chamber through passages *N*. These return channels are staggered so as to make the path as long as possible. The current passes over ribs which act as riffles to allow the particles of metal in the oil to settle. On account of this construction the oil furnished to the rubbing surfaces is always the purest oil in the bearing.

This apparatus is very compact, it being but 8 inches from the end of the shaft to the foundation. After the split coupling *B* has been removed, it will be seen that there is enough space between the shaft and the top of the step to allow the latter to be removed from the base plate as a unit. This feature is of value in the gritty atmosphere in which the bearing is installed, since it may be removed to a clean place, where it is wiped out, assembled and filled with oil. It is then returned in its assembled condition, so that dirt and dust do not get into it. The oil is poured in through the opening closed by the cover *J*. Enough is poured in to just cover the top of the rounded boss projecting up in the center of this compartment.

It will be seen that in this bearing the requisite area has been obtained by making the rubbing surface of large diameter. To do this and keep the surfaces in good condition, requires that they shall be so supported that the deflections of the metal under the dead weight and under the shock will not cause portions of the bearing surfaces to break through the oil film. The construction is worthy of study from this standpoint. The circulation of oil provided is so thorough as to increase the efficiency of the bearing surface, reducing the area below what would be necessary with the ordinary "squirt can" method of lubrication, with the inefficiency and uncertainty always attendant on it.

The first of these bearings was installed in the Akron Fire Brick Co., 1901, where it has been running ever since without any expenditure for repairs and renewals, aside from breakage due to an accident for which the bearing was in no way responsible. It has been oiled in this service in periods varying from six to fifteen months apart, without giving the slightest difficulty. The grinding pans of the Windsor Brick Co. have also been equipped with the same bearing. They are refilled every six months, though the oil is found to be in good condition at the end of that time. The illustration shows a more recent design, intended to carry a 12-ton load, in which the wear plates are 15 inches in diameter.

An interesting point relating to the efficiency of the device is its saving in oil. The ordinary bearing for this use, which is from 4½ to 5 inches in diameter, running on hardened steel and bronze washers, requires on the average about 6 gallons per year on each bearing, as supplied with a squirt can, and even with this large amount there is rapid wear and constant

trouble. The use of the self-oiling feature is in line with an editorial on the subject published in the July, 1908, issue of MACHINERY. Whatever may be said against the use of this principle under other conditions, it is obviously correct practice for the vertical step bearing, working under severe duty. The designer of this bearing is Edward F. Edgecombe of the Edgecombe Co., Cuyahoga Falls, O.

COULANGE SYSTEM OF AUTOMATIC INDEXING

The dividing apparatus illustrated herewith, which was recently described in the *L'Alliance Industrielle*, is designed to index work automatically. It requires no more room on the milling machine table than the ordinary universal dividing head, and consequently the distance between the centers is not lessened. Both straight and helical cuts may be taken, with the spindle set to any angle from 0 to 90 degrees, and the work automatically indexed either 2, 3, 4, 5, 6, 7, 8, 9, 10, 12, 14, 15, 18, 20, 21, 24, 28, 30, 36, 42, 60, or 84 divisions, by the use of four plates *C* and five counters *O*. It is possible to obtain other automatic divisions by changing the plates *C* and *O*, and multiples of these automatic divisions may also be obtained semi-automatically. This dividing head has, in addition, all the advantages of the usual form of hand dividing apparatus, such as that used for gears, etc., as it is possible to obtain from 0 to 380 indexings, comprising the prime numbers; and also to obtain all these numbers (except the prime numbers) on helical cuts with the spindle set at any angle from 0 to 90 degrees.

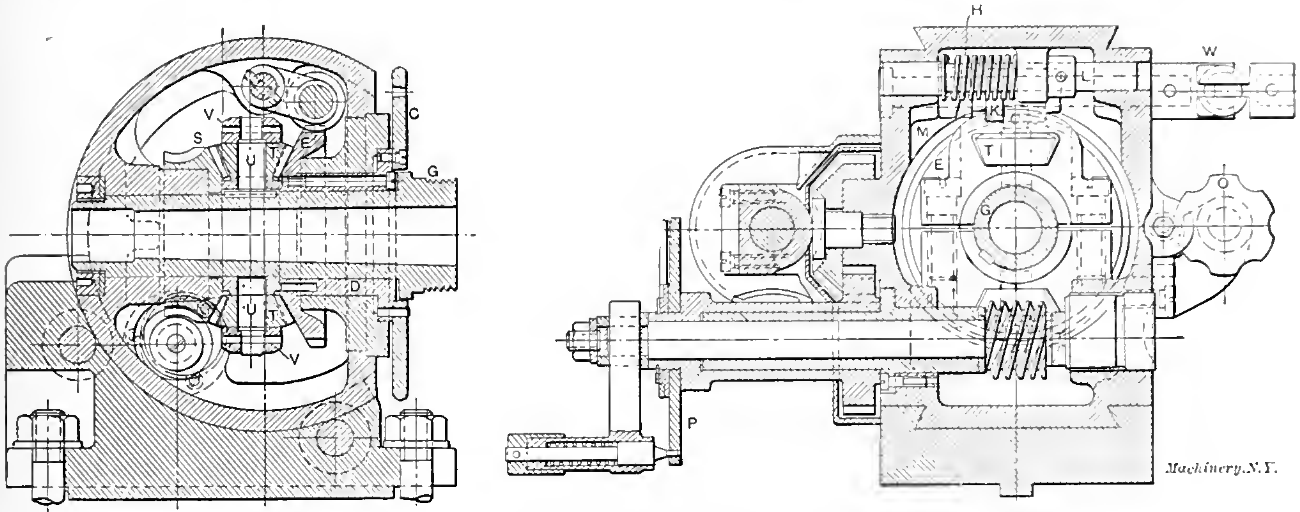

Fig. 1. Dividing Head for Universal Milling Machine which indexes Work Automatically

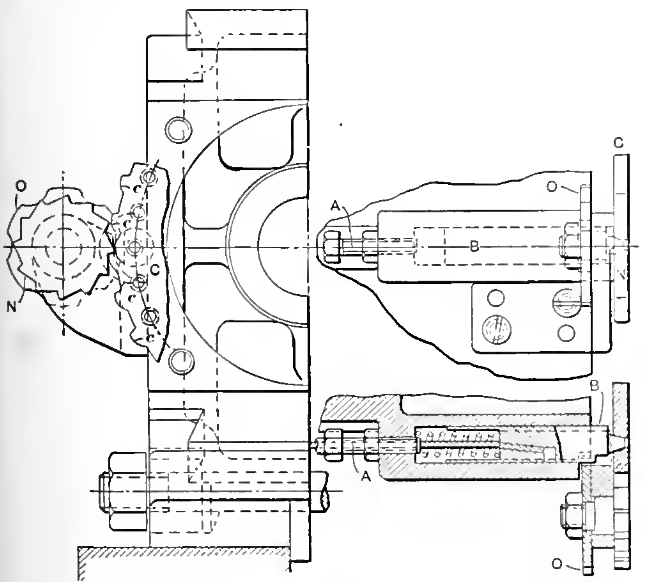

Fig. 2. Detail showing the Locking Mechanism and Plates which control its Movement

The apparatus comprises a differential combining the movement of the dividing plate *C* with the usual dividing plate *P*. This differential includes the plate *C*, the hub *D*, and the bevel teeth formed on gears *E* and *S* which mesh with the planetary bevel pinions *T*, mounted by the pivot *U* on the support *V* which is in two pieces and is keyed to the spindle *G* of the head. In addition, there is an automatic controlling mechanism for the indexing, which includes a spindle *L* driven by a coupling *W*, connected with a special pulley carried in a bracket on the bed of the milling machine; clutch *M* fixed on spindle *L*, and a worm *K*, which is free to revolve on this spindle and which is pressed against the clutch *M* by a spring *H*, rod *I* and finger *J*, when the gear *E* is free to revolve which takes place when the locking bolt *B* (Fig. 2) is withdrawn from the plate *C*. This locking bolt has a spring and Bowden cable which actuate it, the tension of the latter being regulated by screw *A*. The distance which the plate *C* moves at each indexing is controlled by a hole counter composed of the toothed dividing plate *C*, a toothed disk *N* and a stop-plate *O*.

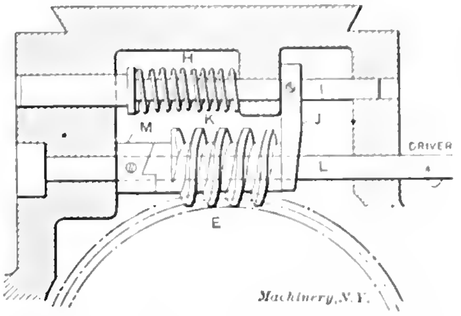

Fig. 3. Detail of the Mechanism which indexes the Work when the Locking Bolt is withdrawn and the Gear E is Free to revolve

The table of the milling machine on which this apparatus is used should be arranged to return automatically. When the cutter has made its first cut, the table returns, and when it is about to finish this return stroke, a suitable mechanism gives a quick pull on the Bowden cable. This pull draws bolt *B* toward the rear, disengaging the dividing plate *C*. The hub *D*, the worm-wheel *E*, the differential and the spindle *G* of the apparatus are thus left free. The pressure of spring *H* gives these parts a gentle movement by the operation of *I*, *J* and the worm *K*. (See the detail Fig. 3.) This last member sliding freely on its spindle *L*, carries the clutch teeth, with which it is provided at one end, into contact with the teeth of the clutch *M* fixed on spindle *L*. Worm *K* thus receives a rotary movement from *M* which it transmits to the differential and to the dividing plate until bolt *B* enters one of the succeeding lock holes in the plate. The division is thus completed, and as the movement of the worm-wheel *E* is arrested, the screw in continuing its rotation is moved backwards, disengaging itself from the clutch *M* and stopping. The dividing plate *C* is provided with a number of teeth *c* (Fig. 2), the number corresponding to the number of its holes. Whenever this plate is set in motion, the first of these teeth strikes the toothed disk *N*.

which is thus made to turn the counter *O*. A solid portion of this counter is thus placed in front of bolt *B* which prevents the bolt from engaging with plate *C* until the required number of holes to bring the cut to the place designated by the counter *O* have passed. The bolt *B* then engages with plate *C* and the division is accomplished. Plates *C*, *O* and *N* are thus furnished with holes and teeth, the number of which depends on the division it is desired to obtain. We show herewith a table of the plates employed to obtain the different automatic divisions mentioned in the foregoing.

[illegible] Plate C	No. Counter	Number of Cuts in the Counter O				
		6	4	3	2	1
12	24	12	8	6	4	2
18	36	18	12	9	6	3
30	60	30	20	15	10	5
42	84	42	28	21	14	7

THE TRIBULATIONS OF INVENTORS

One of the most difficult persons with whom the honest and fair-minded manufacturer has to deal is the inventor who presents to him an idea for the improvement of a mechanical device, but who lacks, utterly, the ability and the mechanical skill and knowledge to put his idea into a commercially acceptable form. Ofter the manufacturer receives from such an inventor nothing but a very crude idea, the working up of which into practical form must be done entirely at his own expense within his own factory. Under those circumstances it is clear that the manufacturer does not consider himself warranted to offer to the inventor a price for his invention equivalent to the value of the device when it has finally been put into practical working condition. But the inventor in most cases considers himself unfairly treated if his compensation is not based on the ultimate value of the device, and he forgets entirely that he did not himself make the invention commercially successful, but merely supplied a more or less crude idea, which, by itself, would have been valueless.

In fact, most inventions offered to manufacturers by inventors outside of their own shops are of this nature, and inventors should always consider before complaining about unfair treatment whether they themselves actually offered for sale a mechanically perfect and commercially successful device. If that is the case, the inventor is entitled to a full share in the proceeds. If, however, merely a crude idea is offered and the inventor is incapable of giving it mechanical perfection, then he has no just reason to complain if manufacturers do not appreciate his offer and refuse to pay an exorbitant price for something, the development of which still largely depends on their own resources.

When the inventor is employed in a manufacturing concern the question usually has a different aspect. He is then, as a rule, able to make his invention mechanically successful, and the full credit for both the original idea and the commercial application is often due to the inventor himself. Inventors of this class, however, have often more reason to complain than has the other class mentioned, for by reason of their employment they are practically forced to sell their invention to their employer at his own price, and the main compensation that they receive commonly consists merely in permanent employment at reasonable wages. This class of inventors, however, seldom complain, because present economic conditions has taught the majority of men to be content as long as they feel reasonably sure of permanent employment.

BIG WORK OF THE MESTA MACHINE CO.

In a business note in the April number of Machinery, it was announced that the Engineers' Club of Western Pennsylvania and others made a trip to the works of the Mesta Machine Co., at West Homestead, near Pittsburg, to inspect interesting new machinery, and office, foundry and pattern storage buildings. A special train of nine cars was run from the Union station to the works on the Monongahela division of the Pennsylvania Railroad, and among the 650 visitors were many prominent manufacturers and engineers.

The illustration, Fig. 1, shows the Corliss rolling mill engine referred to, which was built from "pig iron to 3,500 horsepower" in thirty days. The engine completed weighs 400,000 pounds, of which 200,000 pounds are in the flywheel. It was built for the Phillips Steel & Tin Plate Co., Clarksburg, W. Va., and replaces an engine that was wrecked February 24. The old engine drove the twenty-eight-inch steel mill, and this department was at a complete standstill during the interval

required for building the new engine, hence the effort to replace it in record-breaking time.

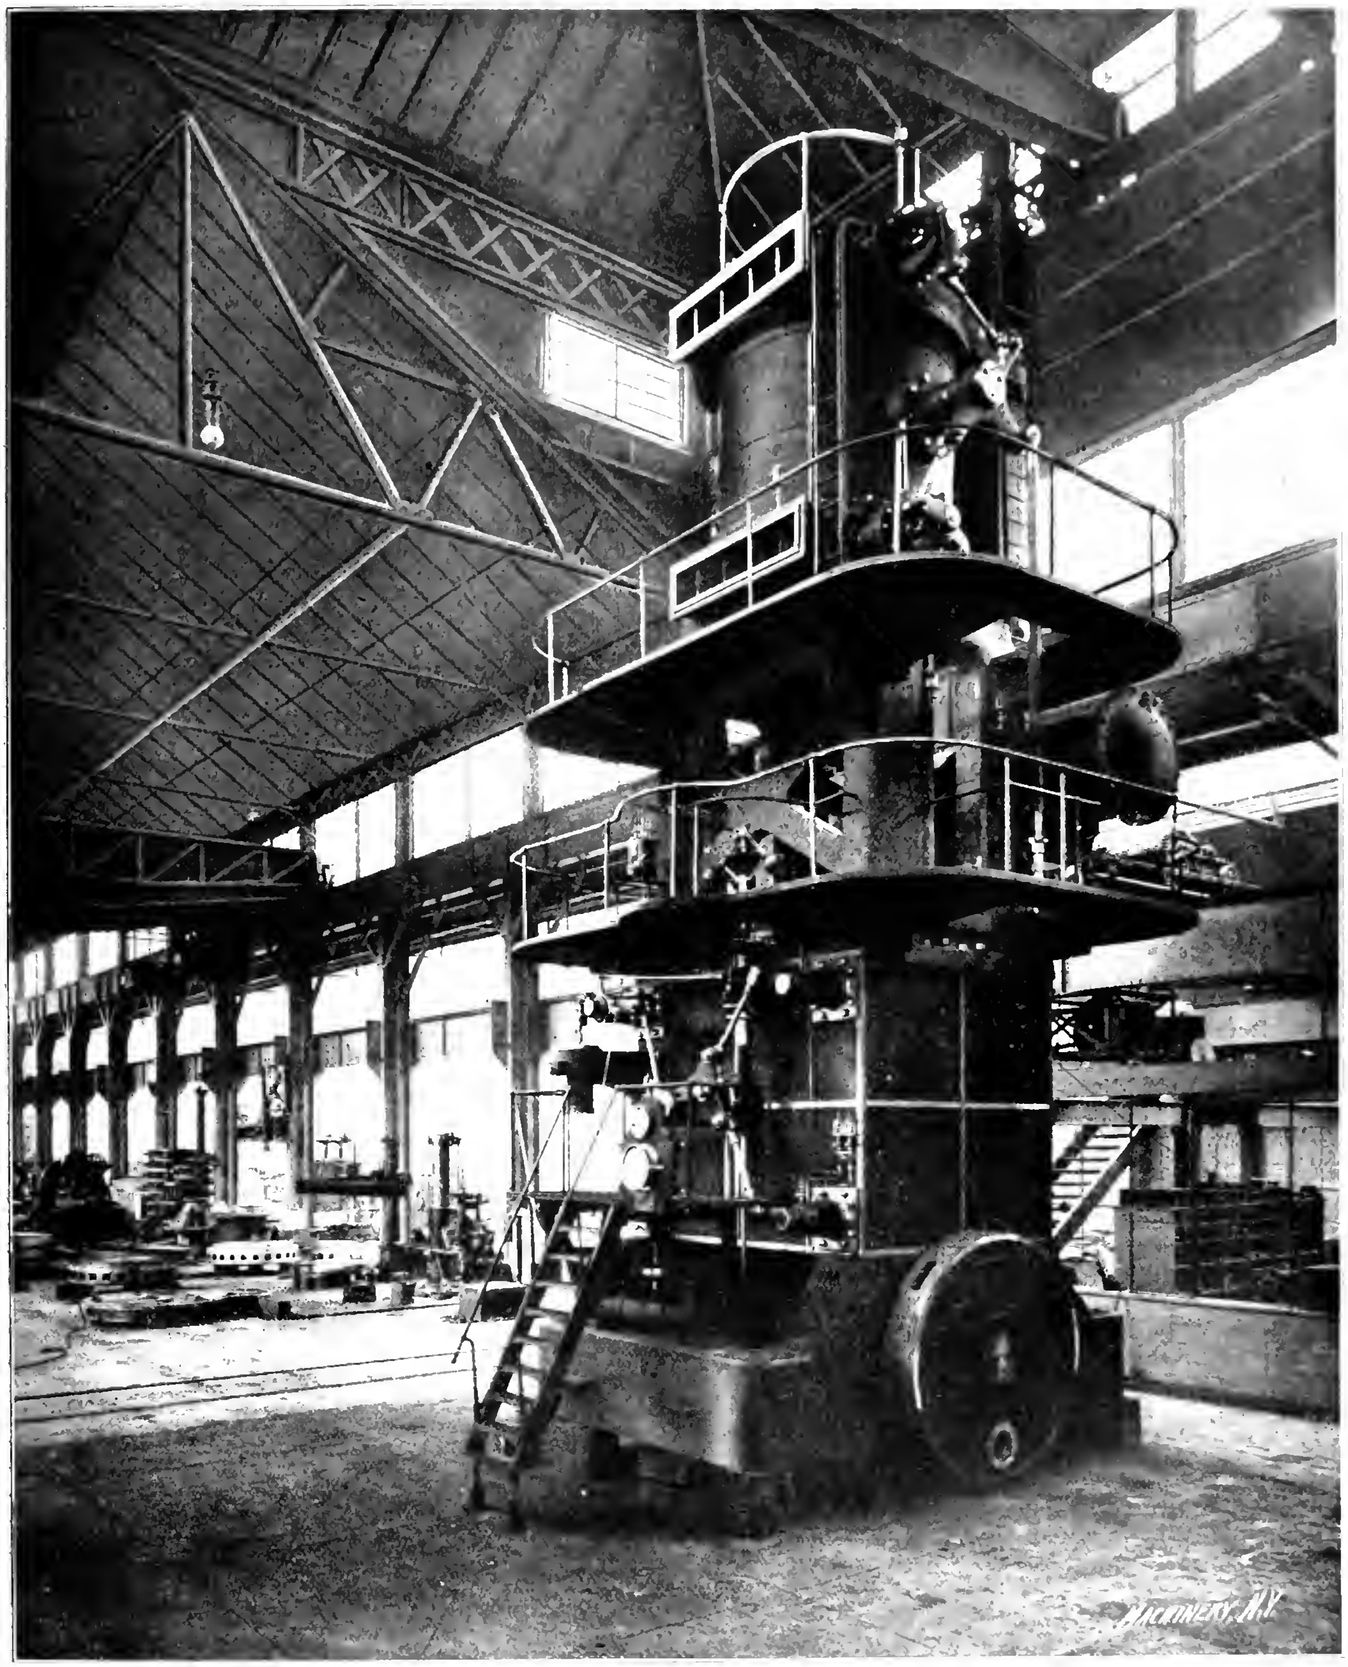

Fig. 2. Long Cross-head Type Vertical Blowing Engine built by the Mesta Machine Co.

The illustration, Fig. 2, is a long cross-head type, low-pressure blowing engine, standing on the erecting floor at the time of the inspection, which had just been completed for the Tennessee Coal, Iron and Railroad Co., Ensley, Ala. The steam cylinder of this engine is 84 inches diameter, air cylinders 84 inches and stroke 60 inches. Twenty-four blowing engines of the same type and size are now in operation at the furnaces of the Tennessee concern, all built by the Mesta Machine Co. The engine illustrated weighs about 250 tons.

Another feature of the machine shop that held the attention of the visitors was the machinery for a 600-ton metal mixer the large [illegible] in size means that the [illegible] of the [illegible] the demands made by the steel [illegible] practically unlimited. [illegible] shown the pouring of [illegible] in use for many years and the [illegible] the Mesta Company. This operation is a revolution in the science of roll-making, as the positive control of the mechanical devices enables the operator to get exactly the depth and hardness of chill desired. In the new iron foundry, an engine frame weighing 160,000 pounds was poured from four huge ladles. This building is equipped with 100-ton traveling cranes for handling ladles and castings.

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit exclusive contributions from practical men on subjects pertaining to machine shop practice and machine design. All accepted matter is paid for at our regular space rates unless other terms are agreed on. All copy must reach us by the 5th of the month preceding publication.

MAY, 1909.

PAID CIRCULATION FOR APRIL, 1909, 21,611 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 650 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

GOLD, AND ITS EFFECT ON PRICES

Bankers, financiers, business men, manufacturers, mechanics and, in short, everyone is vitally interested in the production of gold and the effect of the enormous increase in its production of late years on the finances of the world. Two very interesting books have been published lately on the subject, entitled "Story of Gold" and "The World's Gold," which are worthy of the consideration of every man sufficiently interested in monetary conditions to have some appreciation of the subject. The gold question has assumed an entirely different aspect since the demonetization of silver. Improved methods of mining and reduction have made it possible to work gold-bearing quartz rock with profit that only a few years ago Works of Alaska handle half a million tons of rock each year would have been unprofitable. For example, the Treadwell and find it profitable with a total production of gold of only about $2.50 per ton.

The increase of gold production has had a very appreciable effect on prices. Everyone suffers under the high prices of food, clothing and general living, and the majority cannot understand why costs have so greatly increased. Those who have made a study of this question say that it is due to the great production of gold, which in effect has cheapened it and made its purchasing power considerably less than when it was less abundant. To illustrate how greatly gold production has increased, a few statistics are in order: In 1883, 145 tons of gold were produced; in 1890, 200 tons; and in 1906, 608 tons. In other words, the production of gold had more than quadrupled in twenty years. The increased production of gold is even more strikingly apparent if we look at the production during a long period of years. In the time that elapsed since the discovery of America to the discovery of gold in California in 1849, the world's total production of gold was 4,621 tons, and in the forty years following the discovery in California the production was 7,160 tons. The production of forty years was fifty per cent more than in the three hundred fifty odd years preceding! If the production of gold is plotted, the curve will show a strikingly upward tendency during the last twenty years. The prospects are that the production of gold will increase even more during the next twenty years, which means according to monetary experts that prices will keep in step. Investments in stocks, bonds, mortgages and collateral security will depreciate, while investments in land, buildings, factories and other concrete examples of wealth will materially increase in apparent value. The man who buys a house will have good prospects of seeing its value, expressed in dollars and cents, increase greatly during the next few years, if the gold prophets are not at fault.

* * *

LABOR AND TARIFF

At the Tariff Commission convention held in Indianapolis, February 16 to 18, one of the best addresses made was that by Mr. Henry R. Towne, president of the Merchants' Association of New York. Mr. Towne had well analyzed his subject, and his reference to the interest of labor in the tariff is of especial value. "A tariff," he says, "is an indirect tax; its primary purpose is revenue; it may include the secondary purpose of protection. A tariff rate intended to prevent importation ceases to become a tax and becomes a subsidy. In considering any proposed tax, these questions should be considered: 1. On whom will it fall? 2. What revenue will it yield? 3. Whom, if any, will it benefit? If reliable data are available and if the tax is for revenue only, these questions may perhaps be easily answered, but if it is wholly or partly for protection, to foster and benefit certain classes of citizens, at the possible or intended expense of other classes, the problems become vastly complex. * * * In all discussions of the tariff the plea is made that a chief purpose in view is protection to American labor. Are we not liable to be misled by this plea? Does labor actually share, and, if so, to what extent, in the proceeds of the tax resulting from a protective duty? Is it not a fact, known to all employers of labor, that, in fixing any individual rate of wages, no thought whatever is given to the tariff; that in every case the employer takes account solely of the value or efficiency of the workman, and of the current rate of wages in the trade to which he belongs; that the workman is guided solely by his knowledge as to the current rate, and by his needs; and that each makes the best bargain that he can? Is it not true, further, that the rate of wages, in every trade, depends in large part on the cost of living, and that a high tariff, by enhancing the prices of the products which it affects, tends to increase this cost? Finally, is it not true that the real measure of a wage is its purchasing power, and that needlessly high tariff rates tend to diminish the purchasing power of wages?"

Mr. Towne further called attention to the United States as a great example of free trade, and said that nowhere else, at any time in the world's history, have trade and commerce been so absolutely free and untrammeled as they are to-day among the 80,000,000 people of this country.

The following are the more important of the conclusions given by Mr. Towne in his paper: The tariff embodies the heaviest tax which the people of the United States impose on themselves; it yields one-half of the national revenue; the present method of fixing tariff rates through Congressional committees acting chiefly on prejudiced evidence produces inequalities which are unnecessary, harmful and unjust; it is crude, unscientific and outgrown. A tariff influences wages indirectly only; it chiefly influences the cost of living, which in turn, determines the rate of a living wage; the true measure of wages is purchasing power; hence, anything tending to increase the cost of living, lessens wages; therefore, the tariff should be adjusted with regard to all its effects on all the people, not with regard to protected interests only. Mr. Towne considers that the remedy for our difficulties with the tariff would be a permanent, technical bureau of tariff research, which would collect, analyze and report industrial and commercial data to Congress, and that tariff revision should be made continuous and not intermittent. This would make the tariff flexible, and eliminate the bad influence of intermittent revision on business.

THE WASTE OF HUMAN ENERGY

A European state railway system was recently in need of sixteen new passenger locomotives of identical type. In the particular country referred to there are four locomotive building companies, and in order to "provide work" for the hands idle during the present depression the state railway administration divided the order for the sixteen locomotives among the four companies, ordering four from each. Under present economic conditions, when men willing to work are not permitted to do so, this course was undoubtedly a wise one; but one cannot help being impressed by the waste of human energy involved in the construction of the sixteen locomotives in this manner. Four complete sets of designs had to be worked out and approved, four complete sets of patterns made, and special tools required for the manufacture of the engines duplicated in four different places; and, of course, the work could not possibly be carried out under this arrangement as economically as if the sixteen locomotives had been built by one firm.

In England a reduction in the naval program advocated by the government about a year ago, was vigorously opposed by a portion of the press, not on the ground of national defense, but because a reduction in the quota of battleships to be constructed yearly would throw a number of men out of work; so, in order to give these men an opportunity to earn a living, these papers advocated a continuance of the policy of building battleships whether or not they were necessary for the country's defense.

It is not necessarily lack of employment alone that causes poverty, but also such aimless waste of human energy, which could be employed for the production of useful material. It is not necessary to go to Europe for examples of a similar waste of energy. During every period of trade depression we see examples of it in every country, and in almost every community; and this waste is likely to continue until we apply the axiom that men do not actually want *work*, considered by itself; but they do want the *product* of their work; and that wages, or compensation for work, do not come out of a large, indefinite, inexhaustible fund, but from the products of labor. If labor is expended for useless and unproductive purposes, the fund out of which wages must eventually be paid will be that much smaller, and the total reward for all labor must be less, even if no part of the product were diverted into other channels. Wasteful production, whether on a small or large scale, whether caused by individual or national ignorance or by economic conditions, is the worst enemy to progress; and the mere fact that men are paid for useless work in no way justifies the doing of the work.

The main reason for the industrial progress in America has been that human energy was highly valued; and, with all the waste in our natural resources, the percentage of waste in human energy has been smaller than in the old world. At present, the difference between conditions in this respect in the old world and in the United States is not so marked as in the past, and there is now a greater tendency in this country to employ labor in wasteful ways. Of course, non-employment itself is wasteful, whether it be voluntary or enforced; and whatever is done to prevent the waste of human energy is therefore an important step forward. It is fully as important to the progress of industry and the increase of wealth, as is the designing of labor-saving machinery and the development of improved methods of manufacture.

* * *

It is proposed to include a "worked-to-an-adequate-extent" clause in the French patent law. According to the *Times* the new amendment to the law will provide that patent rights shall lapse in France if the holder of the patent does not exercise his rights in France or in French colonies for a period of three years after applying for the patent. It also appears that the patentee will be expected to "exercise his rights" to an adequate extent. Of course, the purpose of this bill is exactly the same as that of the new British Patents Act, and the "exercise of rights" evidently is intended to mean the manufacture of the patented article.

EXPERIMENTS ON TWIST DRILLS—1

At the March 18, 1909, meeting of the Institution of Mechanical Engineers of Great Britain, a paper was read entitled "Experiments Upon Forces Acting on Twist Drills when Operating on Cast Iron and Steel." The paper was prepared by Mr. Dempster Smith of the Municipal School of Technology, Manchester, England, and Mr. R Pollakoff of the Imperial Technology Institute, Moscow, Russia. The experiments, which have covered a period of three years, have been made by the authors of the paper at the Manchester School of Technology under the direction of Dr. J. T. Nicolson Owing to the thorough manner in which these experiments have been carried out and the extensive records made of the results obtained, together with the valuable conclusions that can be drawn from these results regarding the design of twist drills, the paper is of considerable importance, and the following abstract has been prepared with a view of presenting the most essential points. The results obtained in the experiments are the outcome of over one thousand tests.

Previous Experiments

Before discussing the experiments, it may not be out of place to give a brief *résumé* of the most important work done in this field of research. Amongst the first experiments of any note with twist-drills are those recorded by Professor L. P. Breckenridge in the Journal of the Lehigh University Engineering Society for October, 1898. According to these experiments the pressure on the drill when starting to cut is greater than the pressure on the drill when drilling with the full diameter. It was found that a one-inch drill required 1,450 pounds pressure when starting to cut, and 1,000 to 1,150 pounds pressure when drilling with the full diameter. The material cut, however, was not specified. It would appear from the results obtained that the material drilled was cast iron on which the skin or scale had not been removed, so that on this account a greater pressure was required to start the cut than to drill with the full diameter of the drill.

In 1902, Mr. Norris of the Bickford Drill & Tool Co. made several experiments with carbon steel twist drills in order to determine the most economical feed and speed, and also to get an idea of the power required when drilling cast iron. Mr. Norris found that a ¾-inch drill would withstand a feed of 1/16 of an inch per revolution when drilling ordinary cast iron at a speed of 267 revolutions per minute, this being the coarsest feed provided on the machine. It was also found impossible to break drills larger than the above when operating at the same feed and on the same material. These experiments resulted in the adoption of feeds in the Bickford shops, which were about four times greater than those recommended by the Morse Twist Drill Company, at speeds not less than that given by that company. The conclusions from these trials were: The net horse-power per cubic inch of metal removed slightly decreases with the increase of feed for a given diameter of drill and speed. The net horse-power per cubic inch of metal removed also decreases with the increase in diameter of drill. The cutting speed for each drill varied, however, decreasing with the increase in diameter.

From a second set of power trials carried out on a specially rigid machine designed for testing the durability of the drills Mr. Norris arrived at the following conclusions:

When the speed and feed are constant, the power required to drill tool steel is about 1.10 times, wrought iron about 1.65 times, and machinery steel about 1.90 times that required to drill cast iron. When the speeds and feeds remain constant, the power required is approximately proportional to the diameter of the drill. When the diameter of the drill and rate of feed are constant, the power required is approximately proportional to the speed. When the speed and diameter of drill are constant, the power required is approximately proportional to the feed.

A formula closely agreeing with these results, when operating on cast iron at a speed of 30 feet per minute, is:

$$\text{H.P} = \frac{63}{\sqrt{d}}(dt + 0.01)$$

where *d* is the diameter of the drill in inches and *t* the feed in inches per revolution of the drill.

Messrs. W. W. Bird and H. P. Fairfield, of the Worcester Polytechnic Institute, in a paper presented at the New York meeting of the American Society of Mechanical Engineers, December, 1904, gave the results of investigations on the torque and thrust exerted on a $\frac{5}{8}$-inch "Novo" high-speed steel twist drill with varying rate of speed and feed on different metals.

The results of these experiments with a drill having an included point angle of 118 degrees was as follows: No material difference either in torque or end thrust was found by increasing the speed from 140 to 600 revolutions per minute when drilling soft gray iron. When operating on the same material at 420 revolutions per minute at varying rates of feed, it was observed that the torque did not increase as quickly as the feed, but the thrust increased very rapidly with coarse feeds. The torque required when operating on brass, tool steel, and machine steel was respectively 0.715, 1.67 and 2.44 times that required for cast iron. The corresponding thrusts were found to be 0.575, 1.7 and 2.6 times that required for cast iron. By varying the included point angle of the drill from 75 to 140 degrees, the end thrust increased rapidly with the angle, but no practical difference was observed in the torque.

A similar set of experiments were made later at the Worcester Polytechnic Institute by C. S. Frary and E. A. Adams. The results of these experiments showed that with a constant surface speed the thrust was nearly proportional to the diameter of the drill and also to the rate of feed. With different included point angles, the thrust decreased for angles from 150 to 90 degrees, and then increased for any further decrease in the angles. The moment could not be said to be proportional to the angle of the point, but almost proportional to the feed. The drill giving the minimum torque had a point angle of 130 degrees and the torque increased with drills having angles greater or less than this.

The twisting moment for ordinary twist drills is, according to these experiments, approximately expressed by:

$T = 13.5\ d\ (1{,}000\ t + 2.5)$

where

$T =$ torque in inch-pounds,
$d =$ diameter of the drill in inches,
$t =$ feed in inches per revolution of the drill.

The Manchester Experiments

In the experiments made at the Manchester School of Technology, the results of which are reported in the paper referred to above, two forms of apparatus were used. The first apparatus was of comparatively simple character, suitable for use in the ordinary lathe. The experiments with this apparatus had for their object:

(*a*) To determine the twisting moment required for drilling with different diameters of twist drills at various speeds and feeds in cast iron and steel.

(*b*) The feeding force required for the various conditions mentioned in (*a*).

(*c*) To ascertain the twisting force required to enlarge a hole (which had previously been opened with a drill of smaller diameter) at different rates of feed on cast iron and steel.

(*d*) The corresponding feeding force required under the circumstances instanced in (*c*).

Ordinary commercial A. W. high-speed steel twist drills of $\frac{3}{4}$, 1, and $1\frac{1}{2}$ inch diameter were used throughout these trials. The drills were ground on a twist drill grinding machine and the point thinned to about half the thickness of the web. The cast iron operated upon was of medium hardness and had the skin removed. The steel was Whitworth's (fluid-pressed), of medium hardness, having 0.29 per cent carbon and 0.625 per cent manganese.

Description of Apparatus

The arrangement of the lathe used for the first set of experiments is shown in Fig. 1. The lathe was driven by a 120 H. P. direct-current shunt-wound motor. A large air-cooled rheostat connected to the main circuit between the line and brushes allowed of the speed being varied from 100 to 300 revolutions per minute. The motor drove on to a countershaft whereon was mounted a three-step cone pulley similar to that on the lathe spindle. A further reduction of speed could be obtained through the double and triple back-gears in the machine, the ratio of which was 14.9 and 42.5 to 1, respectively, the combined arrangement permitted of the speed being varied from 1.5 to 450 revolutions per minute. A counter fixed to the end of the spindle indicated the revolutions made by the work.

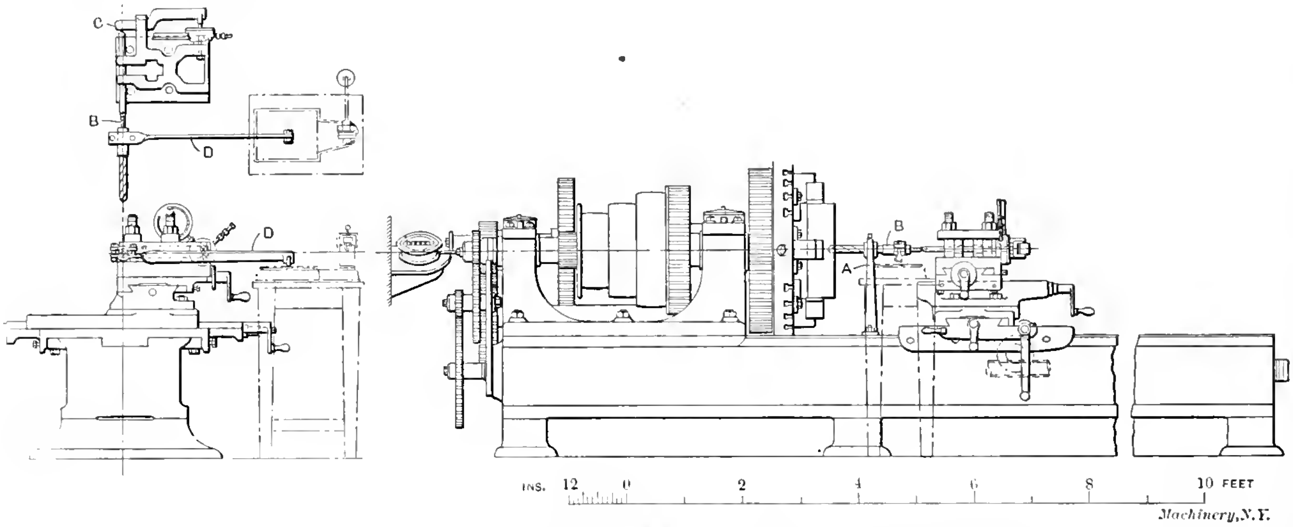

Fig. 1. Apparatus used for the First Set of Experiments to obtain Power required for Drilling

The stand *A*, bolted to the bed of the lathe, supported the drill close to the work. The drill was quite free to slide in the bearing provided in the stand. Suitable hardened steel bushings were used for the various sizes of drills. A small spindle or socket *B* received the tang end of the drill, and the thrust was taken by the knife-edged lever *C* and a diaphragm dynamometer fitted to a cast iron block which was bolted to the top slide rest.

The arm *D* was attached at one end to *B*, while the other end rested on a scale pan, and thus prevented the drill from rotating. As the arm advanced with the drill, the scale pan remaining stationary, the former was fitted with a knife-edged roller to reduce side twist on the drill, due to friction. The force exerted on the pan when multiplied by the length of the arm gives the twisting moment on the drill. By the engagement of the screw-cutting feed mechanism a definite advance was given to the drill per revolution of the work. The diaphragm dynamometer is similar to that shown in section in Fig. 2 and described in connection with the second apparatus. The speed in the ordinary force trials was kept constant at 10 revolutions per minute for each diameter of drills. The revolutions were observed on the counter at the end of the lathe spindle and a tachometer on the motor.

No perceptible difference was observed in the twisting moment and end-pressure with the variation of speed; that is, the cutting horse-power for a given diameter of drill and feed was directly proportional to the speed. The results of the experiments have been reduced to formulas, and are mainly so expressed in the following.

In the formulas given in the following, the notation below has been adhered to throughout:

T = torque in foot-pounds,
d = diameter of drill in inches,
t = feed in inches per revolution of drill,
P = end thrust in pounds,
f = cutting pressure in tons per square inch,
N = revolutions per minute,
V = metal removed per minute in cubic inches.

Results of Experiments with First Apparatus

The results obtained in the first set of experiments are expressed by the following formulas:

Trials (a) on medium cast iron:

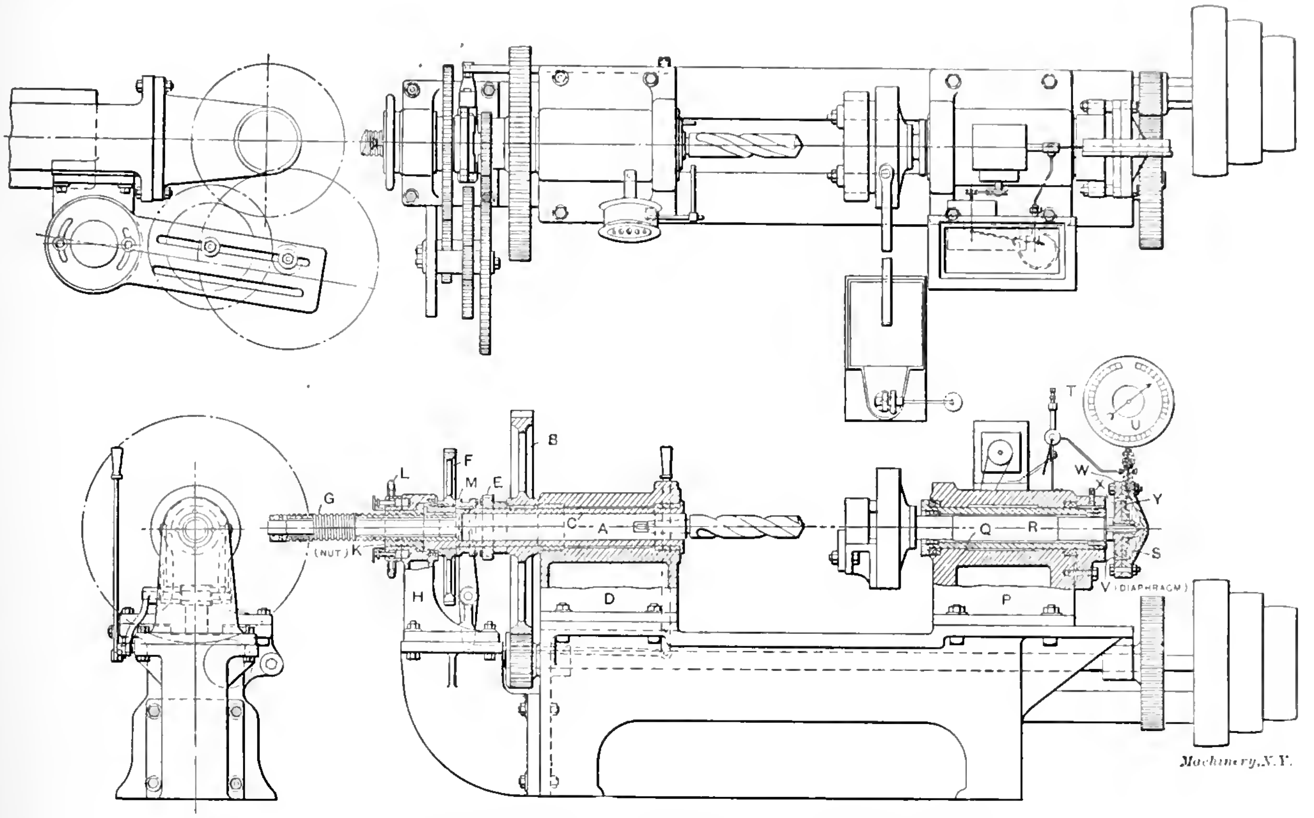

Fig. 2. Section and Elevation of Apparatus used in Second Set of Experiments

$T = 1{,}220\,t + 2.5$ for ¾-inch drill, (1)
$T = 1{,}840\,t + 7.5$ for 1- inch drill, (2)
$T = 3{,}640\,t + 22.5$ for 1½-inch drill, (3)

An equation embracing the whole can be written:

$T = 12\,(d^2 - 0.35) + (500 + 1{,}350d^2)\,t$, (4)

A more approximate but much more simple expression for formula (4) would be

$T = (1{,}800\,t + 9)\,d^2$, (4a)

For the opening out trials (c) on cast iron, the twisting moment is given by the formula

$T = 2{,}812\,t + 17.5$ for opening ¾-inch hole to 1½-inch diameter, (5)

The twisting moment in trials (a) on steel follow a similar law to the cast iron. An expression for each size of drill is given below:

$T = 1{,}530\,t + 15$ for ¾-inch drill, (6)
$T = 3{,}850\,t + 18$ for 1- inch drill, (7)
$T = 7{,}800\,t + 48$ for 1½-inch drill, (8)

An approximate expression for the above which is near enough for all practical purposes is

$T = (3{,}200\,t + 20)\,d^2$, (9)

For the opening out trials (c) on steel:

$T = 1{,}500\,t + 6$ for opening ¾-inch to 1-inch, (10)
$T = 3{,}325\,t + 29$ for opening 1-inch to 1½-inch, (11)
$T = 5{,}025\,t + 31$ for opening ¾-inch to 1½-inch, (12)

The end thrust P is given by the following formulas:

For medium cast iron

$P = 95{,}600\,t - 250$ for ¾-inch-drill, (13)
$P = 93{,}400\,t + 180$ for 1- inch drill, (14)
$P = 154{,}000\,t - 600$ for 1½-inch drill, (15)

and

$P = 115{,}000\,t - 200$ for all diameters, (16)

In the opening out trials (d) in cast iron

$P = 11{,}330\,t + 160$ opening out ¾-inch hole to 1½-inch diameter, (17)

In the medium steel experiments for trials (b):

$P = 26{,}500\,t + 1{,}040$ for ¾-inch drill, (18a)
$P = 90{,}000\,t + 800$ for 1- inch drill, (18b)
$P = 155{,}000\,t + 1{,}300$ for 1½-inch drill, (18c)

and

$P = 160{,}000\,(d - 0.5)\,t + 1{,}000$ for all drills, (18)

For the opening out trials in medium steel:

$P = 15{,}200\,t - 60$ opening ¾-inch hole to 1-inch diameter, (19a)
$P = 25{,}500\,t + 60$ opening 1-inch hole to 1½-inch diameter, (19b)
$P = 30{,}000\,t + 200$ opening ¾-inch hole to 1½-inch diameter, (19c)

In no case did the end force P reach a maximum and then diminish when the drill was fully entered as observed by Professor Breckenridge, and it can only be concluded that he was operating on cast iron having a very hard skin or that the drill had a smaller pitch than those now in common use, *i. e.*, a keener angle. The opening out experiments show the fallacy of a common notion that but for the chisel point the drill would run into the work and break.

The apparatus employed and the results obtained in these first experiments were not entirely satisfactory for the larger drills and heavy feeds. This led to the construction of a second apparatus, and the making of a second set of tests, which will be described in the June issue.

* * *

It is stated in the *Marine Journal* that Sir Oliver Lodge recently succeeded in completely clearing away for a radius of sixty feet, a thick fog, by means of electrical discharges. The method employed consists in discharging electricity into the fog-laden atmosphere at a very high voltage, from a series of disks at the top of poles.

SOME NOTES ON BALL BEARINGS*

ASHER GOLDEN†

Mechanical friction is always a resisting force, whether utilized to effect the stability of structures, or to transmit motion from one part of a machine to another, or even to enable us to walk. In producing these effects, friction is essential and desirable, and means are often taken to increase it; such, for example, as the covering of leather transmission belts with adhesive substances and the covering of icy pavements to prevent slipping. On the other hand, friction is injurious in preventing relative motion of different parts of a machine and producing waste of energy. Under these conditions, friction is a serious disadvantage and its elimination a problem of grave importance. Any discussion relating to ball bearings, therefore, bears directly on the question of eliminating friction, and indirectly on the question of saving fuel and oil, and preventing the wear and tear of machinery.

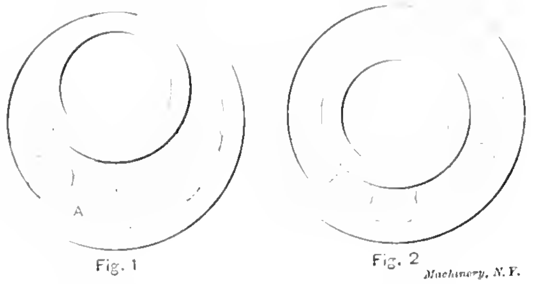

Fig. 1 Fig. 2

Figs. 1 and 2. Method of Assembling a Ball Bearing

One way of minimizing the effects of friction suggested itself to the man who first applied wheels to a road vehicle. It must have been apparent to him that a vehicle would wear better and require less effort to move it if some means were provided to roll it along instead of having to drag it over the ground. This condition of affairs may be exaggerated by assuming that in one case we have two toothed racks in mesh and we try to move one relatively to the other; in the second case, that we replace one of the racks by a gear wheel and move it over the rack by means of a trunnion. The limit of the load required to effect motion in the first case, is that which will break the teeth, and in the second case, the effort required to overcome the comparatively small weight of the wheel and the friction between the meshing teeth. A comparative idea of the advantage gained by substituting rolling for sliding friction may be obtained approximately by taking two smooth blocks of steel, lubricating the surfaces in contact, and then tilting them; one block will begin to slide over the other when the angle through which they are tilted is between 8 and 9 degrees. If now, we replace the oil between the two blocks by a number of steel balls, we find on tilting the blocks, that they will begin to slide over each other when the angle is about 0.08 degree Again, if we take two smooth horizontal blocks of steel, weighing, say 1 pound, it will require a force of approximately 2.7 ounces to move one over the other if the surfaces in contact are lubricated. If, instead of oil, we use steel balls between the blocks, only 0.027 ounce will be required to effect the motion. The only question raised against the use of the concentric ball bearing for stationary machinery and the cheaper grades of automobiles, is in regard to first cost. Aside from this, no one questions the relative advantage of the two-point ball bearing over the plain bearing, or even the roller bearing or cup and cone. In regard to ultimate cost, it may be safely said that the two-point bearing is the most efficient and cheapest. It only remains, regarding the ball bearing as a friction eliminator, to consider some of the inherent mechanical defects found in ball bearings at present on the market. These defects may be put under the following heads: Side slots in the rings for assembling the balls; small number of balls in races owing to absence of side filling slots; separators or spacers made of several disconnected pieces.

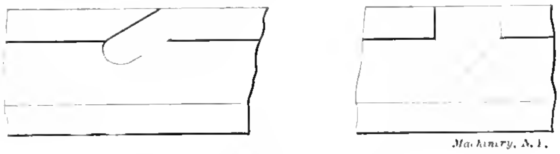

Fig. 3. Two Forms of Filling Slots

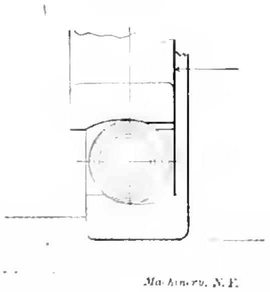

Fig. 4. Displacement of the Rings of a Radial Bearing when it is subjected to an End Thrust

There are employed at present but two general methods of assembling a full or partly full ball bearing. One of these is to arrange the balls and races as shown in Fig. 1, and after placing in the crescent-shaped space *A*, as many balls as can be freely dropped in, the inner ring is shifted, leaving an annular space with the races about half filled with balls, as shown in Fig. 2. The remaining balls are then sprung in through slots in the sides under comparatively high pressure. This process is used extensively by Fichtel & Sachs (F. & S.); Standard Roller Bearing Co. (S.R.B.); and every other manufacturer of ball bearings, with the exception of three or four. The master patents for this process are owned by Fichtel & Sachs. Two forms of these filling slots are shown in Fig. 3. It is claimed by all those who employ the filling slot, that after the balls are assembled, they have practically a continuous race and that the bearing is as perfect as if the slot never existed. It may be said, however, that the existence of a filling slot as a defect is indirectly recognized by every bearing manufacturer. If it were possible to use radial bearings to carry only a purely radial load, almost any ball bearing, no matter how assembled, would give satisfactory service, provided the materials were fairly good and the bearing not overloaded; but, in many instances, radial bearings are used to carry, simultaneously, ordinary radial loads and comparatively excessive thrust loads. This applies particularly to radial bearings used in automobile front wheels, and to some extent in the rear wheels as well. Under these conditions, the inner and outer rings are relatively displaced, as shown in Fig. 4, and it is evident that if a bearing having a side filling slot be subjected to excessive end thrust, the balls are forced into the slot, a treatment which is manifestly

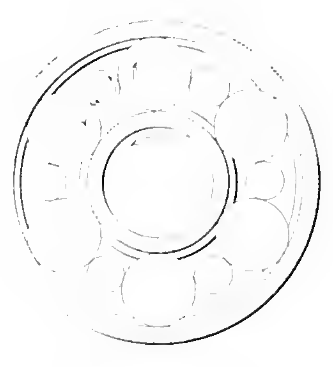

Fig. 5. Bearing Designed to Eliminate Friction

---

* For additional information on this subject see the following articles previously published in MACHINERY: Ball Bearings, December, 1907, and January, 1908, engineering edition; The Discussion on Bearings Held at the December Meeting of the A. S. M. E., February, 1906; Designing Two-point Ball Bearings, April, 1906, engineering edition; Ball and Roller Bearings, December, 1906; Ball Bearings, February, 1905.

† Address: 1779 Broadway, New York City.

not very good for either balls or races. Of course, the extent to which this pinching of the ball in the slot will take place will depend on the depth of the filling slot. The Fichtel & Sachs Co. overcome this difficulty to some extent by employing a slot which is not quite as deep as the ball races. The balls are then forced through these slots under a pressure which is much higher than the thrust loads that can possibly be put on the bearings in practice. This is at least defensible practice, provided that the materials employed are of excellent quality. A bearing may be made without a filling slot, but in that case the limit to the number of balls which may be inserted is set by what will go into the crescent-shaped space *A*, Fig. 1. The balls are disposed around the circumference and some form of separator or spacer used to keep them apart. It has often been stated by those who employ this process, that there is no need of completely filling the races with balls; in other words, that a ball bearing which is only partly filled with balls, is equal to or better than one which is completely filled. One might almost reason instinctively that such statements are erroneous. That they are actually so will be shown.

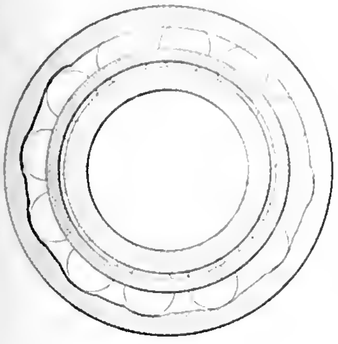

Fig. 9.* Bearing with Outer Ring Grooved to permit the Use of a One-piece Separator

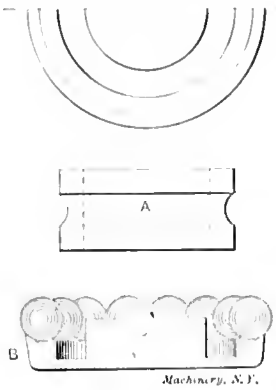

Fig. 10. Inner Race and Section through One-half the Cup used in Assembling the R. B. F. Radial Bearing

Fig. 11. View showing Method of Assembling the R. B. F. Bearing. After the Outer Race is heated with Oil, the Balls and the Inner Race are Forced into Place, after which the Assembling Cup is removed.

The permissible load in kilograms which a two-point ball bearing having one row of balls, will carry is given by the following relation due to Professor Stribeck:

$$P = \frac{K d^2 z}{5} \qquad (1)$$

where *K* is a constant depending on the properties of the material, the form of the ball race and the angular speed of the bearing; it may also be regarded as a factor of safety; *z* is the number of balls; the factor 5 takes account of the fact that only part of the balls carries the radial load; *d* is the diameter of the ball, taking 1/8 inch as the unit. For example:

If diameter of ball is 1/8 inch, $d = 1$
If diameter of ball is 1/4 inch, $d = 2$
If diameter of ball is 7/16 inch, $d = 3.5$
If diameter of ball is 5/8 inch, $d = 5$, etc.

From the above, it is seen that if we take two bearings having the same form of groove and the same dimensions for both of the balls and races, then if P_1 and P_2 are the carrying capacities of the two bearings, and z_1 and z_2 the corresponding number of balls, we have for the same angular speed

$$P_1 = \frac{K d^2 z_1}{5}$$

$$P_2 = \frac{K d^2 z_2}{5}$$

from which

$$\frac{P_1}{P_2} = \frac{z_1}{z_2}$$; or, in words, the carrying capacities of the two bearings are directly proportional to the number of balls. It is seen, therefore, that for a given bearing, other things being equal, the full type has a greater carrying capacity than that only partly filled with balls. While it is seldom stated that the carrying capacity of a radial bearing is some function of the angular speed, it will be seen that such is the case, since, if the speed is zero, the carrying capacity of the bearing is the rupture load of the balls; this load is far greater than the rated capacity of the bearing. For ball bearings made of high-grade material and accurately machined, *K* has the following approximate values for steady loads and uniform speeds.

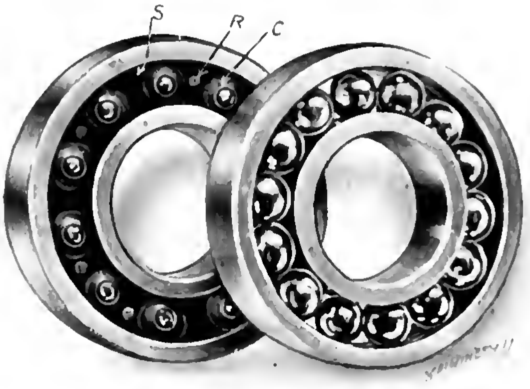

Fig. 12. Radial Bearings with and without Retainer

Revolutions per Minute.	Values of K.
10	20
150	18
300	15
500	10
1000	7.5
1500	5

From these figures, it will be seen that a given bearing will carry only one-fourth the load at 1500 R. P. M. that it will at 10 R. P. M. Since manufacturers employ the same material for all their bearings, and make the ball races of approximately the same form, it would be a simple matter to calculate the carrying capacities after adopting a value of *K* for a definite speed of rotation. There are some manufacturers, however, who assume high values of *K* in order to rate their carrying capacities high. There is no particular harm in this, provided the loads are not excessive. These

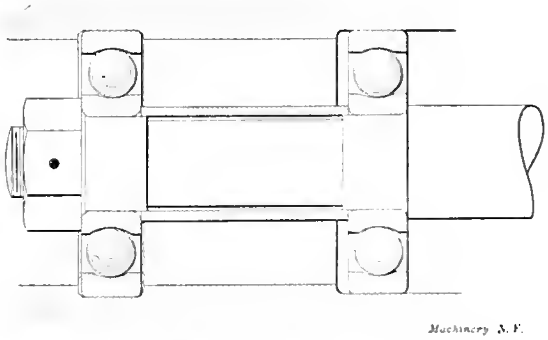

Fig. 13. Radial Bearings Arranged to take Axial Thrust

values of K even vary between the full and silent type of the same size bearings. It may be remarked, however, that the values of K may be the same for all the bearings, and that the capacities are calculated for different angular speeds, but no reason can be seen for such practice. For example, there is no reason why a manufacturer should rate the carrying capacity of his full type bearing, at say, 10 R. P. M., and the silent type of the same size at 300 R. P. M.

To determine the value of K used in rating the capacities, equation (1) is written in the form

$$K = \frac{P}{0.44\,d^2 z} \qquad (2)$$

where P is now given in pounds.

From equation (1), it is readily seen that the load per ball is lower in the full type than in the silent type. It may be argued from this that a full ball bearing will wear better that the other, but it is here necessary to remark that with the better grades of bearings, provided that the load is almost purely radial and within the limits set down in the catalogues, and the mountings made in accordance with the manufacturers' instructions, such a thing as wear is practically unknown, whether the bearing be of the full or silent type. But, as stated above, the load on the radial bearing is never free from end thrust; where this is excessive, the full bearing will give better service than the silent type, since end thrust is taken up by all the balls in the bearing, while a radial load is carried by between one and four balls, depending upon the type of bearing. Hence, everything else being equal, the full bearing is more satisfactory.

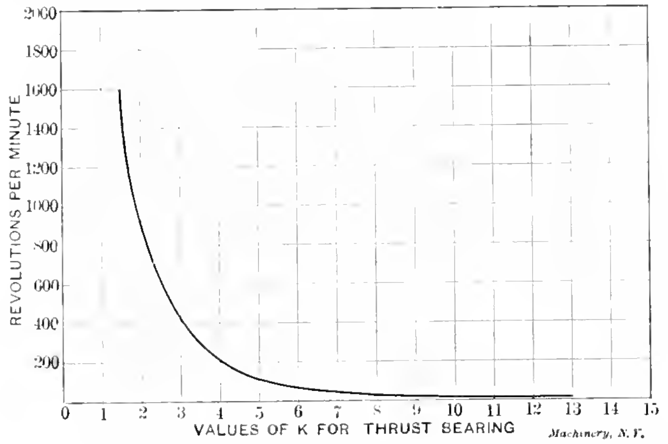

Fig. 14 Diagram showing how the Constant K, which is used in the Formula for Determining the Capacity of Thrust Bearings, varies with the Angular Speed

In regard to the third defect mentioned, it may be said that the employment of the discontinuous spacer, or one made up of several disconnected pieces, is very poor practice. Such a spacer has been used extensively by the D. W. F. Co., but is now being abandoned for a one-piece bronze separator. The discontinuous separator is also used by a well-known American manufacturer, but its use is incidental to the accomplishment of another end, which may be treated under the following head:

"Frictionless" Ball Bearings

Notwithstanding that the friction losses in a full ball bearing are very small, so small in fact as to be negligible, many attempts have been made to eliminate what little friction there is. One noteworthy example is that of the bearing just referred to. Here a series of alternately large and small balls is used, as shown in Fig. 5. This example is noteworthy only because it increases the friction which it is designed to eliminate, and introduces other serious disadvantages not found in the full bearing, or the silent type bearing, having a one-piece separator. Referring to Fig. 6, it will be seen that if the inner race rotates in the direction indicated, the balls will rotate as shown by the small arrows, and in the same relative direction as the outer race. There is in this case practically no sliding, except at the point of contact of every two adjacent balls where, it is seen, the ball surfaces are moving in opposite directions. At first glance, we may be led to infer that, since the balls are in contact and rubbing against each other, there must be an appreciable friction loss and consequent wear and tear. This inference is without foundation, since the balls do not contact under pressure, except in the case of those balls which are not carrying the load; then the pressure is the weight of the ball; this is negligible in comparison with the normal load on the bearing. Referring to Fig. 7, we see that if no load is placed on the inner ring, the balls will come together if the weight of the inner ring is less than that of the balls; but the moment we apply a load to the inner ring, which is in excess of the weight of the balls, there is no pressure between the balls; if there were, they would be together. While it may seem to some that this matter is dilated on to an undue extent, the discussion is nevertheless warranted; this is done in order to correct an impression which seems to be general with those unfamiliar with ball bearing phenomena.

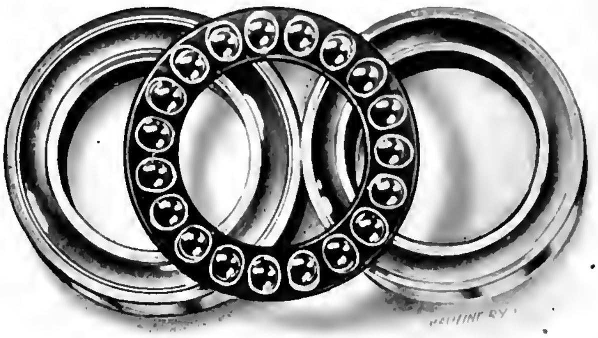

Fig. 15. Upper and Lower Races for Thrust Bearing, and Balls with Retainer having Elliptical Holes

To overcome this imaginary ball friction, this bearing is provided alternately with large and small balls. Referring to Fig. 5, it will be seen that since the small balls are not in contact with the inner race, they are not constrained to rotate in the same direction as the large balls; the small balls, in fact, rotate in the opposite direction, and hence, between every two adjacent balls, there is practically pure rolling; that is, the negligible friction between the balls is eliminated—but at a serious sacrifice. First, since only the large balls are in contact with the inner and outer races, only these balls are useful in carrying the load. As stated in the foregoing, the carrying capacity (in pounds) of a radial bearing is $.44\ K\ d^2\ z$, so that a bearing of this type will carry a load of $.44\,K\,d^2 \times 6$, since 6 is the maximum number of balls that can be inserted in the bearing. A similar bearing when completely filled, will hold about 9 of the large balls; hence, we see that the bearing completely filled with large balls will carry three pounds to every two of the bearing having alternately large and small balls. Second, to sustain the small balls, it is essential that some form of separator be used. The separator used by the manufacturer of this bearing has the form shown in Fig. 8. It will be seen here that the ends of the separator contact with the balls, and that although the friction in this case is admittedly very small, it is considerably greater than in a similar full type ball bearing; the friction is further increased, owing to the fact that the makers of this bearing state that their bearings do not require oil. In addition, if one of the large balls should break, the bearing falls apart. This defect is a very serious one, and is common to all the bearings employing discontinuous separators.

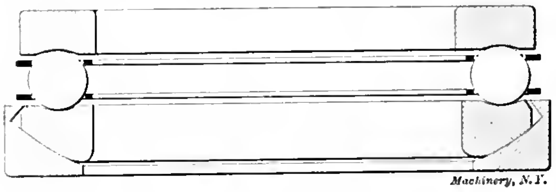

Fig. 16. Section through Thrust Bearing, the Lower Race of which is in Two Parts

As pointed out above, all other things being equal, the carrying capacities of two bearings are directly proportional to the number of balls; hence, it is evident that under all

conditions of service a bearing that is completely filled with balls is to be preferred to one that is only partly filled, provided that the side filling slot can be done away with. Owing to the apparent impossibility of introducing a sufficient number of balls to completely fill the race, most manufacturers have made use of the filling slot, while a few have taken the alternative step of avoiding the filling slot by employing fewer balls. The extent to which some manufacturers may go in order to gain the advantage of a large number of balls, as well as to avoid the discontinuous separator is shown in Fig. 9. This bearing, made by the Auto-Machinery Co. ("A. M.") of Coventry, England, has eight filling slots. The main object in doing this, however, will be best seen from the following abstract of an article in *The Automotor Journal*, January 25, 1908, describing this bearing.

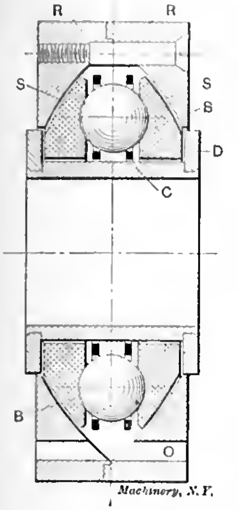

Fig. 17. Bearing Designed for Axial Thrust in Either Direction

"One of the principal difficulties in connection with the use of a cage, is its interference with the process of assembling the component parts. If the balls are inserted separately, they present no great difficulty, but when surrounded by a cage, special provisions are necessary. Some firms have for this reason divided the cages of their bearings, so that they can be fitted in place afterwards, but the Auto-Machinery Co. dislike the use of a divided cage, and have thus evolved a method of inserting the balls and their cage *en bloc*." After the outer ball race is circumferentially grooved, "it has a series of slots cut across its inner surface. These slots, however, are cut on one side only, and do not reach quite to the center of the groove; moreover, they are not provided round the entire circumference. This object is to facilitate the insertion of the balls *en bloc* with their cage * * *."

It is an unfortunate circumstance that the manufacturers of this bearing dislike the divided cage. It may be remarked that the advantage of inserting the balls and their one-piece separator as a complete unit, cannot be readily seen. If there is an advantage, it has been gained, in this case, by a great sacrifice.

We shall now describe the R. B. F. radial bearing made by the Société Française des Roulements à Billes. This bearing is unique in that it has none of the defects discussed above. There are no filling slots either in the full or silent type. The full type contains as many balls as it is possible to get into the races. The silent type has a continuous separator. In the assembling of the R. B. F. radial bearing, two similar steel cups are used of the form shown in Fig. 10. After placing the inner race *A* of the bearing over the central core *C* of one of the cups, the balls are laid around the groove *B*, and the inner race and balls are then covered by the second cup. The outer ring is now heated in a bath of oil, and placed over the assembled ball and cup unit as shown in Fig. 11. This complete unit is now placed in a press and the balls forced into position. After the outer ring has cooled down to normal temperature, it is impossible to detect the slightest axial play. This method of assembling a full ball bearing is an excellent check on the quality of the bearing, since, if the balls are improperly heat treated, they are either deformed or broken, as the case may be, when pressure is applied to force them into the outer race, and are, therefore, rejected. The spacer or separator used by the R. B. F. Co. consists, as will be seen from Fig. 12, of two steel stampings *S*, each having a number of saucer-shaped cavities *C* which serve to engage the balls and keep them apart. The two halves of the spacer are kept apart by a number of distance pieces, and are fastened together by means of rivets *R*. Sufficient room is allowed between the cavities and the balls to provide for a liberal film of grease or oil, so that there is never metal to metal contact under normal running conditions.

Radial Bearings as Thrust Carriers

While ball bearing manufacturers, as a rule, are desirous of limiting the use of radial bearings to their normal function, it has nevertheless become the practice among bearing users to employ the radial bearing to take axial thrust in addition to the normal radial load. To meet this demand, the bearing manufacturer has been obliged to stretch a point and suggest means whereby the radial bearing can also be used as a thrust bearing. To this end, it is considered good practice where two bearings are mounted on the same shaft, to make the inner ring of both bearings a light driving fit on the shaft. The outer ring of one bearing is then made a sliding fit in its seat and clamped up far enough to allow it from 0.5 millimeter (0.0196 inch) to 1 millimeter (0.0393 inch) axial play; the outer ring of the other bearing is also made a sliding fit, but is allowed considerable axial play. The first bearing takes the radial load, and end thrust, and the second bearing, a purely radial load only. This arrangement, shown diagrammatically in Fig. 13, is a preventive against wedging of the bearings, and is an assurance of long life. It is not uncommon, however, to find ball bearing users who are bent on carrying out their own ideas in regard to mountings. It is from these that most complaints come.

It may be said here that although the arrangement just described is considered good practice, it is decidedly poor practice to use a radial bearing to take the end thrust of a shaft having a low speed of rotation. This applies, particularly, where the end thrusts are excessive, as in automobile front wheels. This is the real cause of the complaints heard on every hand as to the unsuitability of two-point bearings in automobile front wheels, and has led many to adopt some form of inclined roller or cup-and-cone bearing, both of which are far inferior to the two-point bearing. The remedy in these cases is very simple. The trouble can be effectively eliminated by making the outer rings of the two bearings a sliding fit and allowing them considerable axial play, so that they cannot possibly take end thrust. This thrust is then taken on a thrust bearing or collar placed somewhere on the shaft, usually between the other two. If the speeds of rotation are very high, say above 1,000, there is no particular harm in taking thrust on a radial bearing, since at high speeds, radial bearings are better thrust carriers than thrust bearings.

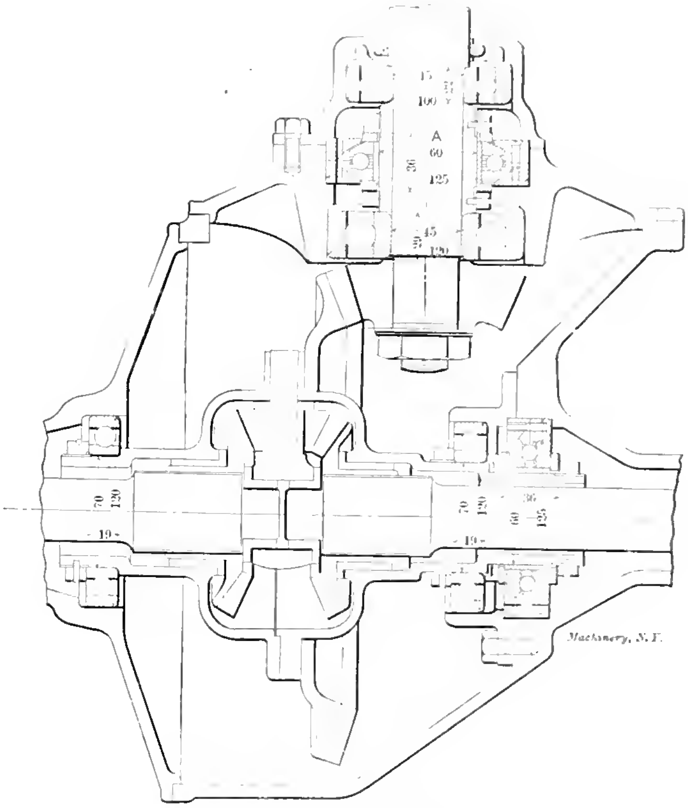

Fig. 18. Automobile Rear Axle and Differential Gearing equipped with the Double Thrust Bearing

Thrust Bearings

For the determination of the permissible load of a thrust bearing, a relation analogous to equation (1) is used. The load P in kilograms is

$$P = K\,d^2\,z \tag{3}$$

This is for steady loads and uniform speeds. This equation is the same as (1), except that the factor 5 drops out, since it is here assumed that all the balls are effective in carrying the load. The curve Fig. 14 shows how K varies with the angular speed. The values of K for speeds usually given in catalogues are shown in the following table:

Revolutions per Minute.	Values of K.
10	12.5
150	4.5
300	3.5
500	3
1000	2
1500	1.5

For parts that execute very little motion, such as crane hooks, K may be taken as high as 18 to 20. For very high speeds above 1500, the ordinary thrust bearing is practically useless for taking end thrusts. Centrifugal force, at these speeds, plays a very important part. The balls are driven toward the outer edge of the race, and against the walls of the ball retainer. To avoid this condition, use is made of a retainer with elliptical holes as shown in Fig. 15. This retainer also permits the shaft to deflect without pinching. It is used in America by the Société Française des Roulements à Billes, and the Hess-Bright Manufacturing Co., who are the only American licensees under the patent. The manner in which the permissible load varies with the speed is seen from the following table constructed for a particular bearing.

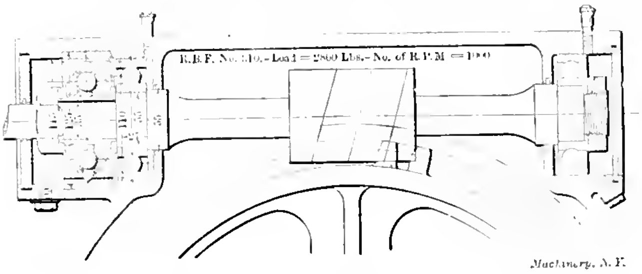

Fig. 19. Double Thrust Bearing applied to a Worm Shaft

Revolutions per Minute.	Load in Pounds.
10	11,000
150	3,740
300	2,640
500	2,420
1000	1,760
1500	1,540

Every shaft, no matter how short, is deflected under load; this deflection, although too small to be seen in many cases, can at least be calculated. In order to take the end thrust of such a shaft, it is customary to provide a thrust bearing having the lower surface of the bottom race of spherical form. The seat for this bearing is machined to the same form. This permits the shaft to deflect and the bearing to move as a complete unit with the shaft. It assures that the plane of the bearing will always be perpendicular to the axis of the shaft, and that the load will be uniformly distributed among all the balls. The use of such a bearing has two disadvantages: first, in the machining of the seat, a special fixture is required to allow the cutting tool to swing over the required radius of curvature of the seat; second, the material of which the races are made is hardened, while the seat for the bearing is machined out of ordinary unhardened material, so that appreciable wear will take place in a comparatively short time. There need be no objection to this bearing, however, if the speeds of rotation are very low, or the loads are very light. To overcome these disadvantages, the Société Française des Roulements à Billes, supplies a thrust bearing having the lower race made of two parts, one floating within the other as shown in Fig. 16. These two parts are made of the same material and heat treated in the same way, so that there is practically no wear even when the speeds of rotation are high and the loads great. All that is necessary to use the bearing, is to machine an ordinary flat seat; no special tools or fixtures are required.

In order to assemble the two parts of the lower race, the bottom portion is heated in oil, and the upper portion forced into position under pressure. The advantage of this arrangement is, that the lower race, although made up of two parts, can be handled as a complete unit. An exterior view of this race is shown in Fig. 15.

It is often desired to take end thrust on a shaft in both directions, as for example, where bevel or worm gearing is used, or on a marine propeller shaft. To do this, it is usual to employ two distinct thrust bearings. Such an arrangement has the disadvantages spoken of above in connection with the single thrust bearing. To permit of end thrust being taken in both directions, the Société Française des Roulements à Billes, manufactures the bearing of which a section is shown in Fig. 17. The bearing consists of two outer rings R, held together by screws, and provided with a number of oil holes O. The inner surfaces of these rings are machined to a spherical form to accommodate the outer surfaces S of the rings B. The rings D are forced on the collar C after expansion by heat in the manner described in connection with the other products of the R. B. F. Co. Every working part of the bearing is enclosed and it is entirely self-contained. One application of this bearing is shown in Fig. 18 in connection with an automobile rear axle and differential, and Fig. 19 shows an application to a worm and wheel.

* * *

THE MACHINING OF MANGANESE STEEL

In an article in the *Railway and Engineering Review*, Mr. James B. Strong refers to some interesting particulars regarding the machining of manganese steel. This steel, whether cast or rolled, is not an extremely hard metal, as most people suppose. It is not as hard as chilled cast iron, and only about 20 per cent harder than high-carbon Bessemer steel; but manganese steel, properly treated, is extremely tough. The particles hang together most tenaciously, and when subjected to severe strains, the metal flows and can endure repeated distortions without surface fractures or cracks. There is practically no loss from the surface of manganese steel in small pieces when subjected to abrasive wear of any nature, except where there is a constant renewal of sharp cutting edges, such as with emery and other grinding wheels. The idea that manganese steel will cut or grind chilled iron or steel-tired wheels is not correct, as a cutting edge of manganese steel will not stand up at all against harder metals.

It is interesting to observe the cutting action on manganese steel of drills or planer tools made of high-grade tool steel which is much harder than manganese steel. The tool takes hold on cast or rolled manganese steel, at first, and cuts, but the chips will not come off as with ordinary steel. They drag, and the tool soon slips, heats up and the cutting edge fuses or crumbles. Cast or rolled manganese steel can be cut slowly, however, by specially shaped and hardened tools in a powerful and heavy machine free from vibration; but even then the cutting edge is very short-lived and must be renewed constantly.

* * *

The strength and elasticity of copper depends to a large degree on its heat treatment. Some experiments to ascertain to what extent the heating and subsequent cooling of copper influences its strength were recently undertaken, the results of which are given in *Engineering*. Ordinary commercial copper wire would stand 44 bendings before breaking. The same wire when heated to bright red heat and suddenly cooled in water would stand 73 bendings, while if it was slowly cooled in the air, after the heating, it would break at 49 bendings. When heated to a dark red heat and cooled in the air it would break at 41 bendings, but, if cooled in water first, at 46 bendings. This seems to indicate that if copper is heated to a red heat it should be suddenly cooled in water rather than by permitting it to cool in the air, if the strength is not to be reduced.

DATA ON HIGH-SPEED DRILLING

GEO. E. HALLENBECK*

The accompanying diagrams show the results of some tests made with high-speed drills on the Baker Brothers high-speed drilling machine. They represent a part of the experiments which have been made at the works of the above company with a view of securing the most efficient design of machine for driving medium size drills, that is to say, drills from ¾ to 2 inches in diameter.

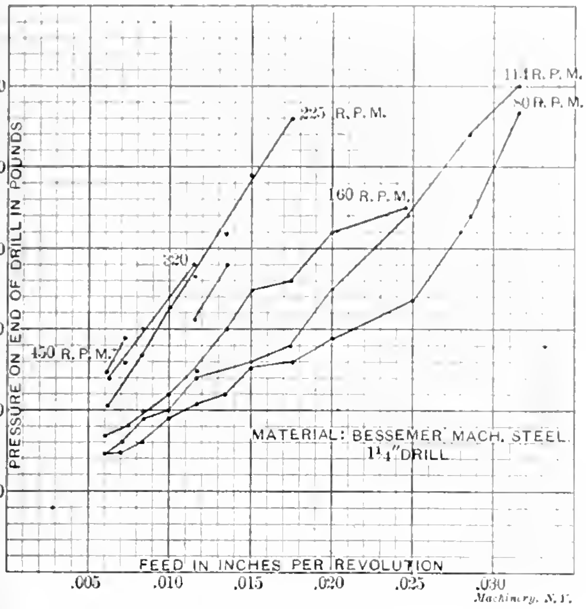

Fig. 1. Diagram showing Relation between End Pressure and Feed in High-speed Drilling

Some of the drilling which has been done on these machines is little short of marvelous. Thus 1¼-inch holes have been drilled through 4¼-inch blocks of cast iron at the rate of 8 2/3 seconds per hole, or a vertical feed of 29 inches per minute. (See MACHINERY, June, 1908.) Several holes were drilled at this speed without necessitating the regrinding of the drill. Some 15/16-inch holes were drilled through a ¾-inch machine steel plate at the rate of 3½ seconds each; a great many similar tests have been made. When we stop to consider that the average punch press when punching a 15/16-inch hole in ¾-inch material will make about 20 to 30 strokes a minute, or, in other words, it will take two or three seconds to punch the 15/16-inch hole which was drilled in 3½ seconds, the really remarkable performance stands out more clearly, especially so when it is understood that a number of holes were drilled at this rate without resharpening the drill. The holes were drilled without lubricant of any kind.

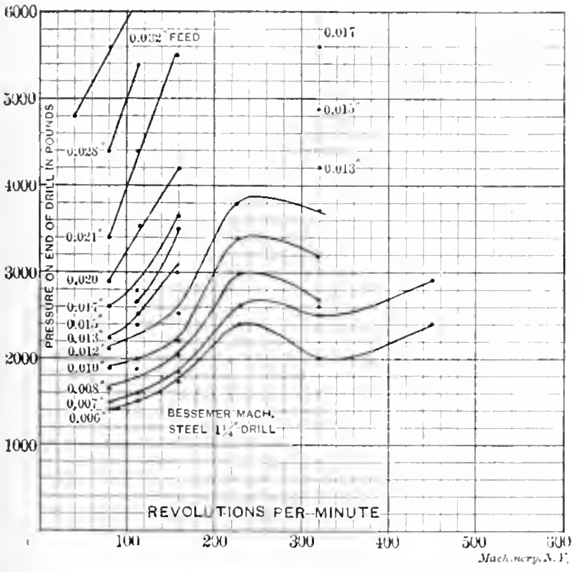

Fig. 2. Diagram showing Relation between End Pressure and Cutting Speeds

Among other things it was desirable to know just what the vertical thrust on the spindle was in order to properly design the thrust bearing and feeding mechanism, experience having demonstrated that the load on the feeding mechanism was far greater than it was ordinarily thought to be.

Fig. 1 shows very clearly the result of some of these tests made with a 1¼-inch drill. The variation of the pressure on the end of the drill is shown in relation to a gradually increasing rate of feed. Several tests are shown at speeds varying from 80 R. P. M. to 450 R. P. M. It will be appreciated that the conditions of these tests are such that nothing more than general conclusions can be drawn from the curves. In the curves shown in Fig. 1, it will be noted that, as a general proposition, the effect of increasing the feed is to increase the pressure of the drill point in a straight line ratio, although the tests made at 80 R. P. M. would indicate that there was a tendency toward an increasing pressure as the feed was increased. So far as it was possible to observe, there was no great variation in the vertical thrust with the increasing depth of hole after the first ¼ inch had been drilled.

Fig. 2 shows the same series of tests as shown in Fig. 1, but here the feed is held constant and the speed made a variable. These curves, together with those shown in Fig. 5, are perhaps the most interesting of the series from the fact that they show a peculiar decrease in pressure by increasing the speed with the feed constant. All the tests show practically the same results in regard to this decrease. It will be seen by referring to Fig. 2 that while it was impossible to drill in the material drilled with a feed of 0.013 inch at 225 R. P. M., it was easily drilled at that and even at 0.015 and 0.017 inch feed per revolution at 320 R. P. M.

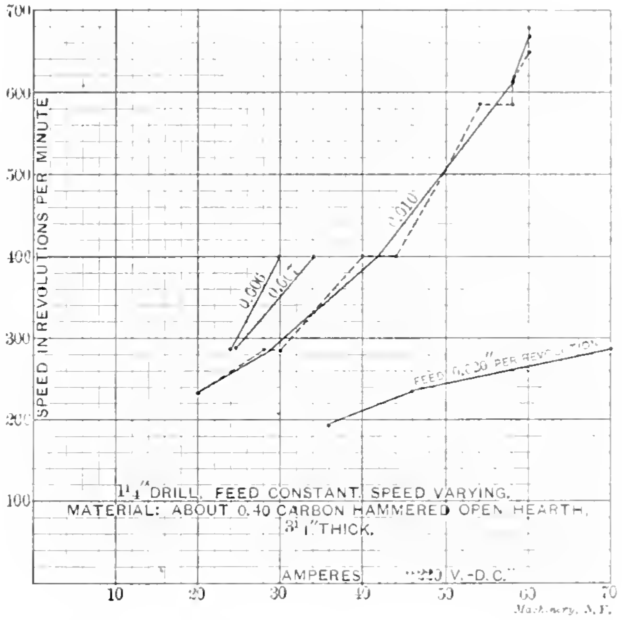

Fig. 3. Diagram showing Power Required for Drilling at Different Speeds

Fig. 3 shows the horse-power consumed and its variation with the variation in speed. It will be noted that at the fine feeds, *i. e.*, feeds of under 0.010 inch per revolution, the amount of power increases in a decreasing ratio as the speed increases, whereas with a feed of 0.020 inch per revolution, just the opposite seems to be true. The ampere readings shown on the diagram represent the total electrical input into the motor, no deductions having been made for either the losses in the motor or in the machine itself, as the data desired is the amount of power which will have to be delivered to the machine.

Fig. 4 shows the variation in power required under a constant speed with varying feed, the increase in power consumption being apparently a constant ratio.

Fig. 5 shows the remarkable increase in production which can be secured by increasing the speed. The curves are plotted showing the maximum feed at which the stock was successfully drilled without destroying the drill. With the next higher feed the drill would be destroyed. In order to

---

* Superintendent, Baker Brothers, Toledo, Ohio.

secure as nearly uniform conditions as possible, all of one series of tests were run with the same drill, it being resharpened when necessary. The curve No. 2 shows quite conclusively that the drill would give a greater production without failing at 200 R. P. M. than it would at 250 R. P. M., and also that it would give a much greater production if the speed were still further increased to 440 R. P. M. This may be an index to the solution of the much mooted question of whether a slow speed and heavy feed or a high speed and fine feed is preferable. It would seem that the adherents of each of the above sides of the question would get into trouble as they began to gradually increase or decrease their speed and so would quickly come to the conclusion that they could gain nothing by going in that direction.

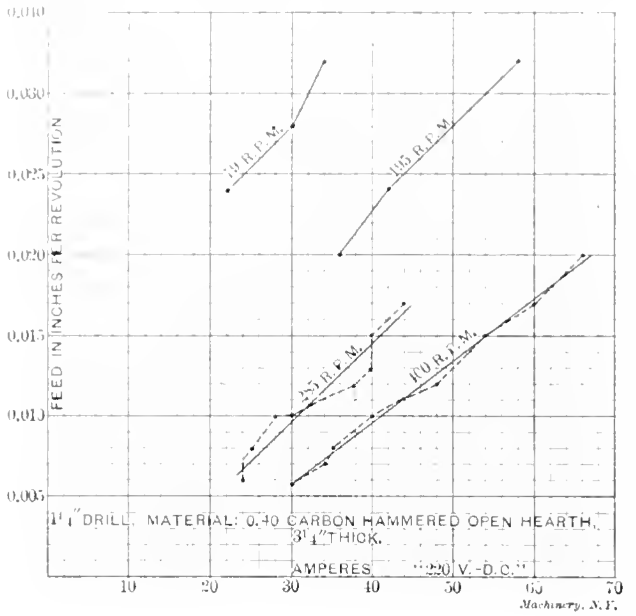

Fig. 4. Diagram showing Power Required for Drilling when Feed Varies

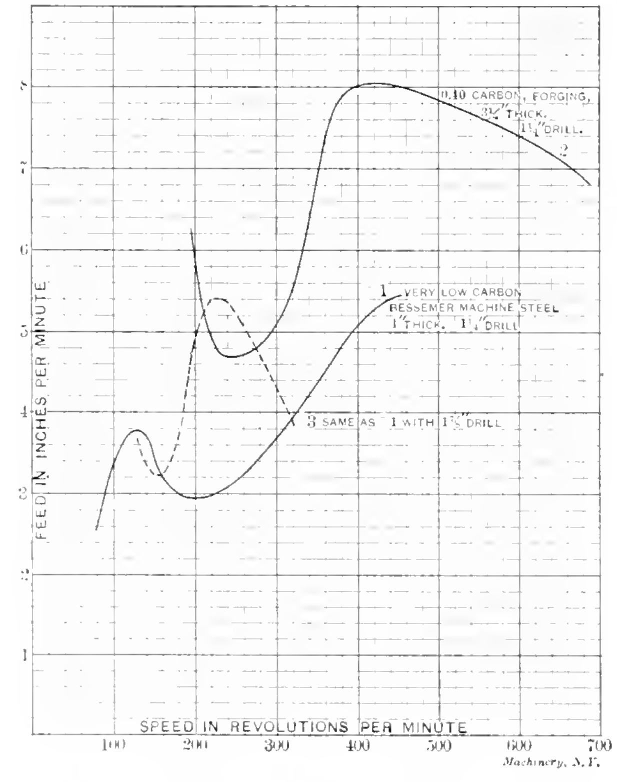

Fig. 5. Diagram indicating Productive Capacity of Drills at Various Speeds

These tests on drilling, although representing many hundreds of drilled holes, are by no means given as conclusive, they having been altogether too few in number to establish permanently the conclusions to which a study of the diagrams would naturally lead; yet they seem to point quite strongly to the conclusion that the best results will be obtained at comparatively high speeds and moderate feeds, as it is possible to carry a heavier feed at a high speed than at the medium speed. It was this fact, often recurring in the writer's tests, that led to making the series of tests the results of which are shown in Fig. 5, for the purpose of demonstrating whether such was actually the case, or whether the apparent increase was due to other causes. In conclusion the writer would add that the majority of the drilling shown on the accompanying diagrams was done with a 1¼-inch drill, and the number of times required to sharpen it were very few.

The Baker Brothers' high-speed drilling machine on which these tests were made is shown in Fig. 6. It is driven by a 4 to 1 variable speed motor, and has a speed range from 70 to 700 R. P. M. By providing suitable gearing a wide range of feeds between 0.006 and 0.032 inch per revolution is secured on this machine. The machine on which these tests were made was provided with roller bearings; outside of this feature it was the regular high-speed drill as now built by Baker Brothers.

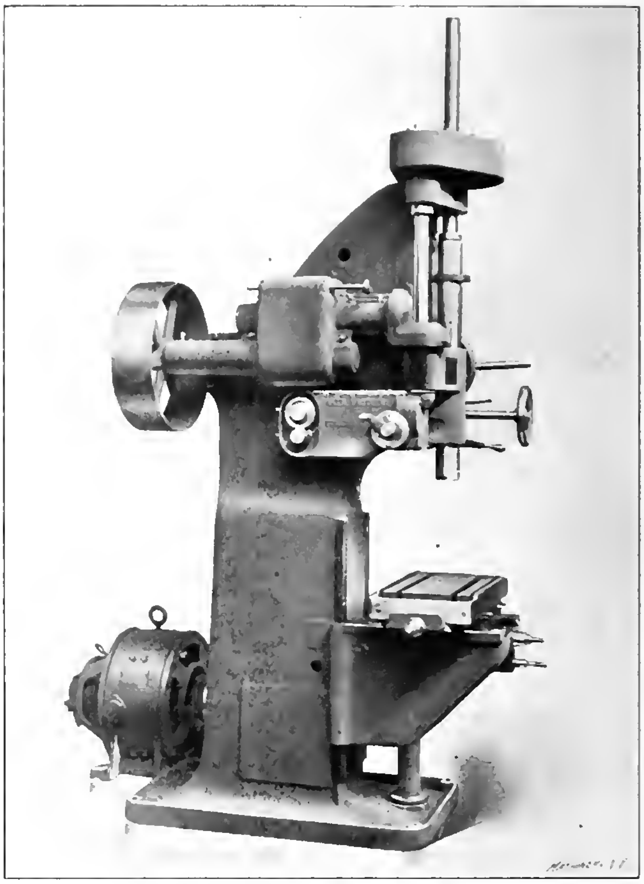

Fig. 6. Baker Brothers High-speed Drilling Machine on which Tests were made

* * *

The five- or ten-cent cotton mitts which are so largely bought by workingmen may be waterproofed by dipping them in melted paraffine; or if a thinner coat is preferred, and only on the palm of the mitts, melted paraffine may be brushed over their surface. For handling damp bricks, for working with plaster, or cement, paraffined mitts are far superior to the original. Leather gloves may be waterproofed in the same way. The coating of paraffine may be removed as often as the surface needs it.

* * *

It is stated by the London *Times* that the British Government has, under the new Patents Act, revoked a patent covering an American invention for the production of a lock-stitch sewing machine "capable of operating at a very high speed with smoothness, ease, and but little noise, upon either thick or thin work." The machines covered by the patent have been wholly manufactured in the United States, and since the new patents act came into force, no steps have been taken to work the patent in Great Britain, and it has therefore been revoked. The patentee must also pay the applicants for the revocation their expenses, amounting in this case to $200.

MACHINE SHOP PRACTICE*

CYLINDRICAL GRINDING—2

In the first installment of this article in the April issue, some information bearing on wheel selection and preparation of work was given; while these subjects are very important, they do not constitute all that is to be considered, if a grinder is to attain its maximum of efficiency. A wheel which is adapted perfectly to a certain grade of steel, for example, will not work satisfactorily if the relative surface speeds of the wheel and work are not approximately correct, as the work speed affects the wear of the wheel which, when excessive, also affects the finish of the surface being ground. The amount of stock that the wheel removes for a given amount of wear, may be increased or diminished by varying the work speed, the wheel wear being excessive when the speed is too high. This close relation between the work speed and the wheel wear makes it possible to use a wheel which is somewhat harder than it should be for a given piece of work, with fairly good results, by increasing the work speed with the result that the grit is dislodged more easily, and consequently does not remain long enough to cause glazing, which would otherwise take place; this practice, however, is not to be recommended. As there are a number of factors, such as kind of material, finish desired, etc., which determine the proper work speed, it is impractical to say just what this should be. A speed of twenty-five feet per minute might be correct for grinding a certain piece of steel, and not correct for another steel piece having a different carbon content. The finish of a ground surface, as stated, is affected by the work speed, and it is possible to grind a very rough or smooth surface by simply varying the speed, depth of cut, and side feed of wheel, the surface becoming smoother as these are diminished. For this reason the speed and feeds (when within, say, 0.002 inch of the finish size) are often reduced before taking the finishing cuts. The best method of ascertaining the proper speed for a given piece of work, and incidentally for determining the wheel best adapted to it, is by experimenting until the desired results are obtained. This does not necessarily mean, however, that whenever a new piece of work is to be ground, considerable time must be wasted, as the speed adjustments are easily made, and besides, experience will soon teach just what the proper combinations are. As the wheel is diminished in size, it appears to get softer, even though the peripheral or surface speed is maintained. This wear is due to the fact that the grit of a small wheel is in contact with the work oftener owing to the increased number of revolutions necessary for the same surface speed.

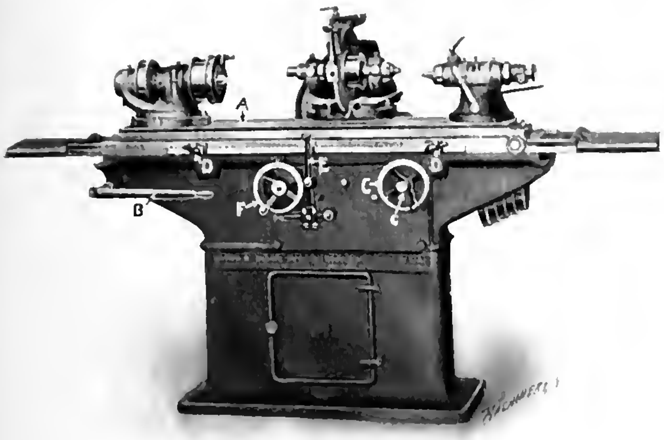

Fig. 1. A Universal Grinder built by the Brown & Sharpe Mfg. Co.

It should always be remembered that the one thing to be sought after is maximum production. If when choosing a wheel, for example, one too hard for the work is obtained with the idea of reducing the wheel wear, the corresponding reduction in the output will much more than off-set the increased expense for softer and more rapidly wearing wheels. The wheel wear, however, should be considered, and as it is dependent upon the work speed, the vibration of work, and depth of cut, these should receive the careful attention of the operator. When certain combinations of speed, feed, etc., have been found correct for a certain kind and size of material, it is advisable to record this information for future reference, for while such data may not always be applicable, owing to a difference in the grade of the material, it will, in many instances, enable one to save considerable time. A speed indicator or revolution counter is a useful tool for determining the proper speeds, especially when used in conjunction with a table giving the number of revolutions and the corresponding peripheral speeds for different diameters. The side feed of the wheel (or of the work) per revolution of the work, and the depth of cut, depend largely upon the construction of the machine. Grinders of the old type were intended for high work speeds with slow side feeds; with the modern machine, the work speed is low, but surfaces are ground rapidly by using wider wheels having side feeds of ¾ to ⅞ of their width for each revolution of the work, except for finishing cuts when reductions in side feed are usually made.

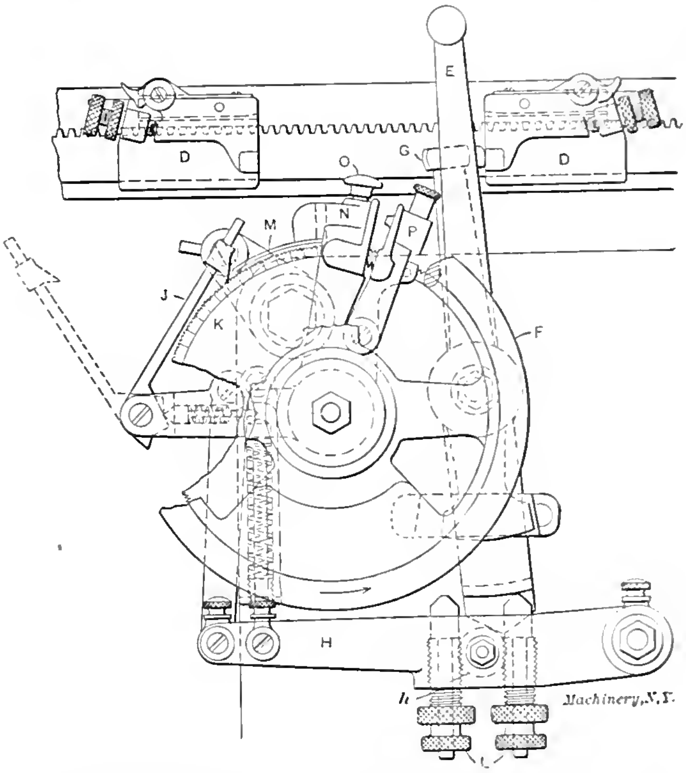

Fig. 2. The Mechanism which feeds the Grinding Wheel at Each Reversal and automatically disengages the Feed when a Predetermined Amount has been ground

Those who read the description of the Landis grinder in the April issue will remember that the grinding wheel of that machine is traversed back and forth past the work, which remains stationary as far as axial movement is concerned. With the machine shown in the accompanying engraving, which is made by the Brown & Sharpe Mfg. Co., this order is reversed, the work and the table *A* moving longitudinally while the revolving wheel remains in a fixed position. This machine is also of the universal type, which, as before stated, is adapted to a wide range of work. The traverse of the table and the rotation of the work spindle may be started and stopped (on the latest design) by the lever *B* to the left. The wheel *C* to the right is used for moving the table back and forth by hand; when so used, the knob *c* is pushed inward. This knob is pulled out when the table is to be moved automatically, and pushed in when such movement is to be stopped. The dogs *D* regulate the stroke of the table, the movement of which may be reversed at any point by the lever *E*. By rotating the wheel *F* in different directions, the grinding wheel is moved to or from the work. The mechanism seen just back of this wheel is that of the automatic cross-feed. The way in which this feed operates will be more clearly understood by referring to the detail Fig. 2. At the

---

* With Shop Operation Sheet Supplement.

same time that the dogs *D* strike the lever *E*, thus reversing the table movement, the lever *G* is also actuated, which, through the roll *h*, operates the lever *H* and the pawl *J*. If this pawl is in mesh with the ratchet wheel *K*, the grinding wheel will be fed forward an amount depending upon the position of the screws *L*, which come against a surface on the lever *G*, thus regulating the upward movement of lever *H* and, consequently, the movement of the pawl at the end of each stroke. This automatic feed will continue at each reversal, until the shield *M* (which is attached to the head *N*) intercepts the pawl *J*, and prevents it from engaging with the ratchet wheel *K*. Thus by changing the position of the head *N*, the machine is set to grind any predetermined amount.

For example, we will assume that the automatic feed is to be set to grind the body *b* of the hardened bearing, illustrated in the Shop Operation Sheet accompanying this issue, to exactly four inches. After the machine is started and the stroke properly adjusted, place the pawl *J* in the position indicated by the dotted lines, and then move the wheel *F* in the direction indicated by the arrow, until the wheel is almost in contact with the work. Stop the stroke of the table by pushing in the knob *c* (Fig. 1), and set the pawl in the position shown by the full lines. Raise the latch *O* and move the head *N* around the periphery of the ratchet wheel until the point of the shield *M* has just passed the tooth occupied by the pawl, which will then rest upon the shield. Now when the table stroke is started, press the thumb-latch *P* until the grinding wheel begins to cut. Stop the stroke so that the wheel will be at the foot-stock end, and measure with a micrometer the diameter of the part ground; then press the latch *P* once for each one-quarter of a thousandth to be removed. If, for example, the body *b* measured 4.003 inches, or 0.003 inch over-size, the latch would be pressed twelve times, thus moving the shield *M* far enough away from the pawl to allow the latter to continue feeding until 0.003 inch is removed. The wheel should be stopped at the foot-stock end, as before, when the density of the sparks is about the same as on the cut taken prior to the first measurement. When the work is to be removed, throw out the pawl *J*, and, without changing the position of the shield, turn the wheel *F* to the right about one revolution. When a new blank is in position, the wheel *F* is turned to the left until the grinding wheel begins to cut, when the pawl *J* is again placed in mesh with the ratchet wheel. If, when the feed is automatically disengaged, the work is oversize, due to wheel wear, the latch *P* is pressed once for each quarter of a thousandth reduction required. It will be seen that with the automatic feed the wheel is fed inward, in unvarying amounts at each reversal. This regularity of feed has a decided advantage in that it increases the "sizing power" or the uniformity of the wear of the wheel, which is essential to the rapid production of duplicate parts.

All work that is ground on centers should be supported by suitable rests or steadies, as their use will permit greater feeds and also increase the sizing power of the wheel. If a piece be long and slender, such support is indispensable, and even for work which is short and rigid, rests are desirable to absorb the vibration which increases wheel wear and affects the quality of the work. These rests or supports are fastened to the table of the machine and are equipped with shoes of wood or soft metal, which bear against the piece being ground. The number and position of the rests depend on the form and diameter of the work; a distance between each rest of from 6 to 10 times this diameter will be found satisfactory for piston-rods, shafts and similar parts.

At the point where the wheel is in contact with the work there is considerable heat generated, consequently it has been found necessary, in most cases, to flood the grinding point with a copious supply of water. The pipe for this purpose is seen attached to the wheel-guard in the accompanying illustration. Such a cooling medium is very essential when grinding work revolving upon centers to prevent the radiation of the heat generated at the point of contact, for without an equable temperature is maintained, the part being ground will bend towards the wheel, owing to the elongation on that side; in other words, its axis will be continually changing, and, obviously, inaccuracy will be the result. This effect is even more pronounced when tubes are ground without water, or with an inadequate or intermittent supply, as there is less mass to absorb the heat.

PRACTICAL TEMPERS FOR TOOLS

J. R. S.

This list of tempers was determined by practical shop tests of the tools mentioned. A record was kept of the number of pieces machined before the tool required sharpening or renewal, and the most satisfactory temper adopted. A thermometer was used to determine degrees of heat, and mutton tallow for the bath.

Degrees F.	Class of Tool.
495 to 500	Taps ½ inch or over, for use on automatic screw machines.
490 to 495	Taps ½ inch or over, for use on screw machines where they pass through the work.
495 to 500	Nut taps ½ inch and under.
515 to 520	Taps ¼ inch and under, for use on automatic screw machines.
525 to 530	Thread dies to cut thread close to shoulder.
500 to 510	Thread dies for general work.
495	Thread dies for tool steel or steel tube.
440 to 445	Circular thread chaser for use on lathes.
525 to 540	Dies for bolt threader threading to shoulder.
460 to 470	Thread rolling dies.
430 to 435	Hollow mills (solid type) for roughing on automatic screw machine work.
450 to 455	Hollow mills (solid type) for use on the drill press.
485	Knurls.
450	Twist drills for hard service.
450	Centering tools for automatic screw machine.
430	Forming tools for automatic screw machine.
430 to 435	Cut-off tools for automatic screw machine.
440 to 450	Profile cutters for milling machine.
430	Formed milling cutters.
435 to 440	Milling cutters.
430 to 440	Reamers.
460	Counterbores and countersinks.
440 to 450	Fly-cutters for use on the drill press.
480	Cutters for tube or pipe-cutting machine.
430 to 440	Dies for heading bicycle spokes.
430	Punches for heading bicycle spokes.
430	Backer blocks for spoke drawing dies.
400	Drawing dies for bicycle spokes.
460 and 520	Snaps for Pneumatic hammers—Harden full length, temper to 460 degrees, then bring point to 520 degrees.

* * *

IDENTIFYING SMITHS

Statistics show that 1.1 per cent of electrical engineers are named Smith. That is, out of every 100 there will be a little more than one Smith. In the office force of a large corporation it often happens that there are so many Smiths holding positions of responsibility that some special means must be taken to identify them. The Crocker-Wheeler Company, manufacturers and electrical engineers, recently had considerable trouble at their main office, at Ampere, N. J., owing to the impossibility of getting their delivery boys to distinguish between the many Smiths there employed. Almost invariably one Smith would receive papers intended for another. This difficulty has been satisfactorily solved by posting on its various bulletin boards the following:

IDENTIFICATION TABLE OF SMITHS AT AMPERE

Initials.	Dept.	Complexion.	Stature.	Characteristics.
J.M.S.	Engineering	Dark	Short	Snappy but smiling
V.T.S.	Engineering	Dark	Long	Handsome and melancholy
L.P.S.	Drafting	Light	Tall and stout	Chubby and angelic
R.W.H.S.	Drafting	Light	Short	Unshaved and grumpy
F.W.S.	Laboratory	Dark	Short and slender	Very nervous
D.S.S.	Sales	Sparse, mixed	Thin	Wide-eyed and serious

(N. B. Shop Smiths will hereafter be numbered.)

* * *

Another feat in wireless telegraphy worth noting is that of the Japanese steamer *Aki Maru*, which, during a recent voyage between Japan and the United States, was in constant communication with land during the whole distance of 4,240 miles. For over 2,100 miles the steamer kept up communication with the Marconi station at Yokohama, and for the remainder of the voyage she was in communication with Seattle.

CYLINDRICAL GRINDING*

It is probably true that there is more misunderstanding among engineers and workmen in regard to cylindrical grinding than in the case of any of the other mechanical arts. Nearly every operator has a different theory; and each maker of grinding machines has his own method of grinding. There is confusion of ideas which can be cleared up by pursuing the investigation to the end. Don't take anything for granted. When you shall come to consider the commercial side of cylindrical grinding, no doubt the first argument you meet will be this one, which is brought forward very often by those who have not pursued the subject to the end. The argument is that, "It cannot be possible that metal can be as economically removed by a grinding wheel with delicate, microscopic cutting points as with a massive steel tool. Metal ground into powder cannot be as economically removed as with a tool that cuts off great chips."

Relative Time Required for Finishing by Turning and Grinding

A shaft 6½ inches diameter, 10 feet long, rough turned, cheaply to within about 1/32 inch of the required finish size, can be finished straight, round and to size by turning with a tool that cuts off a chip removing the 1/32 inch from the diameter and leaving a good surface that requires some filing and polishing with emery cloth, and the time required to thus finish the shaft to a limit of 0.0005 plus or minus, is from seven to eight hours, according to the quality of the cutting tool and of the material in the shaft, and to the skill and ambition of the workman. To remove the 1/32 inch from the diameter and finish the shaft to a limit of 0.0005 inch plus or minus by the grinding method, with a modern grinding machine, requires from one to two hours according to the ambition of the operator, and the finish is superior to the other method. Here is a case where the cutting of the material to a powder with microscopic cutting points was more economical than was the steel tool cutting a chip large enough to be seen and handled.

To be sure, the cutting points of the grinding wheel are small, but in this case there are approximately 1,086,171 cutting points, that cut one thousand times per minute, making, approximately, 1,086,171,000 chips per minute. Although these chips are small, they are essentially the same as cuttings from a steel tool.

The statement that it requires enormous power to grind steel to a powder, while cutting it into larger chips does not, should have careful thought. In the case of the 10-foot bar we use an average of approximately eight horse-power from one and one-half to two hours when grinding the finish cut. When turning to finish, we use about two horse-power from seven to eight hours. In the case of the 10-foot bar we required a nice surface and accurate measurements to a thousandth or less, and in both the lathe and the grinding machine we removed 1/32 inch more or less from the diameter. The production of such a grade of work when removing 1/32 inch more or less, shows greatest economy by the grinding method. When, however, the surface can be very rough and the diameter may vary within much larger limits, a steel tool cutting deeply will remove the same amount of metal in shorter time. If the object is simply to remove a certain number of pounds of metal, turning it off with a steel tool is cheapest. But as we know, nearly all round work must have accurate, or approximately accurate diameter, and from approximately smooth, to very smooth surface. The great majority of round work must finally have a better surface and more accurate dimensions than can be obtained with a steel tool, when it is cutting at sufficient speed and depth to enable it to remove material faster than by grinding. Therefore, the limited amount of material that is removed by the finishing operation on accurate, and approximately accurate work, can be more economically removed by grinding than by turning.

Relative Cost of Grinding and Lathe Work

There are also cases when work not requiring a smooth surface may be more cheaply ground than turned. A case that illustrates this is that of bridge pins, which were from 12 inches to 8 feet long and from 3 inches to 18 inches diameter. These pins are roughly turned from the billet to within 1/32 or 1/16 inch of the required diameter, and then by another, or sizing cut, are completed. The limit of variation from size is 0.010 inch; if the turning tool is made to cut the right diameter at the starting end, the cutting edge of the tool must not wear off quite 0.005 inch when doing the work of removing the steel from the entire length of the pin. Now, in order to ensure that the tool shall not wear away enough to cause an error beyond these limits, it becomes necessary to revolve the work so slowly that the same results can be obtained more quickly by grinding, although the surface may be far from smooth. Grinding is accomplished by a number of rapid cuts, and during the final or light cuts, the grinding wheel does not wear at all, so that we are enabled to produce work of uniform diameter regardless of the length. We are now prepared to grind work up to 22 feet long to a limit of 0.0005 plus or minus.

While practically all round work is turned before grinding, there is a portion of such work that is most economically ground without turning. Owing to certain shapes, or structural weakness, it sometimes becomes difficult to turn; in such cases grinding is more economical than turning. An extreme case of this kind is that of a shaft, or bar of steel, 9/16 inch diameter and 10 feet long, with 1/16 inch to be removed from the diameter to produce an accurate ½-inch bar within a limit of 0.0005 inch plus or minus. It is easy to understand how difficult it would be to turn this bar. We, however, find it very easy to grind such a bar to the limits, and in short time. The roughing cuts that take the place of the turning easily remove the stock to within a few thousandths in about ten minutes, while hours would be consumed in turning such a bar to even coarse limits.

Advantage of Grinding Slender Work

Automobile crank-shafts are of such shape that certain portions of them are difficult to turn rapidly, and at the same time secure accuracy. Therefore we are enabled to grind the pins and short bearings direct from the drop forging in less time than we can turn them, and we secure better work. The long, frail crank-shafts for agricultural machines are also very difficult to turn rapidly, and at the same time secure good work. Many of these shafts are 7 feet long by 1¾ inch diameter of stock, with bearings and pins reduced to 1 5/16 inch diameter. We find it most economical to grind all short bearings and pins without turning, while we find it best to first turn the long part at one end, grinding it afterward.

In the case of slender work that springs badly when it is turned, we can, many times, grind the same work more quickly than it can be turned and ground; because, when grinding off the material, the spring is ground out as it occurs, owing to the many cuts, or passes, of the grinding wheel; while when it is turned, with one cut over, it must be straightened before the finishing cut is taken. It is true, however, that the majority of work should be turned before grinding. I have been quoted as saying that we "grind without turning." I never said so. I did say, as I have done here, that *sometimes* we grind without turning, but *usually we do not.*

Poole Form of Cylindrical Grinding Machine

The earlier attempts at cylindrical grinding were made by mounting grinding wheels on the carriages of engine lathes, and there are those to-day who innocently suppose that the engine lathe produces perfectly cylindrical work, and that they have simply to add a grinding wheel to get a smooth surface on an otherwise perfect cylinder. This was proved to be untrue some thirty years ago, and I trust you will not lose any of your valuable time attempting to secure perfect work with turning lathes. Mr. J. Morton Poole, of Wilmington, Delaware, discovered that it was impossible to secure perfect cylinders by grinding with wheels on engine lathes, and, as a result of his study of the problem, the J. Morton Poole grinding machine was invented in the year 1867.

Mr. Poole's invention was unique, in that it enabled him to grind rolls of perfectly uniform diameter from end to end, regardless of the imperfections of the traversing carriage

---

* Abstract of address made by C. H. Norton, president of the Norton Grinding Co., Worcester, Mass., before the third-year class in mechanical engineering at Columbia University, April 16, 1907. For note on these lectures, see "Elements of Machine Manufacture," by Fred J. Miller, April, 1909.

ways. His invention came at a time when the art of scraping to master plates, and master straight-edges, was practically unknown, and when mechanics had little if any idea that such perfection could be obtained; much less maintained for any considerable time; also when few could appreciate the difference between the results he obtained and those obtained by the ordinary methods. The Poole machine, however, depends for success upon the use of *two* grinding wheels; one on either side of the work, and has, therefore, limited application. It has always been used for roll grinding. (See MACHINERY for January, 1897, and February, 1901.)

The modern grinding machine has ways that secure perfect work with a *single* wheel, thus giving the machine a wide field, covering all work that revolves on its axis, whether rolls, small or large, shafts, spindles, piston rods, work long or short, large or small, and having one single diameter, or many sizes on the same piece. The Poole machine gave accuracy. The modern machine, if rightly constructed, gives both accuracy and large production. Having but one wheel, and being open toward the operator, it is conveniently operated, and work is quickly placed or removed. I make this comparison not to depreciate the Poole machine, for I consider it one of the most important inventions in the development of the art. I wish, however, to have you realize that the development of the art of scraping, and straight-edge making, has made possible the use of very massive, long grinding ways that are really straight, and will remain straight for years. That such a thing was unknown when Mr. Poole made his very valuable and original invention to obtain perfect cylinders without perfect guiding ways.

The Lathe not a Perfect Finishing Machine

One of the most important facts in connection with cylindrical grinding for the young engineer to get clear in his mind is that all perfection in this world is relative, and that this is most certainly true of cylindrical grinding. This being true, to what in the mechanical world should he turn to fix the relation when deciding upon the quality of cylindrical grinding for the various uses it is intended? Why, most certainly to the lathe; because the grinding machine is no more and no less than a grinding lathe. Now, if its product is an improvement on the product of the ordinary lathe, then it has proved its right to the field. The lathe was never a polishing and buffing machine; neither was it a lapping machine. We used its centers and spindle on which to revolve work while we filed and polished, or lapped it; but there was nothing about the lathe that contributed in any way to the quality of the filing, lapping or polishing; that was a matter of hand work entirely. Therefore, when we wish to judge as to the merits of grinding, we must compare it with turning alone, not with turning, filing and lapping. Now, if we can, with the grinding machine, take the finishing cut of the lathe in less time than the lathe, and at the same time produce a better surface and nearer absolute cylindrical perfection, then are we warranted in adopting the grinding machine in place of the lathe for all finishing cuts, or sizing operations. If occasionally we require an absolutely perfect cylinder, we must lap it in addition; and the grinding machine, if well designed and constructed, is a perfect lapping machine also. We should not, however, expect perfect lapped work from any grinding wheel. We can, by taking time enough, produce a polished surface with a grinding wheel, but the same time, spent with a genuine lapping wheel, would produce more perfect work. Glossy surface by grinding wheels means imperfect cylinders. We can secure the closest approach to perfection by the use of grinding wheels that cut without perceptible pressure; thus they must be soft or free cutting, and, therefore, produce a surface without much gloss. He who desires really round work with uniformly distributed contact over its entire area, should use free-cutting wheels of broad face; and the truest work will show, not a bright, glossy surface, but a good surface and broad feed lines, when rubbed strongly through a round, straight hole; but no feed lines before such rubbing.

All cylindrical grinding by whatever method will show lines of cut and feed when rubbed in a round hole or when lapped in any other way. There is a difference between a cylinder with uniformly distributed contact, when tested in a perfectly round hole; and a really *perfect* cylinder. A really perfect cylinder is one whose surface molecules are every one the same radius, or all touch the inner surface of a perfectly round ring when it is passed over the entire length of the cylinder. Such perfection can be obtained, approximately, by some form of lapping. Any one who shall look for such perfection from grinding, will be forever disappointed. Grinding, however, does give us vastly more points of contact than turning or even careful filing to a micrometer and polishing with emery cloth—the method used by those who do not grind.

Broad Cuts Produce Most Accurate Surfaces

Feed lines are caused by the "lap" of the wheel cutting twice on that portion of the surface, i. e., we do not traverse quite the exact width of the wheel at each revolution, but as near as safe and avoid ridges. The wheel cutting twice over this narrow place leaves a different grain, therefore a different color, even though the measurable diameter there be no different than elsewhere. In my apprentice days, we used to plane all work with a very fine feed, and considered the best work that which showed no feed lines. But Mr. William Sellers showed us that the surfaces we produced that way were not perfectly flat surfaces, while he produced a more uniformly distributed contact, tested with a perfect surface plate, by using a wide tool and a broad feed line. The surface he produced was *not so smooth* but it was nearer a perfectly flat surface. No one disputes his theory to-day; all plane with a coarse feed.

Rough Turning Desirable for Economy in Grinding

Another fact in connection with cylindrical grinding that it is well for young engineers to get clearly fixed in their minds when leaving college and starting out in practice, is this: that to secure the greatest economy by the use of grinding machines they should pay less for all turning than when the work is to be finished in the lathe. With well constructed grinding machines, the coarser the turning the quicker the grinding can be done. It is no longer necessary to turn either smoothly or correctly to size. A variation of 1/32 inch more or less on large work is of no moment, and on small work a variation of 1/64 inch more or less is permissible, and the surface may be very rough in all cases.

A large part of the economy is secured by cheap turning. You will find it difficult to secure such turning, owing to prejudice, ignorance, opposition, and fear on the part of many workmen, foreman, and superintendents. As engineers, you will find the greatest problems are not mechanical, but that the solving of the human problems will require everlasting study, and to secure the full economy by grinding you will need generalship in a high degree to get work turned rightly for grinding. All traditions must be upset if work is rightly turned. I think there are few places where grinding machines are used that the turning is done as cheaply and roughly as it should be. I have never been able to secure what I desired in this respect.

About the relative cost of finishing to size by turning or by grinding, it varies greatly in different works, but the grinding method shows a saving according to the sympathy and intelligence that goes into the enterprise and the nature of the work. There is much opposition to grinding in some places, where the saving is small; but where a systematic and intelligent effort is put into it, the saving is large. A manager recently told me that the saving was sixty per cent over their former lathe method of sizing and finishing.

There are not enough good operators to run machines now installed, and the success of these machines is held back owing to the large amount of ignorance of grinding machines and grinding operations on the part of foremen, superintendents and managers. The art is yet new and invites the aid of young engineers in placing it in a still more useful position in the world's service. Cylindrical grinding is, however, firmly entrenched in this country, and, in many lines of manufacture, all round work is ground. All first-class automobiles have every round part ground; all sewing-machines, typewriters, phonographs; large machinery is also ground to a considerable extent.

The cylindrical grinding machine has taken its place as a practical metal-cutting tool to be used by progressive manu-

facturers as a labor saver; and manufacturers to whose attention its possibilities have been brought by practical demonstrations, have accepted it as a settled method of sizing cylindrical work.

PAT'S PROMOTION

C. TUELLS

Just how Mr. Roland Thompson came to be in charge of the foundry at the Morton Steel Company no one seemed to know. In some ways he was admirably capable; he had a prepossessing appearance, his personality was wonderful, and his command of the English language would have enabled him to convince anyone that black was white. As a salesman he would have been a tremendous success, but his lack of knowledge of the foundry business made his success in that line rather dubious. In a nutshell, Mr. Thompson's "bluff" was his stock in trade, and whether it was a case of refusing his best molder a raise or explaining to the super why the production was not greater, his "bluff" always stood by him.

"Pat is still trucking castings from the foundry"

Pat Morrison was the laborer who trucked the castings from the foundry to the machine shop at one dollar and fifty cents per day. It kept him hustling all day to get the finished castings off the foundry floor, and when the foundry was busy the casting pile looked much like a mountain to poor Pat, for it was his daily task to remove that mountain. It was kind of a lonesome job, too, for there were few to talk with on his trips to the machine shop, even if he had the time, so he had plenty of opportunities to think over his trials and tribulations.

One morning when his mountain of castings looked larger than ever he evolved the idea that his job was worth more than fifteen cents an hour, and the more he thought it over, the heavier his truckloads of castings became, and the surer he became that he was right, so about half-past ten he could stand it no longer, and marched up to the foundry office.

Mr. Thompson was just finishing a well-worded letter to the super telling him how hard the foundry was working to ship a rush order of castings, when Pat came in, and stating his case asked for a raise of five cents an hour, which would make his wages two dollars per day. After listening gravely to Pat's request, Mr. Thompson assumed one of his most patronizing airs and addressed Pat as follows:

"Mr. Morrison" (before he had always been Pat), "I have had your case under consideration for some time, and I have decided to promote you. From now on I want you to take entire charge of trucking these castings from the foundry to the machine shop; I want you to personally attend to every detail of this important work, to see that they are properly loaded, safely carried over and deposited in their proper places, and in fact, devote your whole time to this work. Now, if I can safely entrust this great responsibility to your care you can readily see how much better off you will be than if I should give you an increase of a few cents an hour."

As he proceeded Pat commenced to look important, and as he finished, thanked him for the "promotion" and walked out of the office, his head high and chest thrown out, his thoughts concentrated on "Mr. Morrison" and his new job, which was simply his same old job at the same old pay,—trucking castings at fifteen cents an hour, described in flowing terms.

Pat is still trucking castings from the foundry, and for the same money, but he is doing some heavy thinking as a side line. Through the policy of Mr. Thompson the foundry office is being looked upon as a magnificent example of "bluff" by the rest of the works, and over in the machine shop there is tacked upon the wall a little parody that, if we except Pat, seems to fit the foundry situation to a tee.

Everybody works but the foundry,
  They sit around all day.
Always writing letters,
  Expect to ship next day.
Customers keep on waiting,
  New stories we must tell.
Everybody works at the foundry,
  Yes, they do, like ——.

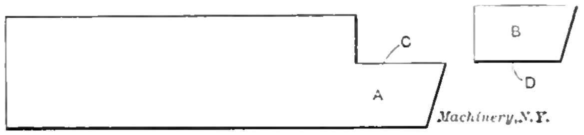
WELDING A HIGH-SPEED STEEL CUTTER TO A MACHINE STEEL BODY

A method for welding high-speed steel cutters to machine steel bodies or shanks has been patented by Mr. Paul A. Viallon, 102 Avenue Parmentier, Paris, France. The process, as described in the *Mechanical Engineer* of January 29, is comparatively simple and inexpensive, and if it should prove successful, would undoubtedly be valuable in the metal trades. The machine steel shank is indented about as shown at *A* in the accompanying illustration, and the high-speed steel cutter may have the appearance shown at *B*. The surfaces *C* and *D* are well finished, and the shank and the cutter are both heated to a cherry-red heat. Solder is applied on the surface *C*, the cutter is placed on it, and the two parts are forced together by heavy pressure. This operation has the effect of melting the soldering material and producing adherence between the cutter and the shank. The tool is now carefully put into the fire, from where it is withdrawn when it has reached a yellow heat (2,000 to 2,400 degrees F.). The weld is now completed by hammering at the top of the tool, first lightly, and then with heavier blows. The tool is permitted to cool slowly, and may then be dressed and finished and re-heated to the required hardening temperature for high-speed steel, and hardened. When the welded-on part of high-speed steel is worn down so that it must be replaced by a new cutter, the old cutter may be detached without injuring the machine steel shank, by heating the cutter and the shank at the joint, and then removing the cutter by pressure applied on its side.



High-speed Steel Cutter to be welded to Shank of Machine Steel

Coke for locomotive fuel is being tried by the Illinois Central R. R. for the purpose of eliminating smoke at its Chicago terminal. It is stated in the *Engineering Record* that the results obtained indicate that the use of coke will be successful, but the trial has been conducted for so short a period that no general conclusion as to the relative cost of the coke as fuel can be drawn. The city has demanded the electrification of the company's Chicago property, but the favorable outcome of these experiments may lead to the adoption of coke fuel, at least for some time to come.

* * *

The New York Central established a new record from New York to Chicago with the Vanderlip special, which made the run March 26-27 in sixteen hours and seven minutes, including twenty-four minutes allowance for six stops to change engines.

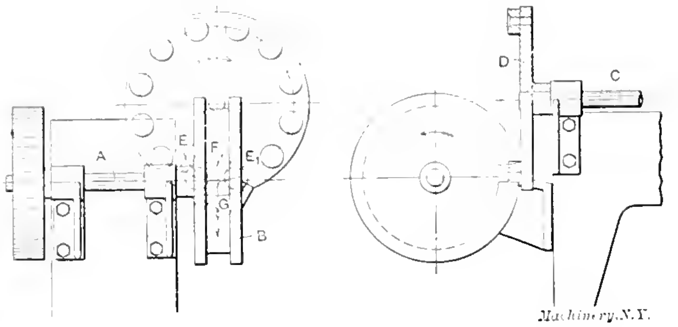
A SEMI-GENEVA DRIVE

To drive a shaft continuously from another shaft also running at a constant speed, the two shafts being placed at right angles to each other and in different planes, is an every-day experience, and can be done by belt, worm gears or spiral gears; but to connect these two shafts so that the driven shaft makes only a part of a turn and then comes to a positive standstill while the driver still runs, is probably out of the ordinary. The illustration shows a drive of the latter type (which was adopted as a feed mechanism on an automatic machine) which worked satisfactorily.



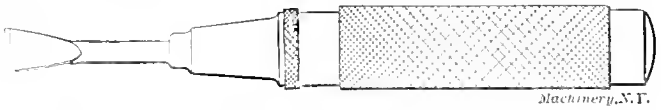
An Intermittent Drive for Two Shafts at Right Angles to each other and in Different Planes

On the outer end of the driving shaft *A* is a cam *B* having a face groove, open on both sides. On the outer end of the driven shaft *C* a disk *D* is fastened, on which are mounted rollers *E*. As the cam *B* revolves in the direction indicated by the arrow, the cam surface *F* pushes the roller *E* over to the left, causing the disk *D* to turn, and the roller E_1, which is pushed over to the central position by the cam surface *G*, is engaged. Roller E_1 remains in the groove until the cam has made one revolution, when it is also disengaged, another roller at the same time entering the groove, and so on.

This drive takes the place of a "Geneva movement" which, in this case, would be quite difficult to arrange. E. P.

ANOTHER USE FOR THE AUTOMATIC CENTER PUNCH

The automatic center punch, though sometimes used merely as a novelty, is nevertheless a very handy and time-saving device when applied to the marking of a large number of holes, as when laying out press tools. The tool's usefulness does not end here, however, for it may be used to even better advantage when equipped with a chisel tip, as shown in the illustration. One is sometimes in a very awkward position when a piece of work has to be graduated which cannot be done in a machine, and when the only tools available are a hand-hammer and chisel. With the automatic chisel we can avert that nervous moment between the setting of the chisel and the dropping of the hammer, which often proves so disastrous, as the eyes can be kept on the work, and the chisel easily held in the proper position. When a line needs to be made which is longer than the width of the chisel tip, it can be extended to any required length by setting a straight-edge in position and sliding the chisel along its edge, repeating the blows. E. W. H.



Automatic Center Punch equipped with a Chisel for Hand Graduating

FISH-TAIL MILLS

About a year ago the writer had a cylindrical piece like the one shown in Fig. 1 brought to him with directions to put a slot through it as shown. Along with the work came the instrument shown in Fig. 2, which was introduced by the foreman as a "fish-tail mill." I had never seen one before, and after inserting it in an ordinary milling machine and living right with it for some hours, I heartily desired never to see another. The cutter speed was about forty feet per minute, the cut three-thousandths and the feed about seven inches per minute, or thirty-thousandths per revolution of the cutter. Since then there have been several jobs of splining and slotting to be done with fish-tail mills. Half a dozen of us took turns at one or another of them. The last one that came to me made me decide right off to get a cushion for my stool at the machine. There were 160 keyways three-sixteenths of an inch wide by an inch and a quarter long. I didn't get any cushion though, as it would have been conducive to undue levity among the kids, and, besides, I had something better. I took the mill shown at *A*, Fig. 3, and ground it as shown at *B*. I was then able to take a cut of five-thousandths instead of three-thousandths, and a table feed of twenty inches per minute instead of seven.

Of course, where spline millers are in operation everybody knows how to grind the fish-tail mills, but this was new to me and apparently not known to any of the several Yankee tool-makers who ground and used the mills at one time or another. The small mill I ground by hand, but the next one I shall grind square the same as any other end mill by using the cutter grinder. The corners and centers are, of course, touched off free-hand. A cutter like *B* makes chips instead of crumbs, and they say "You can tell a workman by his chips." J. C. T.

A CAM WITH SOME SPECIAL FEATURES

In Fig. 1 is shown an arrangement (which is not entirely new) for economizing space in a special machine. The general scheme is as follows: The drum cam *E*, which is pinned to its shaft, is required to turn 90 degrees while it moves lengthwise 6 inches, and to resume its original position as it returns. The cam is shown in its central position. When it is at the extreme left, the roller *A* is in the groove while the roller *B*, which is 3 inches to the right, is freely suspended. When the cam moves toward the right, the groove will engage the roller *B*, and, as the cam continues to advance, it will leave the roller *A* and move under control of the roller *B*. As the cam is 3½ inches long, and has a movement of 3 inches on each side of its central position, the entire space which it occupies is 9½ inches, while if a single roller were employed, the cam would be 6½ inches long and would require a space of 12½ inches for action; thus a saving of 3 inches is made. This arrangement causes extra wear in the cam groove to compensate for this, but extra grooves may be cut around the periphery of the cam when it is being made, and these grooves may be brought into use by resetting the cam on the shaft, when necessary.

In order to secure satisfactory results, it is essential that the rollers *A* and *B* be aligned properly in the path of the cam groove. It is the method of locating these rollers that

is of special interest to mechanics. The stud *W*, for the roller *B*, was located without difficulty directly over the center of the cam shaft. A ⅜-inch hole was then drilled in the bracket *H* as near the position of the stud *X*, for the roller *A*, as could be done easily. The spiral groove in the cam being cut and finished, the two rollers *A* and *B* were made and ground so that they could be crowded under pressure into this groove. The cam was then placed on its shaft under the bracket *H*, and the stud *W* set in position, holding the roller *B* in the groove. The roller *A* was then pressed into the groove on the left side of the cam. Before this roller was placed in the groove, however, a 5/16-inch bushing was driven into the half-inch hole in its center. Into this bushing a test-bar, *Y*, of straight 5/16-inch drill rod, was carefully fitted. With the two rollers in position under the bracket *H*, an attempt was made to put the test-bar through the ⅜-inch hole (which had already been drilled in the bracket) and into the bushing in the roller. In order to do this, it was necessary to enlarge the hole at one spot with a file, after which the bar was set in the bushing. The assembled mechanism was then taken to the drill press, and, after some adjusting, the test-bar was brought to a vertical position directly under the drill press spindle. The bar was then removed, and a 7/16-inch counterbore with a long pilot which reached into the bushing in the roller, was used with care to enlarge the hole for the stud *X*. Proceeding in this way, changing counterbores several times, the hole was finally reamed to size. The rollers were then ground to a good running fit, and reassembled in position. This method of procedure made the alignment of the two studs *W* and *X* perfect. It is unlikely that this result would have been obtained in any other way, except at a cost of much more time and effort.

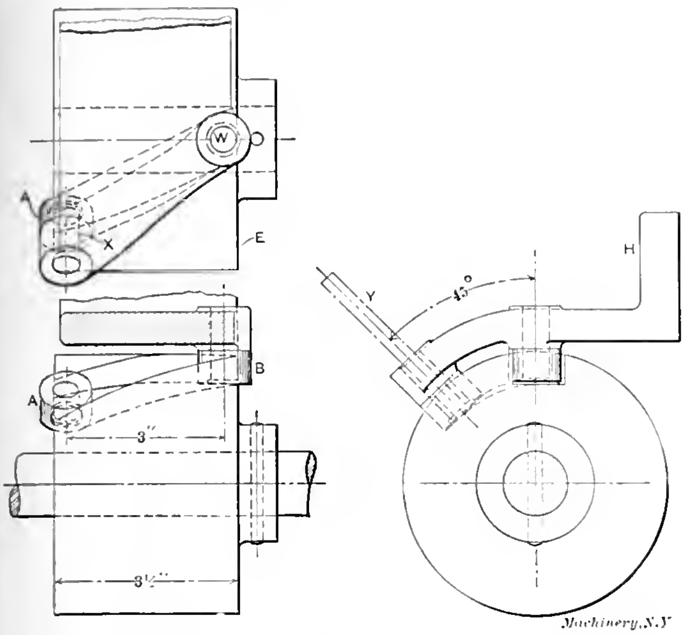

Fig. 1. Cam with Two Rollers which reduce its Longitudinal Movement

In Fig. 2 is shown a type of roller stud which also is not new, but which is not in such general use as its advantages warrant. The sketch explains itself. When it is desired to remove a roller, the clamping screw *A* is loosened; the operator then places the end of the screw-driver into the groove in the stud and easily draws it out of the lever. This is a much simpler matter than is usually the case with the old type of studs which are held by set-screws. The screw generally makes a burr on the stud, which causes all manner of trouble for the machinist. The stud shown is especially convenient when soft rollers are used in the cam race-ways, as these, of course, wear much faster than hardened steel rollers. The practice of using soft, rather than hard rollers, is growing as it is being more widely realized that there is greater economy in frequently renewing cam rollers than in occasionally renewing cams. There are comparatively few cam movements which will not admit of some wear in the rollers, without serious inconvenience. HERBERT C. BARNES.

Brooklyn, N. Y.

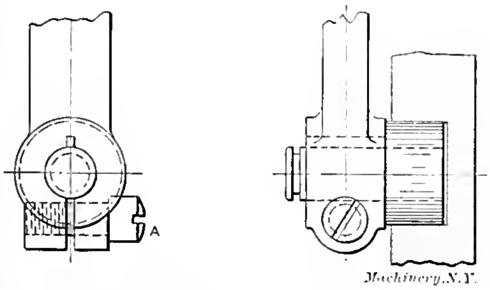

Fig. 2. Type of Cam Roller which is easily removed

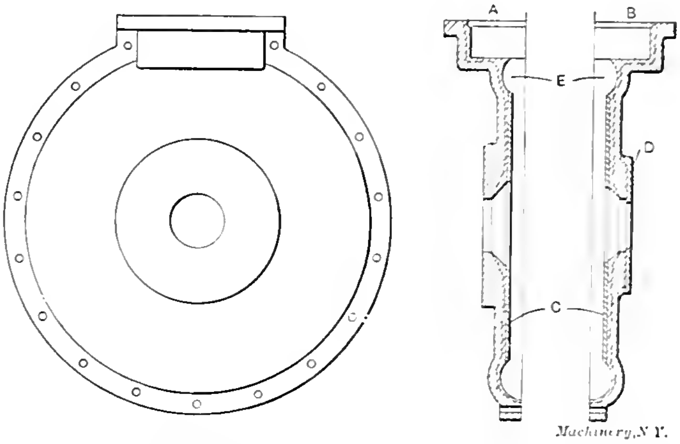
SMITHERS' PATTERN EXPERIENCE

I dropped in on Smithers the other day and while there saw an iron pattern for a centrifugal pump casing which had been made from the old casting. Smithers said he had acquired considerable experience through that pattern, for while the casting was badly eaten away on the inside, as indicated by the dotted lines in the engraving, the outside was in good condition and so he thought he could save time and money by using the casting instead of making a new wooden pattern. The shrinkage did no harm, since one side of the pump wore out as soon as the other and the new halves were always finished and bolted together. As the flange on the casting *B* was smaller than the one on the casting *A*, he decided to use *B* for a pattern. Plugs were driven in all the bolt holes and the strips for the finished surfaces of the flanges secured to them. Holes were also drilled through the pattern to secure the wooden plate to make up the necessary thickness at *C*. The central holes were cored and a loose flange *D* slipped over the hub made the pattern right for casting *A*. Two core-boxes were required for the central openings. The irregular shapes at *E* gave Smithers some thought, but he decided to fill them with composition and hold this composition in place by means of wire pins. These were driven in holes drilled in the castings, and were cut off slightly below the surface of the finished castings. Now, Smithers knew that in a jobbing shop patterns did not always get the same careful handling that they do in manufacturing shops, and, as from time to time he would have castings made from this pattern he wanted a composition that would harden and would not crumble nor peel off. After looking over a large number of receipts he found one which he thought would answer the purpose. This called for 10 parts of iron filings, 3 parts chloride of lime, and enough water to make a thick paste. The formula says that if placed between surfaces under pressure it will harden in 12 hours, and the casting will break elsewhere than at the joint. Smithers thought that if it did that it would surely work all right on his pattern. Not being able to secure sufficient lime in town he sent away for it; then made up the mixture, and applied it to the pattern. At the end of 24 hours it was still as soft as ever; at the end of 48 hours, no better; and at the end of 72 hours he got disgusted and scraped it all out. Two or three weeks later he came across some



The Iron Pattern for Centrifugal Pump Casing

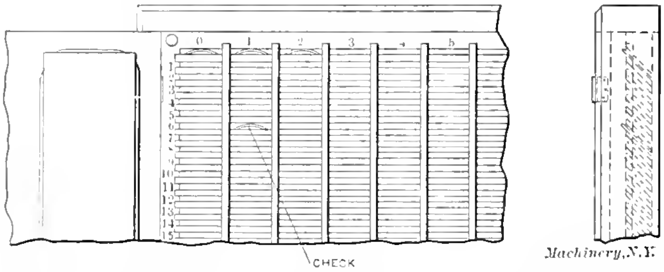
of it in the yard, and found that while it had dried it was simply a crumbly mass, with no strength. His pattern-maker wanted a chance to try his hand and made up a new mixture consisting of $3\frac{1}{2}$ parts Portland cement, $3\frac{1}{2}$ parts iron filings, 2 parts common sand, and 1 part common salt. This was thoroughly mixed together, and made into a thick paste by the addition of water. Smithers said this composition worked like a charm. It was slicked up smoothly, shellaced, and sand-papered, and made a fine-looking job. He showed me some of this composition, which was hard and seemed to have considerable strength. It stands the usage around the foundry, and also the handling to and from the pattern store-house. Smithers says that while the experience cost him something he was willing to stand for it, as the composition will come in handy on other similar jobs.

Covington, Va. WM. SANGSTER.

CHECK SYSTEMS FOR THE TOOL-ROOM

There are many tool checking systems in use in the modern machine shop, but those which are not complicated are more or less conspicuous by their absence. Tool checking plays an important part in the up-to-date shop; therefore the writer will endeavor to bring to light a very good method of procedure in handling checks to the best advantage. In some shops tools are given a certain classification letter or number. In this case the tools are numbered consecutively, in much the same manner as the shop blue-prints are. Fig. 1 will give an idea of the construction of the cabinet for the checks. There are ten vertical rows of slots which, as will be seen, are numbered at the top. By combining these numbers with those seen on the left-hand side of the board, different checks are located. For example, if we want check No. 61 we read down six figures on the vertical row to the left and move to the right under the row of slots with the figure 1 above. It takes less time to number the slots in this manner and the usual maze of figures generally found on the check boards is eliminated, thus facilitating the location of checks placed therein. The slots are at an angle of 45 degrees, as shown in the end view, so that the checks will stay in their respective places. The size of the slots will depend, of course, on the diameter of the checks, but the depth should be somewhat less than the diameter, to allow the checks to be lifted out easily. By using this type of board the tool supply man will have all checks under lock and key, and the tools given out under constant observation, so that the chances of their disappearance to places unknown is eliminated. L. H. GEORGER.

Buffalo, N. Y.



Board for Keeping Tool-room Checks which are numbered consecutively

---

After having had an experience of more than twenty-five years in machine shops and in some of the largest factories in the country, I was surprised to read the article by Mr. Hadun in the March issue, where he states that he abandoned the check system whereby the workman has the check in his possession. In the following article I shall give a description of a system in use in the large supply room of a certain company, which has proved effective, and which may contain some points of interest.

When a new man enters the employ of this company, he receives a brass admittance check with his check number on it. This check is always in his possession and must be shown to the watchman at the door on entering. A white tag 1 7/16 inch in diameter (see Fig. 2) is received by the foreman of the tool supply room from the office. On one side of this tag is the man's name and admittance check number, on the other side is stamped the date when the check is received by the foreman of the supply room. On the check board there are a number of checks (usually fifteen or twenty-five) corresponding to the number on the admittance check. The number of checks found on the hook is then written on the white tag under the date. The new man must show his admittance check before he can receive his tool checks.

The check board shown in Fig. 1 is mounted on a ball-bearing so that it revolves easily. There are eight spaces, as shown in the plan view, each of which contains 200 hooks, making 1,600 in all. When a man leaves, he must return the number of checks charged to him on the back of the tag. If he does not have the required number and they are not found in the supply room, blue-printing room or jig room, he must pay for them. He understands this when he receives his check on entering the employ of the company. The attendant of the supply rooms enters the lost checks or tools on the tag, and the man takes the tag to the office; without this tag it is impossible for him to receive his money. When a man is transferred from one department to another, he receives a new admittance check, the old one being taken from him. He must return all checks, and if they cannot be found, the attendant charges those which are lost against the man on the old tag, which is sent to the office so that the loss may be taken from his pay. If at any time any of the lost checks are found, the money paid is refunded. A new tag is received by the foreman with the man's new admittance check number, and after dating and writing the number of checks that is on the hook on the tag as before, the man is given a new lot of checks.

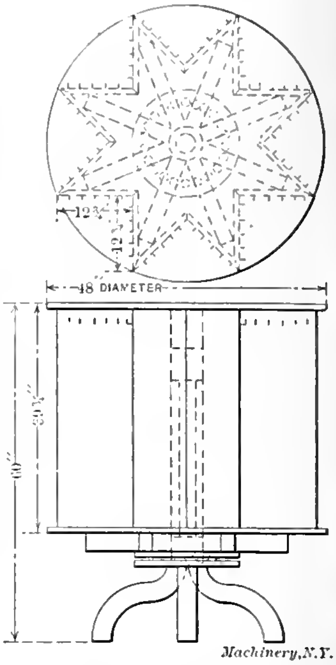


Fig. 1. Revolving Check Board

All tools, such as drills, reamers, taps, etc., are marked alphabetically, and a brass strip with the letters stamped on it and filled in with black shellac is tacked on the tool cases. There is also a hook under each letter to hang the man's check on. The advantage in marking the tools is this: a workman cannot return another man's drill, reamer, or any tool having another letter than the one on which his check hangs. When the men become acquainted with the system of marking the tools, they seldom bring in a wrong letter. If a workman loses a tool of any kind and does not remember the letter, he can find out what it is at the tool-room; then he has a perfect right to take the tool wherever he finds it and bring it to the tool-room and receive his check. Taps of all sizes are set on end in a hardwood block, three in a set, and the block is marked with a letter and placed in the case over that particular letter. The machine screw taps are arranged in a block with a full size drill, a tap drill, and two taps. Tags about one inch in diameter and of different colors are used for broken tools, lost tools, tools being repaired, and also for those that are sent out on the road with the erecting gang. The tool inspector's bench is located just

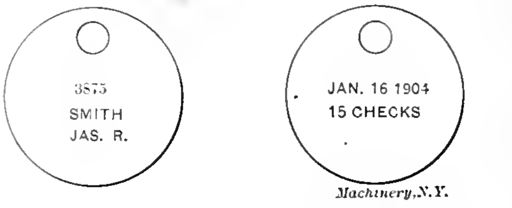

Fig. 2. Tag which is filed in the Tool-room, giving Name and Number of Employe, and Number of Checks in his Possession

back of the delivery window, and all tools received are placed on this bench so that they may be inspected and any errors corrected before the tools are put away. All gages that are received at the supply room are tested on a Pratt & Whitney 80-inch measuring machine before being put in their cases.

Every four weeks each tool has to be accounted for, and on the Thursday morning of the fourth week a card is posted announcing that the following Saturday is check day. On this particular Thursday half-round checks are hung over the checks that hang on tools, and a wire clip is attached to the checks where a number hang on one hook, such as those used for bolts, straps and other such tools which are not lettered. As the tools are returned, the half-round checks and clips are put in a box, no account being taken of them. The different foremen are supplied with a printed form for the use of those workmen who cannot return their tools. This printed form must be filled out with the workman's name, check number, name of tool, and letter, and signed by the foreman. No account is taken of tools that are given out after the half-round check and clip are put on. The checking is done after one o'clock Saturday afternoon, as the factory stops work at noon. The first operation in checking is to write on a small slip of paper, the size, letter and check number of all tools on which a half check is found. The slip is then hung on each hook corresponding to the tool and number, after which the slips are collected and arranged in hundreds. The printed forms for the tools in use and the corresponding slips on which the different tools are checked, are compared and if found correct are put aside. Lists (with carbon copy) are then made out and a copy is sent to each foreman containing check numbers and list of tools charged to each workman under him, and these tools must be accounted for or the workman must pay for those which are lost. A list of all lost tools which are paid for in this way is kept in the office, and if a tool is found at any time, the office is notified, and the workman receives his money. The small number lost, however, was surprising when the men became acquainted with the system. Albert C. Sawyer.

Dorchester, Mass.

It is evident that Mr. Hadun, judging from his article on Check Systems for Tool Rooms in the March issue, has had considerable trouble in determining *the* system for checking tools. I have been up against the same proposition, but my conclusions are somewhat different from his. In the first system mentioned in the article referred to, each man kept his own checks. This, I think, is the most common method and seems to give the greatest satisfaction, all things being considered. When the workman realizes that in the event of his services being dispensed with his pay will be held up until all the checks are accounted for, he will see that his checks tally with the tools in his possession. If they do not, as a rule he will immediately take steps to see that the matter is straightened out, and usually, if taken in time, it is a simple matter. I have worked in many shops where this system is in vogue, and have yet to learn of an instance where a man used another man's check dishonestly. For one to count the tools and checks in hand in order to see just where he stands, is simplicity itself. I fail to see where the written slip has any advantage over the first system mentioned as it is as easy to forget to have the slip removed from the card case as it is to ask for the check—then there is the extra expense. There are, however, some who prefer the printed slips and for those who do I show herewith the form used by the General Electric Co. in the tool room at Lynn, Mass. Each man is furnished with blocks of probably fifty, and as these are used, more are furnished at the tool room window.

Lowell, Mass. William B. Hubbard.

A MILLING FIXTURE FOR THE WEBS OF CRANKSHAFTS

The accompanying illustration shows a milling fixture intended for milling the webs of crankshafts on both sides at practically one setting. It will be seen that by using this fixture the webs will be milled at equal distances from the center on either side. The crankshaft is held in position by its center journal by a vise-like clamp. After milling one side, it is only necessary to loosen the set-screw shown, and twist the shaft until it rests on the opposite side of the fixture. The set-screw is then again tightened, and the opposite side milled. When the shaft is to be removed, the two collar-head screws are loosened, and the strap on the right-hand side slid towards the right, which permits it to be pulled over the collars of the screws, and one of the jaws holding the crankshaft to be folded back so that the crankshaft can be taken out and a new one put in place. Bridgeport, Conn.

Fixture for Milling the Webs of Crankshafts

BLUING METALS

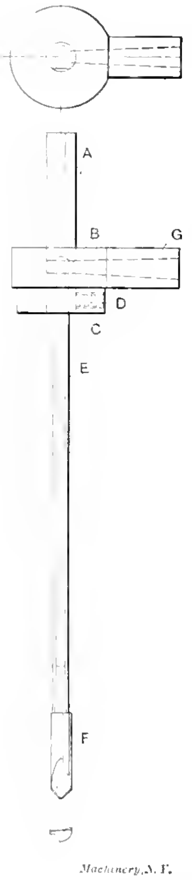
In answer to C. L. L.'s question in the March issue for a formula for bluing metals, the following method is submitted. A good color may be obtained on small articles by the following solution, which, while particularly intended for obtaining a gold color on brass, is frequently used for imparting a steel-blue color on brass or other metals. The solution consists of water, one gallon; sugar of lead (acetate of lead), four ounces; hyposulphite of soda, four ounces. The sugar of lead is dissolved in water previously heated nearly to boiling, and then the hyposulphite of soda is added. The solution has a milky color from the precipitated hyposulphite of soda, but it should not be filtered out. In order to get the best results, the solution should be heated to a temperature of 200 degrees F., or just short of boiling, when it turns black. When immediately made, the white precipitate in the

solution is fine and adheres to the articles being colored, but after heating for five or ten minutes it collects and settles to the bottom. It is then that the best results are obtained in coloring brass. After some time the solution does not work so rapidly and finally a new one has to be made up. A large quantity of work can be passed through, however, as the color is a mere film.

The brass to be colored should be cleaned in the usual manner, and may be polished and then dipped. The articles are immersed in the hot solution (nearly boiling) and carefully watched. It takes a few seconds for the first shade of color to appear and it is then very light. Soon a darker yellow forms and then a brownish gold shade is produced. The articles are removed as soon as the desired color is reached and should not under any circumstances be allowed to remain, as the shade rapidly darkens and becomes purple. By allowing to remain longer, a blue and finally steel black can be produced. Rinse first in cold, and then in hot water, then dry in sawdust. The articles are then lacquered.

Plainfield, N. J. JOSEPH WEANER.

TOOL FOR DEEP-HOLE DRILLING



Drill for Deep Holes

The line engraving shows a drill used by the Waltham Watch Co., which has proved to be a very useful tool for drilling deep holes. The feature of this tool is that the chips are carried away from the point of the drill by compressed air. Many of the machines in the shop are operated by compressed air, and for this reason it is very handy to apply the air for the removal of the chips as well. The drill shank *A* is held in the collet of an upright drill. The collar *B* has a running fit on the lower end of the shank. The air connection is attached to the lug *G*, projecting from the side of *B*. The collar *B* is held in position between the collar *C* and the end of the drill collet. The collar *C* is simply held by a screw *D*. The part *E* is a seamless steel tube extending into the shank *A* to the air inlet or groove around the shank, and is soldered in place. The shank *A* is solid above the air inlet. The drill proper is shown at *F*. This drill is provided with a taper shank soldered into the tube *E* and having a hole drilled through the taper shank connecting with two small holes in the drill point as shown in the end view. It is easily seen that the air supplied through the nozzle *G* to the tube *E* will exhaust through the holes in the point of the drill, and by this means the chips are removed.

These drills are commonly made of different lengths to drill deep holes in succession. The first drill is four inches long, the second eight inches, etc. Extreme care must be used to have the drill start central with the center punch mark for the drill. Holes have been drilled with this tool four inches deep in one minute through ordinary cast iron. The air pressure used is 35 pounds per square inch.

Waltham, Mass. FRANCIS P. HAVENS.

SAVING TAPS AGAINST BREAKAGE

Taps frequently break off while tapping out holes with a drill press, thus ruining the tap. A method which has proved its value for saving taps against breakage is illustrated in Fig. 1. The device is simply a safety pin which provides a breaking point that will give way or shear off when the tap gets stuck, before the strain is sufficient to break the tap, which will occasionally happen through carelessness or otherwise. If the drilled hole is too small, or if the tap reaches the bottom of the hole sooner than expected, the safety pin will shear off and thus save the tap. As shown in Fig. 1, the shank of the tap fits nicely into the bore of a sleeve and through both sleeve and shank is the safety pin, which is a light drive fit. The outside diameter of the sleeve is made to fit into the holder shown in Fig. 2. The sleeve is provided with two keyways which fit keys in the holder, which do the primary driving. The holder may be fitted with a shank suitable for the drill press spindle. The taps which go with each holder may have the same outside diameter of sleeve, but the shank of the tap and the bore of the sleeve, and the diameter of the safety pin will be of the sizes given in the table. HARRY L. RAMBO.

Milwaukee, Wis.

SIZES OF WORKING DRAWINGS

In the March number of MACHINERY, engineering edition, Mr. William Breath in his article on "Sizes of Working Drawings," advocates the use of small drawings for detailing. His plan may be all right, but I think that he carries it too far. For instance, in his illustration of the drawings for a cast-iron bed, he puts the outline drawing on one sheet and the various section drawings on separate sheets. If there are two sections to be shown, this makes three sheets for showing the detail of one casting. Now this particular detail drawing could have been put on one sheet and the following advantages obtained: The man machining this casting would have the whole thing before him all on one sheet, from which he could more clearly see into the construction of the piece; he would not lose one of the sheets, since he has only one; the draftsman would not have to tack down but one sheet; he would not have to repeat some of the dimensions; the work could be done faster, as some of the lines could be projected from the outline view to obtain the cross-section view; there would be only one title and one number to put on the drawing and one record to make in the number book or card index; the checker's work would also be facilitated; the man who approves the drawings would only have to write his initials once; and the blue-print boys would have less work. I agree with Mr. Breath that it is much easier on the draftsman to work on small drawings, but I am in favor of using medium-size sheets for such work as has just been described, and a small scale where dimensions are not too numerous.

In the drawing room in which I am employed we have four standard drawing sizes. The largest is 21 × 33 inches, the next 16½ × 21 inches, or just half the large size, and the smallest 8¼ × 10½ inches. We generally use the large size for assembly drawings and the next size for details. The sizes are designated by letters, which always follow the drawing number. If there is more than one sheet the numbers are put on the drawings in the following manner: No. 536-A-Sheet 1; No. 537-B-Sheet 2; etc. We use no tracing cloth, but instead the best grade of bond paper; it blue-prints well and does not turn yellow from age. This paper does have a tendency to curl and after being rolled up it is difficult to straighten it out, but this difficulty is overcome by filing the drawings away in large envelopes made from heavy wrapping paper.

By doing this we can file a great many drawings in one drawer; they are easily gotten out, and the drawings are well kept. We mark each envelope on the outside for 100 numbers; for example, one envelope will be marked from 500 to 600. Suppose drawing number 267 were wanted from the file; it would be found in the envelope marked from 200 to 300. The beauty of this scheme is in putting the drawing back in place. Those who have had to file drawings under a big stack of other drawings know how hard it is to get them in place without turning the corners down or disarranging the other drawings. When a new drawing is completed, its number is entered in a book with the subject, the initials of the draftsman and the date. Then cards are made out for the card index, which are filed alphabetically. When the foreman of the machine shop puts several men onto the same job he gets a blue-print for each man and marks with a red pencil the details each man is to make up. J. E. WASHBURN.

Cleveland, O.

SPECIAL JIG FOR DRILLING ELL FLANGE

In a factory which manufactures one of the popular makes of automobiles, it was desired to produce more of the pump outlet elbows shown at *A* in the accompanying engraving. Therefore, to facilitate the drilling, a jig was designed as shown in the three views, which, after a thorough test, proved practical and did accurate work. The ell casting, which was of brass, had but one finished surface, which was that of the flange to be drilled. The two bolt holes had to be at right angles with this surface and the holes in all the elbows had to be drilled alike, in order to make the parts interchangeable. The body *B* and the cap *C* of the jig are held together by fillister-head screws. There are two steel V-blocks *D*, located so as to receive the flange of the casting. A thin bar of steel *F*, held by pins through the split ends of the studs *G*, clamps the work in place. The thickness of this clamp is only ¼ inch, as there is not room for one of greater width. One of the studs *G* is stationary, while the other is drawn upward by a knurled nut *H*. When a casting is to be clamped in the jig, one end of the flange is inserted over the bar *F*. The nut *H* is then tightened, and, at the same time, the screw *E*, upon which the casting rests, is also adjusted to the proper height, in order to bring the finished face of the flange against the plate *C*. In this way the casting is clamped square and firm in the jig with little loss of time. Usually when the nut *H* is loosened in order to remove the work, this may be accomplished without changing the adjustment of the screw *E* owing to the uniformity in the castings and the thinness of the V-blocks *D*. Elbow which has Little Gripping Surface, and Jig for Drilling it

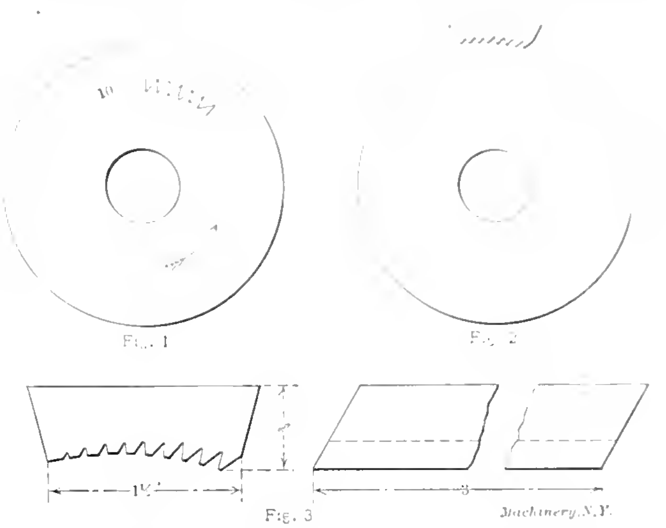
GROOVING CHILLED FLOUR MILL ROLLS

The following matter is submitted in answer to the inquiry of K. A. T. concerning the grooving of chilled cast iron flour mill rolls, published in the "How and Why" column of the March, 1909, issue of MACHINERY.

When the rolls arrive at the shop for grooving, they should be unpacked and correctly marked as to the number of grooves per inch, and the direction in which the teeth are to lean. (See Fig. 1.) It is essential that the rolls be marked when taken out of the boxes as the box is often marked with the words, "fast roll" or "slow roll," "1st break," "2nd break," etc. This marking avoids confusion since it would be impossible to identify the rolls. The marks are stamped on the ends of the journals, or proper tags attached. The journals are inspected for truth and smoothness. If they are scored, the roll is put into a lathe and the journals turned, previous to grinding.



Figs 1 to 3. Tools for Grooving Chilled Flour Mill Rolls

The grinding machine consists of a bed with two V-grooves to receive and guide the carriage or wheel slide. On one end of this bed is mounted a driving mechanism for operating the carriage and roll, being connected to the roll with a universal coupling. The carriage is actuated by a lead-screw within the bed, and the traverse of the carriage is reversed by a shipper rod on one side of the bed. On the carriage are mounted two emery wheels each on its slide, on opposite sides of the roll to be ground. One wheel may be very coarse and rather hard for roughing down the old corrugations, and one wheel must be soft to produce a good finish. The roll is placed in two V-bearings between the grinding wheels, which bearings are adjusted to allow very little end play of the roll. The roll may now be ground true and parallel, using a copious stream of water. The emery wheels are driven by belts from an overhead drum.

After grinding, the roll is put into a roll-grooving or corrugating machine. It is assumed that the roll is properly chamfered to prevent breaking out at the ends. The roll is held in the corrugating machine between centers, and it also rests on V-bearings, which are placed near the roll proper. It is of paramount importance to have the work rigidly supported.

The machine platen has a head-stock mounted on one end, which carries the feeding mechanism, and through which the helical motion is transmitted. The spiral attachment is similar to the taper attachment of a lathe, and by intervention of a rack and pinion the motion is imparted to the live spindle of the head-stock. From the foregoing it will be understood that the teeth are helical (or spiral as commonly expressed).

The spacing of the teeth is not by the dividing method, but by the feeding method, as it might be termed. For example, a nine-inch divided roll is to be grooved ten corrugations

per inch. Now we find it requires five teeth of the 150-tooth ratchet wheel to move the nine-inch roll one-tenth inch on its periphery. When the machine is properly adjusted and tool set (Fig. 2) the cut is started by making only slight scratches on the roll for an inch, after which the tool is sunk to full depth, yet not reducing the diameter more than a few thousandths inch. When the roll comes near to the starting point again, a pair of dividers are set in the corrugations to get the proper pitch, then the dividers are set in the corrugations, bridging or spanning the remaining blank portion. If the dividers fit correctly the feed may continue until finished, otherwise the roll must be adjusted to make the teeth match properly.

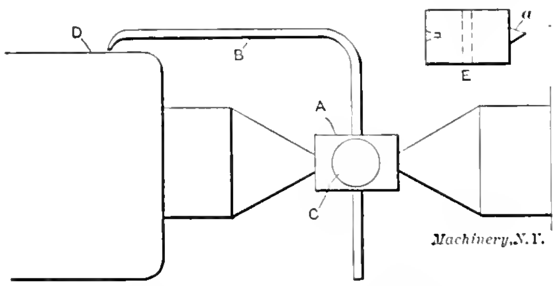
The cutting speed may be anything from twenty-four inches to thirty inches per minute. The steel used for tools should be of a very high carbon steel. The following brands are good: "Crescent Double Special," A1 temper and Firth-Sterling Extra Special," highest temper. High-speed steel is not good because it cannot be made hard enough.

The tool as shown in Fig. 3 will give the best results, since the flat chip is more easily curled than a chip of half round cross-section. The best over-all shape for these tools is that shown in this engraving. M. B. Stauffer.

Scottdale, Pa.

INDICATOR FOR ALIGNING LATHE CENTERS, ETC.

The indicator shown in the sketch is useful for aligning lathe or milling machine centers, or for setting a center punch mark or jig button central with a boring mill spindle. The gage consists of a short cylindrical piece *A*, accurately centered in each end, through which the adjustable gage wire *B* passes. This wire is held in place by a knurled thumb-screw *C*. When two centers are to be aligned, the gage is placed between them, as shown. The gage wire *B* is adjusted close to the concentric surface *D* and then slowly revolved. When the centers are in alignment, the pointer will follow the surface *D*. If the center of a circle is to be set in line with the axis of a boring mill spindle, a center in the latter is essential. The cylindrical piece *E* is then used instead of *A*, and the male center *a* is inserted in the center punch mark of the scribed circle. The gage wire *B* is then swung around to come in contact with the surface of the work, which must have been previously set square with the axis of the spindle. When the pointer, as it revolves, follows this surface, the center of the work and the spindle axis are in alignment. To true up a jig button, it will be necessary to have the corner ground to the same angle as the center in the piece *A*, which will have to be enlarged for a button of any size. H. W.



Indicator for Aligning Lathe or Milling Machine Centers

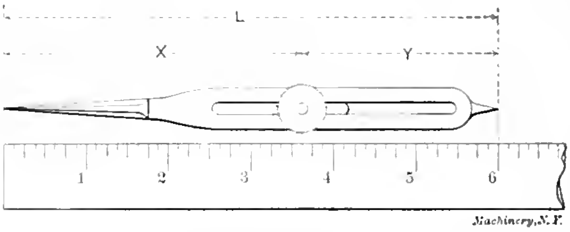
USE OF A LATHE CONSTANT FOR CALCULATING CHANGE GEARS

I wish to suggest a change in Machinery's Data Sheet No. 10 under the head "Change Gears for the Engine Lathe," in the paragraph beginning "Frequently the lathe is designed." Instead of finding out the ratio of the spindle and the stud by counting the number of teeth in the gears of the head-stock, simply look at the index plate and see what thread is cut when the gears on the stud and lead-screw are of equal numbers of teeth. For example, if a screw, three threads to the inch, is cut with equal gears, then call the lead-screw 3 to the inch, notwithstanding what number of threads to the inch it actually has. This we call "the lathe constant." Then if $12\frac{1}{2}$ threads to the inch are to be cut, multiply by any convenient number, 6, for example, and we have $12\frac{1}{2} \times 6 = 75$, and $3 \times 6 = 18$, the numbers of teeth that are required in the lead-screw gear and stud gear, respectively. I have used this rule for many years and have found it very convenient. James Eaton.

Burlington, Vt

TO OBTAIN RATIOS NOT PROVIDED ON PROPORTIONAL DIVIDERS

Users of proportional dividers have, at one time or another, had use for them when a ratio was required other than was provided for by the graduations thereon. To obtain this ratio, I have tried the tightening nut in many different positions before the proper setting was obtained. After doing this recently, for the last time, I concluded that a little calculation would do away with all this trouble. A scale can be used as shown in the illustration, from which to measure to the tightening nut. The position of this nut for any ratio may be found by simple proportion as follows: $R + r : R : : L : X$ or $R + r : r : : L : Y$, where R and r represent the antecedent and the consequent of the ratio; L the total length of the dividers, and X or Y the distance from the ends to the center of the nut. For example, the distance X for a ratio of 0.68 to 0.44 would be obtained thus: $0.68 + 0.44 : 0.68 : : L : X$. C. E. J.



Setting the Nut on the Dividers after the Proper Position has been found by Calculation

BLUE-PRINT PROTECTOR

The plan of covering blue-prints used in the shop with celluloid, as suggested by Mr. L. H. Georger in the February issue of Machinery, and the accompanying editorial note referring to the varnishing method, brought to the writer's mind a method used in the factory of the Coates Watch Tool Co., Springfield, Ill. In the watch-part department of this plant, all the working blue-prints are 5 x 7 inches in size, and are enclosed in strong oak frames, the face being covered with glass. The frames are very similar to cheap picture frames, but heavier, and have a screw-eye at the top to hang them up by, a hook being placed above each machine for this purpose. While this method could not very well be used for large drawings or blue-prints, it is unexcelled for small ones which are in constant use, and the drawings will last indefinitely when protected in this way. E. V.

WOMAN MACHINE SHOP PHOTOGRAPHER

In looking over Machinery for April, we notice under the "Personal" notes a statement to the effect that Miss Mimmette Ives Meade is the only woman in the United States who is making a specialty of machine shop photography. We would like to point out that for the past ten years our photograph department has been under the control of Miss Emma G. Moerlins, and we believe that she is the first woman in this country to fill such a position. J. A. MacIntyre,

West New Brighton, N. Y. C. W. Hunt Co.

LOCATING FINE CRACKS IN STEEL

Fine cracks in tools or other metal surfaces are often difficult to discover as even the microscope frequently fails to disclose them clearly. Their presence and extent, however, are easily detected by moistening the suspected surface with petroleum, and then wiping it clean and covering it with chalk. Some petroleum enters the fissures and afterwards sweats out, moistening the overlying chalk. The cracks can then be readily traced. O. M. B.

HOW AND WHY

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST

Give details and name and address. The latter are for our own convenience and will not be published

The following questions are referred to the readers:

J. A. J.—How are rolls for rolling silver and gold ground and lapped? What kind of a grinding wheel is used and what diameter and speed are best? At what speed should the work be run? The rolls that I wish to grind are four inches diameter. How much larger should the roll be ground in the center than at the ends to compensate for the deflection caused by the pressure of the stock rolled?

F. W. B.—I would like to ask the readers of MACHINERY for information regarding a reliable and economical method for brazing a large number of conical tubes, which are formed of sheet copper. These tubes are 4 inches long, and have inside diameters at the ends of ½ inch and ⅜ inch, respectively, as shown by the illustration. The seams where the edges come together must have a butt joint, and must present a neat appearance.

C. K.—I will have a large number of pipe thread dies to recut when they are worn. They are of the inserted or adjustable type 16, 11½ and 8 threads per inch. What is the best and most practical method for doing this work in the average shop? What special appliances are necessary besides the hobs and the holders for the dies.

This question is also submitted to the readers, and an article illustrated with sketches or photographs will be acceptable.

GRINDING BRASS VALVES—TURNING SHAFTING FOR SCREW CUTTING

F. L. Z.—1. What is the proper way to grind and lap brass valves used for steam, water and air, and what material should be used for the operation? 2. What is the best way to turn small shafting, say, four or five feet long, ¾ inch diameter, on which a screw thread two feet long is to be cut?

A.—1. The valves and seats of brass valves for any purpose should be carefully trued on a lathe before grinding. The seats or bearing surface should be made narrow, and very little grinding should be done. Too much grinding tends to destroy the accuracy of the seat, and defeat the object of grinding. Use powdered glass sifted through a cloth bag, mixed with oil. Grind the parts together for a few moments, oscillating the valve and lifting it from the seat slightly so as to prevent scoring and scratching the seat. After a few moments grinding, carefully wipe off the grinding material and note where the bearing is. If all parts appear to be ground alike, put on a little clear oil and grind a few moments longer, and then test the valve, if possible. The watchword in grinding valves is to grind as little as possible. Accuracy must first be obtained by machining operations and the grinding should be limited to just enough to smooth down whatever roughness may be left by the cutting tool. 2. Small shafting of the kind described, should be carefully centered, the centers being drilled and reamed with a combination tool. Turn the shafting in an engine lathe using a back rest to steady the work under the pressure of the cut. Take a roughing and finishing cut, and then cut the thread. The back rest should have two jaws made of brass so as to prevent marring the work.

TO FIND THE DIAMETER OF A CIRCUMSCRIBED CIRCLE

J. F. P.—Three hardened and ground plugs are placed in position as shown by the three inside circles in the accompanying engraving. What is the radius R of the circle which will be tangent to all the three plugs? The only dimensions known are the distances P and C, shown in the illustration.

A.—To solve this problem, we first require the radii of the three plugs. The radius b of each of the two smaller plugs equals one-half of C. The radius a of the larger plug must be calculated. It will be seen that $a = mn - b$, but $mn = \sqrt{mh^2 + hn^2} = \sqrt{P^2 + (\frac{1}{2}C)^2}$. Having thus determined the radius a, we can now proceed to determine the radius R, which is the quantity to be ultimately found in the problem.

Assume that the center of the large circle to be found is at o. The length om, which is not known we call x. We can now write two equations which can be simplified so as to contain only the two unknown quantities x and R. We first have

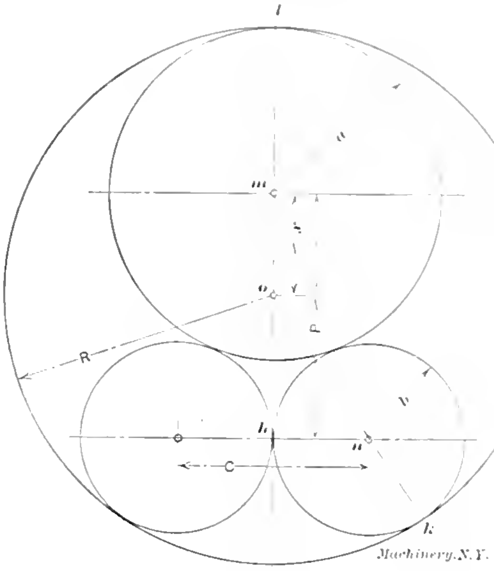
$$R = om + ml = x + a.$$

We also have

$$R = on + nk = \sqrt{oh^2 + hn^2} + nk = \sqrt{(P - x)^2 + b^2} + b.$$

As the members on the right-hand side in both of these equations equal R, they are also equal to each other. Thus we have

$$x + a = \sqrt{(P - x)^2 + b^2} + b.$$



To Find the Diameter of a Circumscribed Circle

If this equation is solved for x, we get,

$$x = \frac{P^2 - a^2 + 2ab}{2a - 2b + 2P}$$

and

$$R = a + \frac{P^2 - a^2 + 2ab}{2a - 2b + 2P}$$

Assume, for example, that the problem was given with the dimension $P = 1.2$ and $C = 1$ inch. Then $\frac{1}{2}C = b = 0.5$ inch. Radius $a = \sqrt{1.2^2 + 0.5^2} - 0.5 = \sqrt{1.69} - 0.5 = 1.3 - 0.5 = 0.8$.

If we now insert the values of P, a and b in the expression for R above, we have

$$R = 0.8 + \frac{1.2^2 - 0.8^2 + 2 \times 0.8 \times 0.5}{2 \times 0.8 - 2 \times 0.5 + 2 \times 1.2} = 1.333 \text{ inch.}$$

COMPARISON OF FIXED AND VARIABLE SPEEDS

M. S.—Two steamers start from New York at the same time for Liverpool. One steamer makes 18 knots and the other 16 knots. Upon its arrival at Liverpool, each steamer immediately returns to New York; the steamer that made 18 knots continues to make 18 knots on the return trip, but the steamer that made 16 knots makes 20 knots on the return trip. Apparently both steamers should arrive at New York at the same time, as the steamer which makes slow time on the outward trip, makes fast time on the return trip, and the average speed is the same as the speed of the 18-knot steamer. I have seen stated, however, that the 18-knot steamer will arrive at New York first. How can that be explained?

A.—The steamer making 18 knots continuously will arrive at New York first, due to the fact that the average speed of the other steamer which makes 16 knots on the outward trip and 20 knots on the return trip is not 18 knots, as would first appear. The time required on the outward trip by the 16-knot steamer is greater than the time required when returning at 20 knots, so that it is going at 16 knots considerably longer than it is going at a 20-knot speed; consequently the average speed for the time required for the combined outward and return trip is not the arithmetical mean between

16 and 20. Expressed as a formula, the average speed equals:

$$\frac{16\,T + 20\,T_1}{T + T_1} = \text{average speed,}$$

in which T = number of hours required for the outward trip,
T_1 = number of hours required for the return trip.

As an example, assume that the total distance from New York to Liverpool is 3,040 knots, then T will equal 190, and T_1, 152, and the average speed would equal:

$$\frac{16 \times 190 + 20 \times 152}{190 + 152} = \frac{6080}{342} = 17.77 \text{ knots.}$$

There is a common application in ordinary shop work of the principle involved in this problem. A planer has a cutting speed of 20 feet per minute, and a return speed of 60 feet per minute. At first thought it may seem that the average speed of the planer platen is 40 feet per minute, but that conclusion is not correct. For simplicity, assume the exaggerated condition in which the stroke of the planer is 60 feet. The cutting speed being 20 feet per minute, the forward stroke will require 3 minutes; and the return speed being 60 feet per minute, the return stroke will require one minute. The total time required for one forward and one return stroke is thus 4 minutes. During this time the platen has traveled two times the stroke, or 120 feet. The average speed thus is 30 feet per minute. The formula for finding this could be expressed:

$$\frac{2\,S}{\dfrac{S}{C} + \dfrac{S}{R}} = \text{average speed per stroke,}$$

in which S = length of the stroke in feet,
C = cutting speed in feet per minute,
R = return speed in feet per minute.

This formula can be simplified so as to take the form:

$$\frac{2\,C\,R}{R + C} = \text{average speed per stroke.}$$

If we substitute the quantities of the planer problem above in this formula, we have:

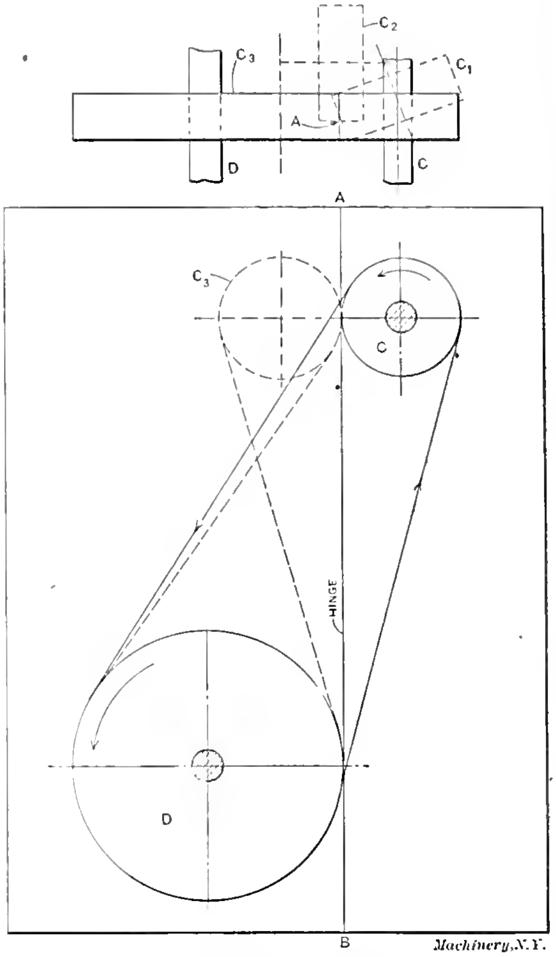
$$\frac{2 \times 20 \times 60}{20 + 60} = \frac{2400}{80} = 30.$$

It should always be borne in mind that the average speed is the arithmetical mean between two given speeds only when the periods of time, during which each speed is in operation, are equal. In this case of forward and return strokes at different speeds, one stroke is made in a shorter time than the other, and the average speed is *not* expressed by the arithmetical mean of the two speeds.

LOCATING ANGLE BELT DRIVES

F. O.—What is the general rule for locating a driving and driven pulley on shafts not parallel?

A.—Reference to the accompanying sketch, which is based on one shown in Spooner's "Machine Design, Construction and Drawing," will make the problem easily understood. First, suppose pulley C to be driven by a straight belt from pulley D on a parallel shaft, and that the vertical line AB is tangent to the middle planes of both pulleys. Now, imagine that the right-hand part of the diagram is bent backward on AB as a hinge. Pulley C and its shaft successively take the positions C_1, C_2, etc., until C_3 is reached, when the shafts of C and D are again parallel, pulley C having been swung through an angle of 180 degrees. In position C_3 the belt would be twisted as indicated by the dotted lines. The belt will run in the twisted position required by C_3 or any intermediate position including the common right-angle position C_2, provided its direction of motion is that shown by the arrows. Hence, the general rule: *Pulleys connecting horizontal shafts out of parallel must be so placed that a plumb-line dropped from the center of the upper pulley face will touch the center of the lower pulley face; and the retreating part of the belt from each pulley must follow the direction of the tangent (AB) to the pulley faces.* When the belt is twisted as shown at C_3, the shafts then being parallel, the belt will run in either direction, and, of course a face of the upper pulley need not be directly above a face of the lower pulley. In case it is desired to run an angle drive from a horizontal shaft to a vertical shaft, the same rule can be followed as given in the foregoing, except that AB will not be a plumb-line, but will be a horizontal line tangent to the middle planes of a driving and driven pulley face.



Locating Angle Belt Drives

LARGE GAS ENGINES

A comprehensive table referring to large gas engines developing over 1,000 horse-power appeared in a recent issue of the *Zeitschrift des Vereines deutscher Ingenieure.* According to this table 628 gas engines of 1,000 horse-power and larger and representing a total amount of power equal to 1,035,700 horse-power, have been built or are under construction at the present time. Of this total, 412 engines of 613,200 horse-power, or considerably more than one-half of the total, have been built in Germany; 154 engines with 337,500 horse-power in the United States; 33, with 42,200 horse-power in Belgium; 9, with 16,800 horse-power in France; 10, with 13,600 horse-power in Austria; and 11, with 12,400 horse-power in Great Britain. It is rather difficult to explain why the building of large gas engines has made so little progress in so highly developed a country as Great Britain, unless we ascribe this to the traditional conservatism of the Briton. The average size of the engines built in Germany was 1,500 horse-power; in the United States, 2,200; in Belgium, 1,300; in France, 1,900; in Austria, 1,400; and in Great Britain, 1,100 horse-power.

DATA SHEET CORRECTIONS

We soon shall publish a revised edition of MACHINERY's data sheets, and it is desired that the typographical and other errors in the first edition be corrected. We ask the cooperation of readers using these sheets to help make the new edition free from all mistakes, no matter how trifling. For the best list of corrections and criticisms we will give a prize of $5, and for the second best, $3.

INDUSTRIAL TRAINING THROUGH APPRENTICESHIP SYSTEMS*

The financial statement of every organization summarizes the assets and liabilities of that organization, and details with more or less accuracy the items composing them. Good form forbids the inclusion of any but tangible assets and actual liabilities, yet every organization is dependent for its success on the personnel of its executive and working force, which may be an asset if efficient and aggressive, or a liability if inefficient and decadent.

Efficient organization is the keynote of success. All available sources are exhausted by the modern business manager for material to construct his product, for means for financing his operations, and for energetic men to develop and execute his ideas. We frequently hear that Mr. Blank is a great man; he is identified with a dozen or more corporations; his name alone insures success to those who associate with him. We ask: How can he intelligently direct so many widely diversified industries? Why do his subordinates succeed? The answer is plain: He is a judge of men. He selects the right man for the place, reposes confidence in him, and through him controls an industry as a general through his subordinates controls an army. He recognizes the fact that these men are an asset of his business as much as is the capital invested, and he makes provision to supplement them as necessity demands, just as he provides for a future supply of raw material or sufficient capital to carry out his projects.

He may be able for a time to secure all the men he needs from others who have trained them, just as he may be able to borrow money for the development of his business, but he will have to make both men and money before his success is assured. Every enterprise requires men skilled in the manipulation of its affairs, versed in its various details and operations. The supremacy of an industry, a community, or a nation, is dependent upon the skill and intelligence of its working people.

Prior to the recent business depression, the utmost difficulty was experienced by employers of labor in securing sufficient numbers of skilled workmen. It was no uncommon experience for a concern to hire and discharge five men for every one retained. Really skilled men were not to be had at all in certain lines, and development was arrested on account of the inability to get desirable men. On the other hand, inefficient and unskilled help was plentiful. It is admitted by all that we need more skilled men and that some means must be devised for developing the inefficient and unskilled so that they may be valuable to themselves, their employers, and the community.

The supply of skilled men is not equal to the demand. Our public schools do not educate for any particular trade; our colleges educate broadly but not specifically; our technical schools lay the foundation for engineering professions, but relatively few men have an opportunity to avail themselves of the courses offered. Ninety-five per cent of the children who enter the public schools never reach high-school, and less than twenty-five per cent go above the fifth grade. This means that less than six million out of twenty-four million children in our public schools in 1907 will learn more than is taught in the primary grades. The average child in the United States attends school for less than five years. What does this mean industrially? It means that if we are to have industrially intelligent workers, we must devise means independent of our public school systems for training and developing them.

What Would Apprenticeship Systems do toward Raising our Standard of Industrial Intelligence?

Carefully devised apprenticeship systems operated in the majority of our factories would do much to augment the existing supply of skilled workmen. The need to employers of skilled workmen has already been pointed out; but not only are they necessary as producers—civilization itself has advanced along mechanical lines in such gigantic strides that there is a tremendous demand for, and a serious lack of, skilled men, simply to keep going the wheels of modern life; our towering buildings, our enormous ships, our great bridges—the thousands of mechanisms which are required to transport, to house, to feed, to clothe, to light, to heat, and amuse our people, present an immense field for trained men.

Apprenticeship systems would insure workmen being educated along *definite lines*, thereby meeting the demand for competent leaders. It is of the utmost importance that those who are to occupy executive positions should have familiarized themselves with the various details of the work under their supervision; they should be able to decide whether the judgment of their subordinates is sound, whether the operations required to make some particular piece are correctly performed, whether the quantity and quality of production for which they are responsible is of the required standard. This knowledge can be gained only by actual contact with the work, and a personal study of the conditions under which it is performed.

Apprenticeship systems would offer to young men of limited means, who would otherwise be forced into that large and growing class of unskilled labor, an opportunity to learn a trade. Poverty, disease, and crime are frequently the result of ignorance and environment. Every individual, workman or capitalist, is buoyed up, spurred on, by hope. Picture to yourselves the unskilled workman, earning the minimum wage on which a man can live and support his family. His greatest anxiety is concerning steady employment for himself, his one hope, an opportunity for his children. Where is this opportunity to be found? Not in an education which yields no immediate return, for he cannot support them during that period. His sons must find work, and that as soon as the law will permit, and it must be work which will support them from the beginning, for the father cannot. This means that these boys must take situations which require little, if any, skill; situations which pay practically as much at the beginning as at the end; unskilled work, unskilled wages, with no chance of advancement in either skill or remuneration. So they go on through all their lives, bequeathing to their sons what their fathers bequeathed to them—ignorance and poverty, possibly disease and a tendency for crime. What have they to hope for, to buoy them up, to spur them on? Give boys of this class an opportunity to learn a trade, to be skilled workmen and in demand, rather than unskilled and not in demand, and you solve a large problem in American economics. Apprenticeship systems offer this opportunity.

Do apprenticeship systems pay the employer? Most emphatically *yes*. Many successful concerns who have had apprenticeship systems in operation for a period of years are unanimous in their statements that apprenticeship systems do pay. If properly instructed and intelligently directed, the employment of apprentices is more profitable than the employment of the so-called skilled workman who has been available in the past. Apprentices pay as producers during their term of service; as skilled journeymen when they have completed their course; and as intelligent foremen and executives later on. Those boys who leave at the termination of their apprenticeship become staunch supporters of the mother-shop; always ready to say a good word for it; as loyal as college graduates to their *Alma Mater*; an unequalled advertising medium.

Does it pay the employe to serve an apprenticeship? I firmly believe that it does. He is raised from the ranks of unskilled labor and given an earning power which he could not otherwise command. He is taught to work intelligently and to apply his mind to his work, thus increasing his opportunity for further development and advancement.

What Provisions should Apprenticeship Systems Make for the Employed?

Apprenticeship systems should provide for a proper term of service to insure ample time for thorough instruction. A distinct proportion should exist between the period of time required to learn a trade, and the degree of skill required in the trade. Apprenticeship systems should provide for sufficient remuneration to support the apprentice during his term of service. Applicants for apprenticeship courses will, in the majority of cases, come from the working classes—from the farms in many instances; and they must of necessity have an opportunity for self-support during their period of apprenticeship.

Apprenticeship systems should provide instruction in the technique of the trade and allied studies. The average boy

---

* Paper read by E. P. Bullard, Jr., before the National Metal Trades Association Convention in New York, April 15, 1909.

begin to learn his trade between the ages of 14 and 17 years. He has not advanced beyond the fifth grammar grade, and probably could not pass an examination on any subject which he has studied. He has not been taught to reason or apply such knowledge as he has. If he is to become a skilled mechanic, it is essential that he should be well grounded in the elementary studies which are allied to his trade. He should be taught the mathematics of his work, the technical terms usually employed, and sufficient reading, writing, and spelling, to supply the deficiencies of his common school education.

Apprenticeship systems should provide instructions in the manipulation and care of the appliances of the trade. I believe there are many who either own or are responsible for valuable manufacturing equipment which is practically at the mercy of unskilled employes or uninstructed apprentices. The average employer would deny this statement, believing as he does that the foreman supervises and instructs his workmen and apprentices. As a matter of fact, the foreman seldom has time to explain to each man or boy such items as the necessity and economy of sufficient lubrication, the function of each mechanism, and the means which should be employed to obtain the most economical results. Being occupied with what are to him more important matters, he is content to let the boy find out these things for himself—an expensive and inefficient system. Every large plant maintains a repair department at a cost which is no inconsiderable portion of its operating expense. Instruction in the care and manipulation of the appliances which it uses would do much to reduce this item.

Apprenticeship systems should provide for the fostering of a spirit of ambition and desire for increased knowledge. Let the apprentice see that his diligence will be rewarded, that he may in time be foreman, superintendent, or manager, if he applies himself to his work, and no difficulty will be experienced in securing all the boys required. If there is anything in a boy this will bring it out; if not, get one who will appreciate his opportunities.

As the employes of any industry may be divided into two classes, producers and non-producers, workers and executers, and as there is need for trained men in each of these classes, I recommend that apprentice courses be arranged to meet these conditions. Let the boy who is bright and ambitious, and who otherwise shows the necessary qualifications, become more than a mere workman, have an opportunity to learn the full trade, including instruction in the studies allied to the trade. Impress upon him the fact that he is given an exceptional opportunity, and demand in return exceptional interest and effort. Advance these boys systematically through the course and weed out such as are not up to a high standing. Select your executives as far as possible from among their number, and thus show them that their efforts will be rewarded.

As the workers outnumber those having executive ability, it is fully as important that as much attention be paid to the development of the former as the latter. Relatively few applicants for apprentice courses have any expectations of ever becoming more than skilled specialists. Why then waste time and money in teaching the full trade to a boy who has neither the intelligence nor ambition to become more than a mere specialist? Provide special courses for these boys covering the various branches of the trade; make the time of service relatively short and wages high as compared to the full apprentice course; give graduates of these special courses an opportunity to learn the full trade later on if they show special ability, allowing credit for the time already served on the special course. The full apprentice course would train boys to fill executive positions. The special courses would develop skilled workmen with a minimum expenditure of time and money.

What is the attitude of labor unions toward the apprentice system? No labor union having the welfare of the workingman at heart can be opposed to well-organized and well-conducted apprentice courses. They may as well be opposed to our public school system on the ground that education is dangerous. The labor union which sets its seal of disapproval upon well-organized and well-conducted apprentice courses admits its ignorance of industrial and social developments and requirements. It cannot have the welfare of its members or the working classes at heart. It should be recognized as hostile to the best interests of employer and employe alike and should not be tolerated in any community. Labor unions can in no way more conclusively show their interest in the welfare of the workingman than by endorsing and furthering the adoption of apprenticeship systems and schools. The apprentice school is a necessary adjunct to any well-organized apprentice system. Few concerns are large enough to support a school of their own as is done at Lynn and Schenectady, and not every community is prepared to establish a technical school such as Wynona or Cincinnati University. Fortunately, however, like industries usually locate in the same neighborhood, so that it is possible for manufacturers employing a similar class of labor to cooperate in the establishment and maintenance of apprenticeship schools.

In Bridgeport, Conn., this has been done very successfully. The members of the local manufacturers' association, working in conjunction with the Y. M. C. A., have established a school for apprentices, who attend two hours per day five days a week. The boys are paid regular wages for the time they spend in the class-room, and the expense for the instructor, who is especially employed for this purpose, is borne by the manufacturers who have boys in the school. The Y. M. C. A. was selected, as the building was provided with class-rooms and had all facilities for carrying on the work. The courses are laid out by a committee of manufacturers, and the work is directly under their supervision. The expenses are nominal and the results secured thus far are satisfactory.

SPRING MEETING OF THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS

The American Society of Mechanical Engineers will hold its Spring meeting in Washington, D. C., May 4-7. Professional sessions will be held at which papers on the conveying of materials, gas power engineering, steam turbines, the specific volume of saturated steam, oil well pumping and various other subjects will be discussed.

At the reception, which will be held in the New Willard Hotel, an address of welcome will be made by the Hon. B. F. Macfarland, President of the Board of District Commissioners, with a response by Mr. Jesse M. Smith, President of the Society. During the convention President Taft will hold a reception for the members at the White House. The War Department will give a special exhibition drill of the U. S. troops at Fort Myer, to which the members and guests will be invited. At the same time, if the conditions are favorable, an ascension of a dirigible balloon will be made and probably also that of an aeroplane. An address will be given by Rear-Admiral Melville, retired, Past President of the Society, and former Engineer-in-Chief of the Navy, the subject being "The Engineer in the Navy." This evening will be made the occasion for the presentation to the National Gallery of a portrait of Rear-Admiral Melville presented by friends and admirers. It will be received for the National Gallery by Dr. C. D. Walcott, Secretary of the Smithsonian Institution. F. H. Newell, Director of the Reclamation Service, will deliver an illustrated address on "Home Making in the Arid Regions." Trips will be made to various points of interest about the city and a number of pleasurable excursions have been planned. The papers to be presented are as follows: "A Unique Belt Conveyor," Ellis C. Soper; "Automatic Feeders for Handling Material in Bulk," C. Kemble Baldwin; "A New Transmission Dynamometer," Prof. Wm. H. Kenerson; "Polishing Metals for Examination with the Microscope," A. Kingsbury; "Marine Producer Gas Power," C. L. Straub; "Operating System for a Small Producer Gas Power Plant," C. W. Obert; "A Method of Improving the Efficiency of Gas Engines," T. E. Butterfield; "Offsetting Cylinders in Single-Acting Engines," Prof. T. M. Phetteplace; "Small Steam Turbines," Geo. A. Orrok; "Oil Well Tests," Edmund M. Ivens; Safety Valve Discussion; "Specific Volume of Saturated Steam," Prof. C. H. Peabody; "Some Properties of Steam," Prof. R. C. H. Heck; "A New Departure in Flexible Staybolts," H. V. Wille.

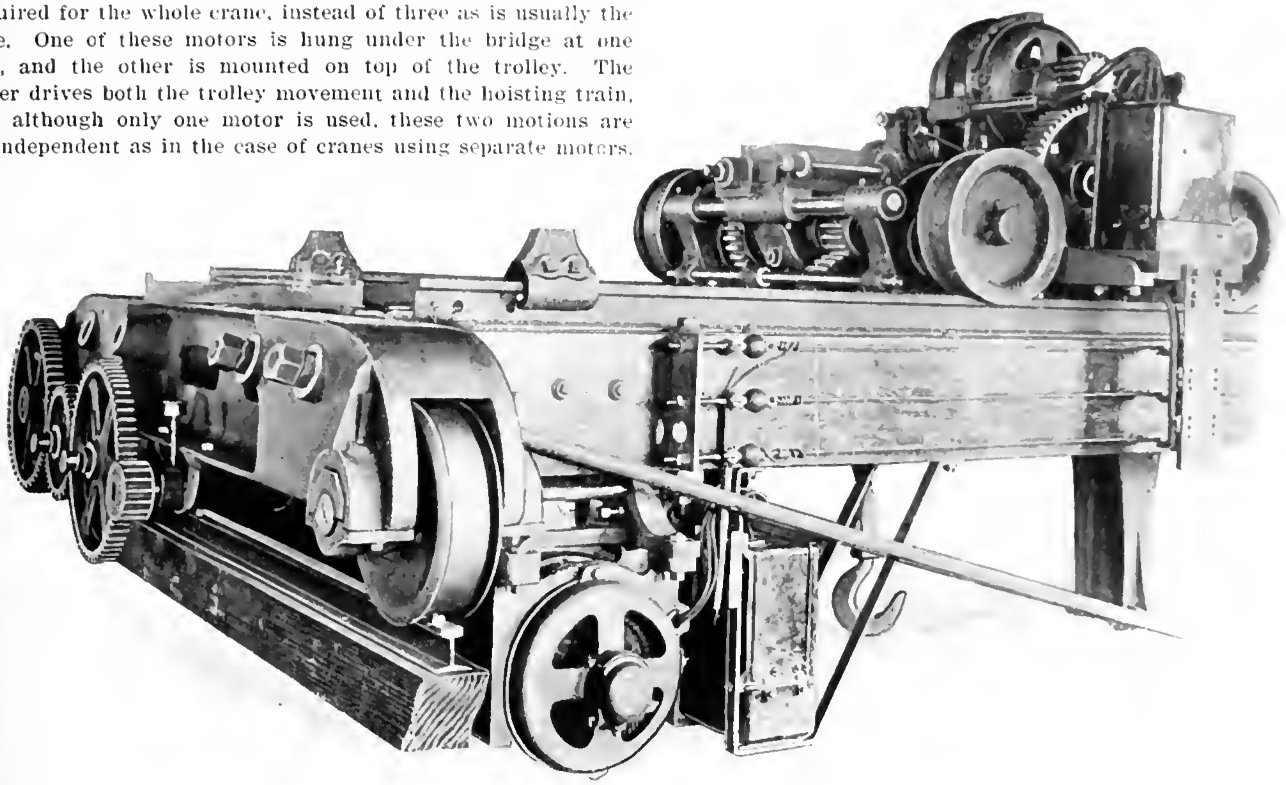
NEW MACHINERY AND TOOLS

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP

NEW ELECTRIC TRAVELING CRANE

The electric traveling crane illustrated herewith is built by the Lane Mfg. Co., Montpelier, Vt. It is a radical departure in design from usual types, particularly in its use of non-reversing motors. In the conventional electric crane the motors must be stopped, reversed and again brought up to speed for each and every change of movement. As the armatures are heavy and run at high speeds, this means a large consumption of energy in doing useless work.

In the crane here shown, this waste is avoided, and the motor armatures serve as flywheels of considerable capacity in compensating and equalizing the varying demands for current, especially when loads are applied suddenly. The reverse motions are effected by means of bevel paper-and-iron friction wheels, and these are so combined that only two motors are required for the whole crane, instead of three as is usually the case. One of these motors is hung under the bridge at one end, and the other is mounted on top of the trolley. The latter drives both the trolley movement and the hoisting train, and although only one motor is used, these two motions are as independent as in the case of cranes using separate motors.



An Electric Crane with Power Movement in all Directions, operated by Two Non-reversing Motors

The motors are of a special, enclosed dust-proof type, made by the General Electric Co., and are connected to the friction wheels by rawhide spur gearing. The paper frictions are the driving members in all cases, thus doing away with any tendency to wear into ridges or get out of round. They are of the same type as those long and successfully used on rope-driven cranes made by the same company under the Anderson patents. The starting boxes of both motors are controlled from the operator's seat, which is located at one end of the trolley. From this position the driver always has an unobstructed view of his work, and he is not dependent on signals from those below.

The hoisting train is driven by a worm and worm gear running in an enclosed chamber filled with heavy grease and flake graphite, and provided with stuffing boxes to prevent the lubricant working out in hot weather. Owing to this form of drive, a brake is almost unnecessary, but one is provided to prevent racing of the worm in lowering heavy loads. In addition to the customary oiling arrangements, grease cups are provided at all important points, and most careful provision made to prevent the dripping of oil or grease from any part of the crane.

With the exception of the hoisting rope and hook, all parts of this crane are designed with a factor of safety of five. These two elements are purposely made weaker to insure the more expensive and important portions of the machine against serious overloading, as well as to insure that such overloading would be indicated by a gradual failure of the rope or hook rather than by the sudden yielding of some more rigid member. As evidence that only good material and workmanship enter into their construction, the makers state that these machines have on several occasions lifted and carried overloads of more than 2½ times their rated capacity; and while they do not advise such practices, or guarantee the machine for more than its rated capacity, they state that this was done without apparent effort or injury to any portion of the mechanism.

So far these cranes have only been made with bridges of Southern pine, trussed with wrought-iron rods, but the makers expect to be able to offer them at an early date with steel bridges, when these are required. For spans not exceeding fifty feet the timber bridge has proved perfectly satisfactory, and when this type of bridge is used these cranes are sold at prices far below those at which such machines have usually been marketed.

These electric cranes are fully guaranteed by the makers, who claim great economy of their machines in current consumption, as based not only on the argument set forth above, but also on tests made in actual operations.

PROVISIONS FOR WATER COOLING ON THE COLBURN BORING MILL

In the January issue of MACHINERY we printed a little story, at least 95 per cent true, entitled "The Adventures of a Water-Cooled Boring Mill." In this story was described the evolution of an effective guard to retain water or other lubricant used for cooling the tool and the work, when using high-speed steels in the boring mill. The Colburn Machine Tool Co., of Franklin, Pa., has sent us a description and photographs, herewith reproduced, of an arrangement of the same kind as that we described, which it has applied to one of its latest 34-inch boring mills.

The essential features in a guard of this kind are: First, it must thoroughly protect the operator and catch all the lubri-

ant, it must thus extend above the highest and below the lowest part of the revolving chuck or table. Second, it must be so designed that it will not be in the way of the wrench in the clamping or unclamping of the chuck, and it must not interfere with the placing or removing of the work. These conditions are fully met in the device shown in Figs. 1 and 2.

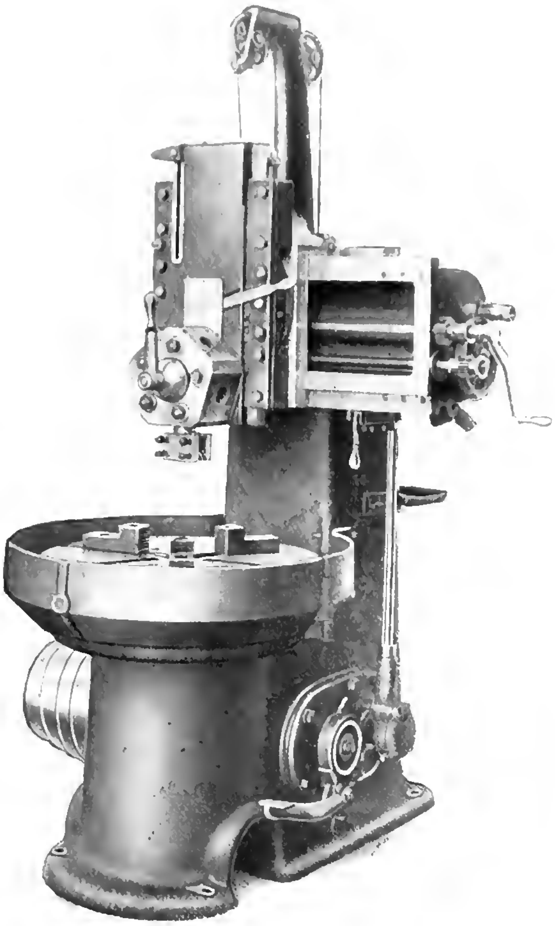


Fig. 1. The Colburn Boring Mill, as arranged for Water Cooling

As may be seen in Fig. 2, the guard consists of four pieces. Two supporting brackets are bolted to the frame of the machine, one on each side. These brackets form part of the guard and are of the same shape as the front part. The stationary brackets encircle one-half of the entire table or chuck, and at their outer ends have hinges to which are attached the front sections of the guard. These two front sections, or wings, may be opened and swung backward as shown in the illustration. When in this position the chuck is perfectly accessible for opening and closing the jaws, and for putting on and taking off work.

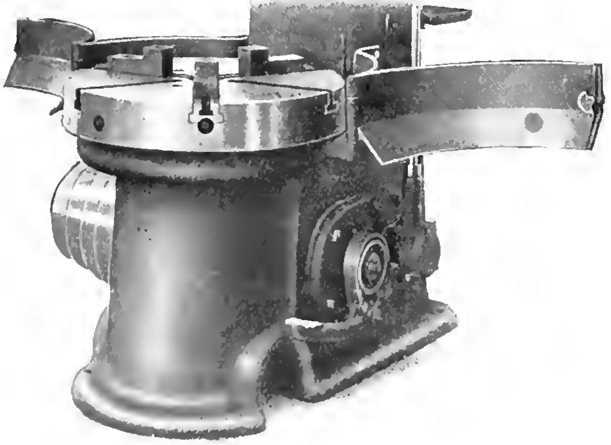

Fig. 2. Construction of the Guard for the Water or other Cooling Liquid

When closed, as shown in Fig. 1, the two wings are locked together by means of a latch operated by the handle or knob in front. A suitable trough made of sheet metal can be attached underneath the guard to drain off the lubricant and catch the chips, or the chips and lubricant can be allowed to fall to the floor into a large pan under the entire base of the machine. By using a large pan of this kind, all the lubricant and chips falling from the guard, as well as through the hollow spindle, can be caught, and by means of a suitable pump the lubricant can be carried back to the work again.

This provision greatly increases the capacity of the boring mill on certain classes of work, such as the machining of steel and aluminum, where it is very advantageous to use oil, water, kerosene or other lubricant adapted to the particular material in hand. This is regular practice in certain kinds of lathe and screw machine work, and suitable means for taking care of the liquid are regularly provided. The same advantage results from their use on the boring mill, though it is not so easy to make effective guards. This arrangement, however, appears to serve its purpose well, and should thus be of material advantage in increasing the output of the machine.

NEWARK GEAR-CUTTER GRINDING MACHINE

The illustration presented herewith shows a form of cutter grinding machine especially adapted to the sharpening of gear cutters, which has recently been devised by the Newark Gear Cutting Machine Co., 66 Union St., Newark, N. J. The cardinal points aimed at in the design are a combination of simplicity and accuracy in operation, and the supplying of a machine which is always set up for grinding gear cutters, without the use of special, loose attachments as required by universal grinding machines.

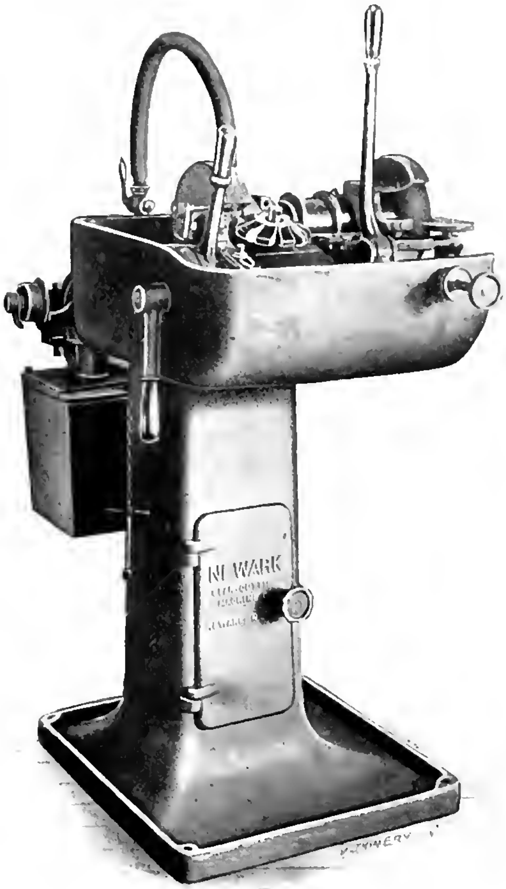

Fig. 1. Special Water-cooled Grinder for Sharpening Formed Gear Cutters

The cutter to be ground, *A* in Fig. 2, is mounted on a fixed stud to which it is fitted by bushings which are part of the equipment. The table in which the stud is fixed is adjustable parallel to the axis of the grinding wheel spindle, so as to set the edge of the wheel in line with the center of the cutter stud *A*. The stand *B*, upon which the table is mounted, is adjustable upon a horizontal trunnion *C*, thus providing means for tilting the table up and down. This allows coarse-pitch gear cutters, as shown in Fig. 2, to be ground in two corners

between the teeth, without changing the wheel or removing the cutter from the stud. It also affords a quick adjustment for placing the cutter central with the wheel to suit the different thicknesses of cutters used. This tilting adjustment is controlled by the upright handle at the left of the machine, and is locked by the handle hanging down on the outside of the pan at the left. The feeding of the wheel in toward the cutter is effected by the vertical handle at the right. A stop screw is provided for this movement.

There is a pawl on the cutter table which is adjusted to touch the back of the tooth to be ground. After being once set, the cutter can be rotated from tooth to tooth past the pawl. After cutting once around, an adjusting screw shifts the pawl so as to rotate the cutter slightly, giving a little deeper cut. This adjustment, which constitutes the feed, always results in a radial tooth after the wheel is once set in line with the center of the stud. No dials are used for indexing, as the pawl operates on the backs of the teeth of the cutter itself. For this reason it is not necessary to count the number of teeth in the cutter, or to select suitable dials for that number. This makes the action of the machine very rapid, the makers claiming that it is possible to grind the cutter while the indexing mechanism of other machines is being set. Its simplicity also gives it the advantage of being less subject to the wear which is bound to occur in a grinding machine of any kind.

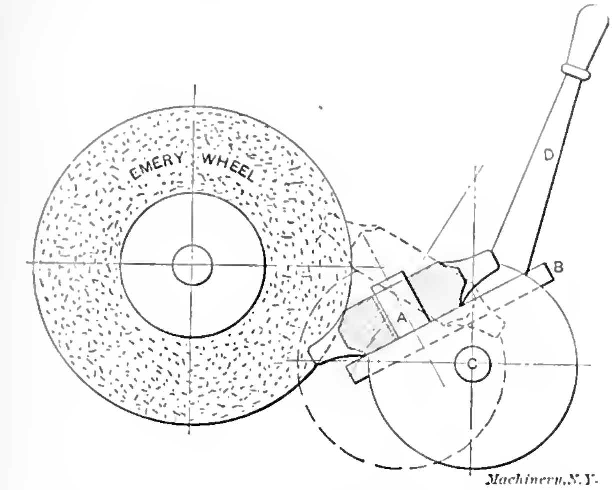

Fig. 2. Adjustment of Table, permitting Grinding the Sides of Large Cutters

As may be seen, this machine is arranged for water cooling. The liquid is supplied by a centrifugal pump supported at the rear of the column. Baffle plates are provided for separating the grinding dust from the water. The large pan is a splash basin merely; the water does not remain in it but flows into a reservoir. Among the other conveniences furnished with the machines is the provision of fixed handles, largely avoiding the use of wrenches, and facilitating the use of the machines. Where wrenches are required, they are fastened to the base of the machine by chains, as shown, to prevent them from being lost or taken away for other machines. This arrangement was found advisable in the shop of the builders, as it is a great advantage to have this machine always ready for instant use. The column is of box form and contains a cabinet for cutters, grinding wheels, etc.

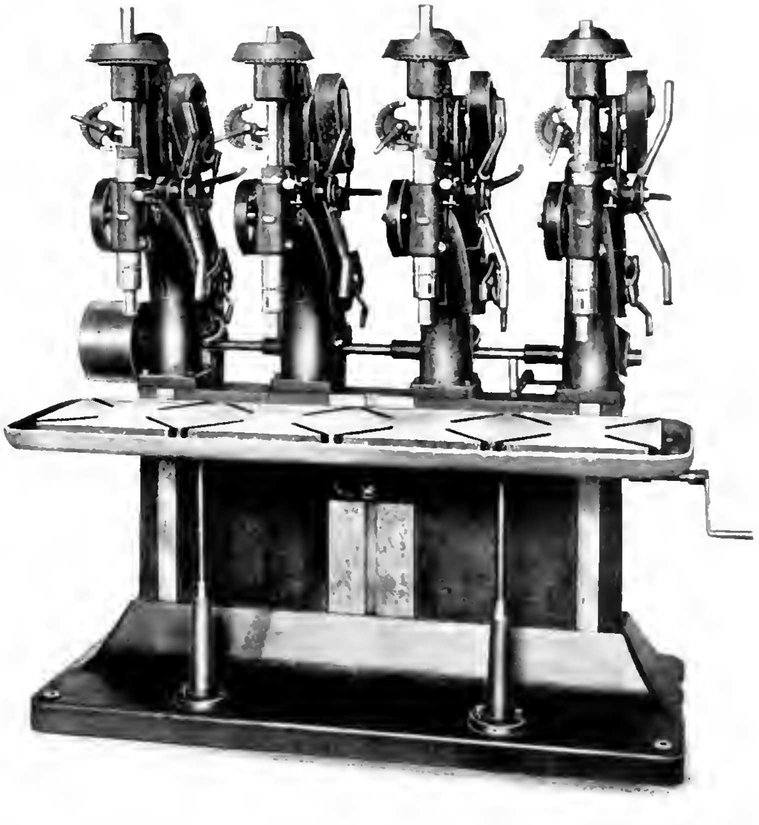
The machine will take cutters from $1\frac{3}{4}$ up to 8 inches in diameter. The grinding wheel is 8 inches in diameter with a 1-inch hole, and is of dished form. It is mounted on a hardened and ground spindle running in bearings of phosphor bronze adjustable for wear. The end of the spindle at the right, outside of the water basin, is used as a hand tool grinder, and will use up wheels after they are worn too small for the gear-cutter grinder. A hand rest is provided for this end of the spindle. The regular equipment includes two grinding wheels, the diamond truing device, and bushings which, in connection with a $\frac{7}{8}$-inch stud, will take cutters having $\frac{7}{8}$-, 1-, $1\frac{1}{16}$-, $1\frac{1}{2}$-, $1\frac{3}{4}$- and 2-inch holes. An overhead countershaft is also furnished.

BARNES DRILL CO.'S GEAR-DRIVEN GANG DRILL

The geared drive drill press made by the Barnes Drill Co., 602 S. Main St., Rockford, Ill., was described in the New Tools department of the May, 1908, issue. On this drill press a gear box giving four changes, and a back-geared drive which doubles this number to eight, are used, eliminating the use of cone pulleys entirely. Positive and quickly obtained feed changes are also provided, ranging from 0.001 to 0.025 inch. Four of these tools have been combined by the makers in the form of the gang drill shown herewith, for use on work requiring several operations.

The four spindles are driven by a single shaft passing from side to side through the machine. Any single spindle may be instantly stopped by throwing the speed-changing lever into the central position, thus throwing the transmission gears out of mesh. All the changes of speeds and feeds are made instantly by the operator from the front of the machine, without stopping the spindle. This holds true with the back gears as well as the regular changes. The feed-changing lever is shown at the left of each spindle, centered on the ratchet-faced segment by means of which it is set. For tapping, any or all of the spindles will be furnished with reversing friction clutches. The spindle at the right of the machine in the engraving is so equipped.

The table is surrounded by an oil channel as shown, and is supported by two screws, thus making it very rigid for heavy pressure on large work. The table is raised and lowered by means of a crank at one end. When desired, this gang drill will be furnished with independent columns for each spindle to sit on a heavy bed base with separate tables, either round or square. Either style of machine can be furnished in two, three, four or six spindles.



A Four-spindle Gang Drill, with Independent Gear Speed and Feed Changes

General strength and convenience have been carefully looked out for in this machine. Each spindle has the same capacity as the makers' all-geared 20-inch drill—that is to say, it will properly handle 1-inch twist drills in steel without back gears, or $1\frac{1}{2}$-inch drills in steel with back gears. It will drive a tap up to 2 inches in diameter in cast iron. Each head has a

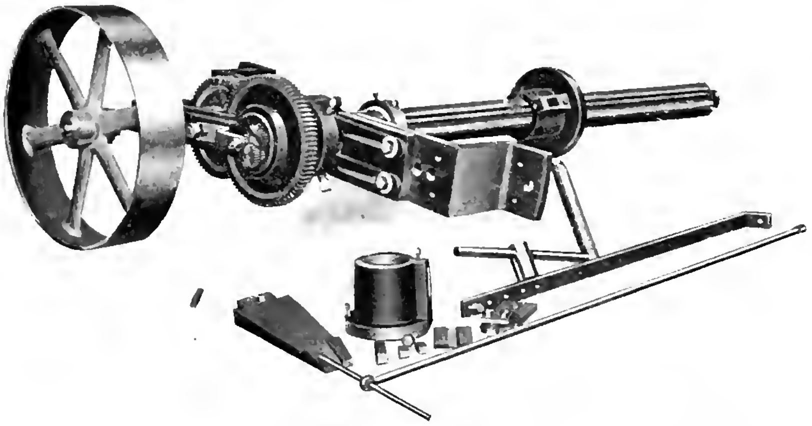
back brace which adds greatly to its strength and stiffness. The driving gearing is unusually large and strong, as is also the spindle, which is double splined. A No. 3 taper is regularly furnished on the spindle, but a No. 4 will be supplied when desired The drift hole is placed below the sleeve, so that it is unnecessary, when removing the drill, to rotate the spindle to match a hole in the sleeve.

The machine stands 72 inches high in all, and the spindles are spaced 5 inches from center to center. Each of them will drill to the center of a 20-inch circle. The vertical travel of the spindle is 10 inches, and of the table 11 inches, giving a maximum distance from the spindle to the table of 27 inches. The planed surface of the table for the 4-inch spindle machine measures 14 by 60 inches. The four-spindle machine is driven by a pulley 12 inches in diameter and 5 inches wide, running at 100 revolutions per minute.

NAPPANEE PORTABLE BORING BAR

The boring bar illustrated herewith is made by the Nappanee Iron Works, of Nappanee, Ind. It is designed for general boring, though especially adapted to the re-boring of cylinders up to 36 inches in diameter. By the use of this tool the cylinders of all kinds of engines, air compressors, steam hammers, pumps, blowing engines, Corliss valve seats, etc., can be re-bored in place in any position and in cramped quarters if necessary, such as are met with on board ship.

This tool is of the construction which provides for the supporting of the boring bar at one end by bushings in the stuffing-box bore, and at the other by a universal adjustable support, fastened usually to the flange of the cylinder. When supported in this way, cylinders can be re-bored in less time than it would take to remove them from their fixed position. All steam connections, studs, anchor bolts, etc., remain intact. Enough cutter heads, arms and tools are furnished with each size of bar to cover the full range. The bar is powerfully geared and can be driven by hand or power. The steel feed-screw is firmly mounted in the bar, giving a strong and rigid movement. The feed nut is made of brass, and is accurately fitted with a square thread, 8-pitch feed-screw.



A Portable Rig with Automatic Feed, for Re-boring Cylinders of Steam and Gas Engines, etc.

The features to which the builders desire to call particular attention are the compactness, strength and simplicity of construction. The wide range should also be noted. The No. 3 size will bore from 7 to 36 inches in diameter. The simplicity of construction enables the device to be sold at a low cost. Inquiries addressed to the manufacturers will be referred to the nearest dealer handling these machines.

LATHE GRINDING ATTACHMENT FOR INTERNAL AND EXTERNAL WORK

The accompanying illustrations show an electric grinding attachment for the lathe which may be arranged for either external or internal grinding, provision for the latter operation being made by the use of an internal attachment similar in principle to that applied to regular cylindrical grinding machines. This tool is built by the United States Electrical Tool Co., of Cincinnati, Ohio.

The grinding spindle, and the motor, of which it forms the armature shaft, are adjustable on a horizontal slide, which is, in turn, vertically adjustable on the face of a knee clamped to the swivel of the compound rest of the lathe. This method of supporting gives a feed at any angle by the adjustment of the compound rest base, and the operation of the lead-screw on the horizontal slide attachment. It also permits the centering of the wheel spindle with the center line of the lathe by the vertical adjustment of the motor and slide on the knee.

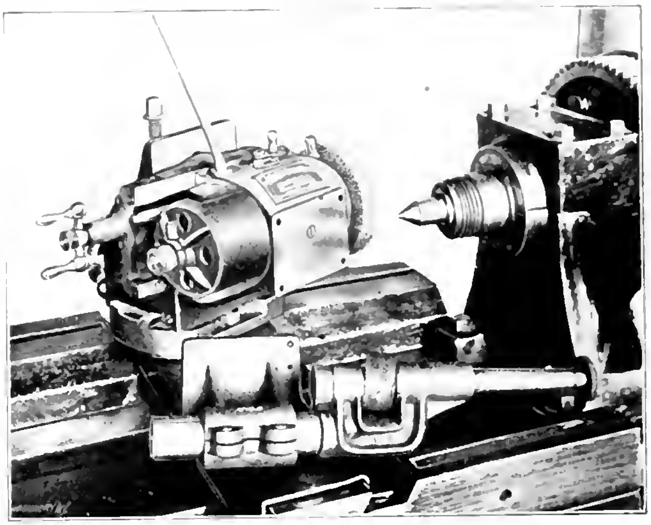


Fig. 1. Electric Grinding Attachment Mounted on Compound Rest Swivel of Lathe

Fig. 1 shows the device as used for external grinding. In this particular case the compound rest has been set at an angle to true up the live center. The wheel is fed back and forth for this operation by the feed-screw of the attachment. When arranged for external grinding, it may also be employed for sharpening reamers and cutters in the lathe, and in finishing mandrels, dies, etc., in a lathe, planer or shaper, it being evidently adaptable to surface grinding as well as to cylindrical grinding.

Fig. 2 shows the internal grinding attachment (which is dismounted in Fig. 1) attached to the face of the motor and in use grinding a hole in a die. Conical, dust-proof bearings, adjustable for wear, are also used in this attachment as well as on the main grinding spindles. The device is belt-driven by means of a large pulley on the armature shaft and a small pulley on the grinding spindle. When a 1¼-inch wheel with a ¼-inch face is used on the latter, it may be speeded up to 18,000 revolutions per minute. When arranged for internal grinding it is adapted to the finishing of dies, gasoline engine cylinders and internal grinding of all kinds.

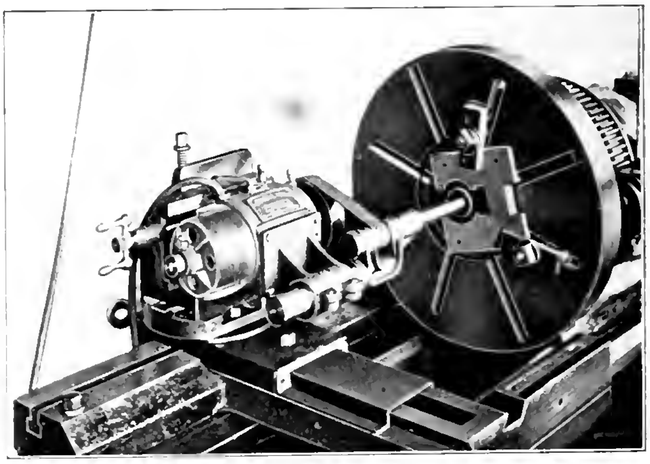

Fig. 2. Internal Grinding Spindle in Use

This grinder can carry emery wheels ranging from 4½ to 12 inches in diameter throughout the range of the four sizes for which it is made. Internal grinding attachments which will grind holes varying in depth from 4½ to 8 inches will be supplied. The motor is wound for 110 or 220 volts direct

current, or for the same voltages on a 60-cycle, one-, two-, or three-phase alternating current circuit.

GRAHAM PRESSED STEEL GRINDER CHUCKS

Fig. 1. A Chuck for a Face Grinding Wheel having a Pressed Steel Body

The Graham Mfg. Co., of Providence, R. I., has placed on the market an all-steel chuck designed for holding ring emery wheels. While intended primarily for use on machines of the disk grinder type, they are adapted also for any other machines in which the side of the wheel is used for the grinding. The main points of interest in this device are the use of a body of pressed steel without any projections to speak of, the provision of an adjustable backing flange for setting the ring out as it wears down, and the provision of a simple and effective clamping device. Care has also been taken to make the design of the centers on which the chuck is mounted such that they will readily fit machines of widely varying construction.

A reproduction of a photograph of the chuck is shown in Fig. 1, while Fig. 2 gives details of its construction. The body *A*, as has been mentioned, is made of pressed steel, turned and finished all over. While very light this has all the strength required for the work it has to do. In this respect, it is much more reliable than cast-iron or steel castings, owing to the small amount of stock which has to be removed and the avoidance of blow holes and other hidden defects.

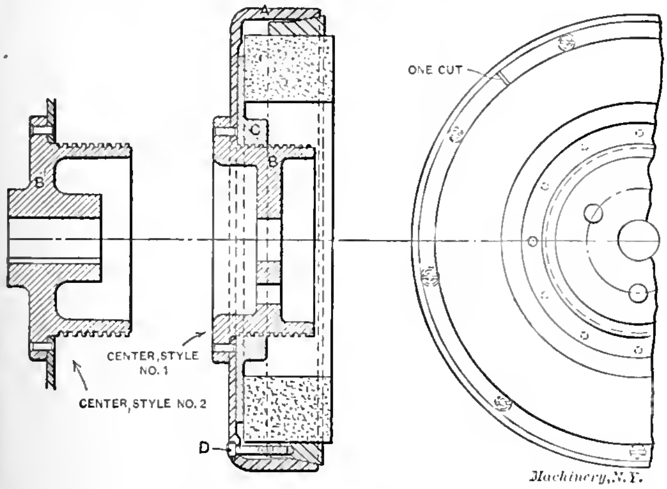

Fig. 2. Sectional View of the Graham Pressed Steel Grinding Chuck

This body is fastened by small rivets to the cast-iron center *B*, which is made to suit any style of spindle. Two examples of varying styles of center are shown, one at *B* and the other at *B'*. The first would be used for disk grinders, and the second for all kinds of face grinding machines, such as used for work on knives, safe plates, guide bars and special work. This center *B*, which is threaded on its periphery, serves also as a screw for the setting-out nut *C*. This nut is turned by a straddle wrench provided with pins to engage holes drilled for the purpose, which show quite plainly in Fig. 1.

The clamping device consists of a split ring drawn into a tapered conical bearing in the body *A*, by numerous screws *D* at the back. This ring has but one cut in it, which has been found by experience to be sufficient. This gives a very powerful and satisfactory grip. Provision is also made, when necessary, for the use of sectional blocks of emery, in place of solid rings, though this is not illustrated in either of the engravings.

Chucks of this kind are called for principally by users of disk grinders, whose work requires something less expensive and more durable than emery cloth. These chucks are known in size by the outer diameter of the grinding ring rather than the over-all dimension. In this particular design this outside diameter has been reduced greatly in comparison to that of the wheel, owing to the use of the pressed steel body. These chucks are made to take rings from 9 inches to 30 inches in diameter and weighing from 40 to 330 pounds for the different sizes. On the very largest of them the outside diameter of the body is not more than 2 inches larger than the diameter of the ring.

WRIGHT QUICK-ADJUSTING WRENCH

The Wright Wrench Co., of Canton, Ohio, and Tacoma, Wash., has designed the simple and quickly-adjusted wrench shown herewith. Fig. 1 shows the tool in the workman's hand, while Fig. 2 shows its construction. Its simplicity is evident.

It is composed, as may be seen, of two main members—the outer jaw and handle *A*, of one piece, and the sliding jaw *B*. The latter carries in a recess a toothed gripping block *C*, which engages the corresponding teeth of a ratchet strip *D* Spring *E* tends to hold the teeth of the block in contact with those of the strip and thus lock the wrench. By pressing down on the outer end of the jaw with the thumb, however, as shown in Fig. 1, these teeth are disengaged, and the thumb is free to slide the jaw to any adjustment throughout its range. Releasing the hand of the operator again sets the adjustment in the new position.

Fig. 1. The Wright Quick-adjusting Wrench

The handle and outer jaw are made of 20-point carbon, open-hearth, drop-forged steel, carbonized, mottled and hardened. The sliding jaw is made of carbonized semi-steel, also mottled and hardened. The rack and pawl are of carbon tool steel. All these parts are hardened. The spring steel wire is of oil tempered steel. The parts are milled, ground and polished before putting on the mottled finish, which resists rust and is far superior to a bright finish in durability. The carbonizing is done from the makers' special formula.

The American Locomotive Co., recently made a comparative test to destruction of a series of 12-inch wrenches, using many forms and shapes. These failed at a leverage of 7 inches from the center of the nut at pressures varying from 1,700 to 4,000 pounds. All the other wrenches fractured in such ways as to make the jaw useless. The Wright wrench became inoperative at 2,600 pounds, owing to the giving out of the ratchet mechanism. Since this can be repaired at a cost not to exceed 10 cents, it will be seen that the tool is easily made as good as new, and ready for service even at this high pressure.

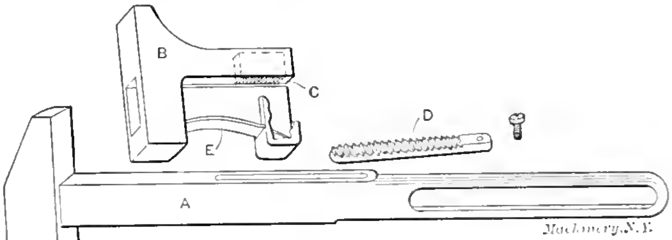

Fig. 2. The Construction of the Wright Wrench

The tool is made in various sizes from 6 inches up to 18 inches. It will take small hexagon nuts or finished screw

heads and leave them in as good condition as the ordinary screw adjustment wrench, since provision is made to avoid back lash, and the wrench will not lock on the nut or lose its adjustment while in operation.

WALTHAM CLUTCH CUTTING MACHINE

The Waltham Machine Wks., Newton St., Waltham, Mass., makes the automatic clutch cutting machines shown herewith. They are designed for cutting the ratchet-shaped teeth on the clutches used in the stem-wind mechanism of watches, or for cutting teeth of any shape on small parts, in which the direction of the cut is at right angles to the axis of the work. They are made in two styles, shown in Figs. 1 and 2 respectively. In Fig. 1 the machine is arranged to stop after the completion of the last cut so that the work may be removed and a new piece put in by hand. With the machine in Fig. 2 the mechanism runs continuously, the blanks being fed from a magazine and removed automatically from the machine.

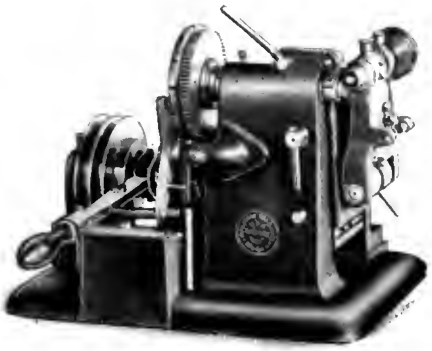

Fig. 1. Automatic Face Clutch Cutting Machine for Small Work

The blank is held by a spring chuck in an indexing spindle at the front of the machine. The cutter spindle is carried in bearings attached to a swinging arm. These bearings are normally at right angles to the axis of the work spindle but may be swiveled somewhat so that a slight undercut may be made. The swinging arm in turn is carried by a vertical slide operated by a cam. The support for this slide can be swiveled 5 degrees to either side of the vertical position, so that angular cuts can be made. Screw adjustments are provided for centering the cutter and setting it to the depth of cut. The adjustment for the location of the cut is made by an eccentric on the swing shaft.

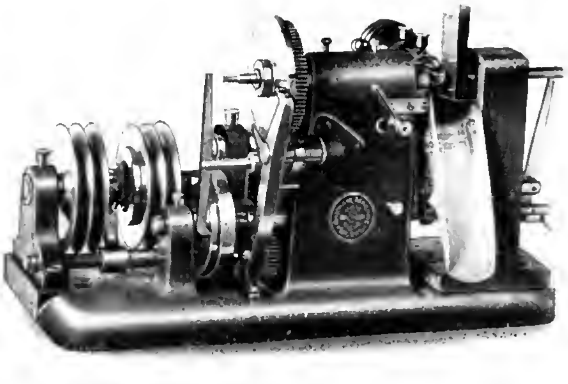

Fig. 2. Clutch Cutting Machine, with Magazine and Automatic Feed

The pitch of the feed cam is made to suit the particular work on which the machine is to be used. The cut is made from the top downwards and the cutter is swung away from the work during the return to allow for indexing. A friction indexing mechanism is used. An important provision in the machine is that for cutting the work around twice for the purpose of removing the burr on the tops of the teeth made by the first cut. This second cut is made at a considerably increased speed.

The machine shown in Fig. 2 is practically identical with that shown in Fig. 1 except for the addition of the mechanism necessary for the automatic handling of the work in placing it in the chuck and removing it after completion. The magazine in which the blanks are placed is shown extending upward at the right. The use of this automatic attachment adds from 20 to 25 per cent to the production of each machine and permits one operator to care for a large number of them. The machine illustrated here will cut teeth of 64-pitch or finer.

NORKA TWO-GROOVED HIGH-SPEED TWIST DRILL AND CHUCK

In the department of New Machinery and Tools in the April, 1908, issue of MACHINERY, we illustrated two designs of high-speed drills, made by the Whitman & Barnes Mfg. Co., of Akron, O., and Chicago, Ill. One of these was a flat drill, and the other a twist drill made of high-speed steel, twisted while hot so that the grain of the steel was not disturbed. This method of making gives these tools great strength and durability in the most refractory materials. The construction has since been improved, as shown in the accompanying illustrations, giving apparently a drill of somewhat simpler form and a more compact chuck.

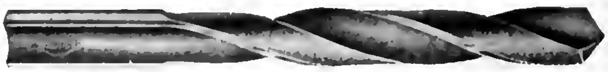

Fig. 1. The Norka High-speed Twisted Drill

The drill, it will be seen, has no tang, the driving being done on the whole length of the shank. In twisting the drill, a section of the stock is left untwisted and this part, being grooved, forms the shank. The jaws of the chuck are carefully machined to fit this groove, so that the drill is not only held securely, but centrally as well. The whole drill is ground to size, and may be used for work of the highest accuracy. It is made of "W. & B." high-speed steel, mixed to the manufacturer's special analysis, which gives the drills the necessary hardness to secure the maximum amount of work, and at the same time retains the toughness required to reduce splitting and breakage to a minimum.

Fig. 2. Special Chuck for Norka Drill

The chuck, as stated, is accurately made. The jaws are locked on the drill by a heavy clamping nut. Figs. 2 and 3 show the chuck alone, and with the drill in place, respectively. The thrust of the drill is taken (it will be seen) by a loose key inserted between the jaws at the bottom of the slot. There are thus but three pieces in this tool.

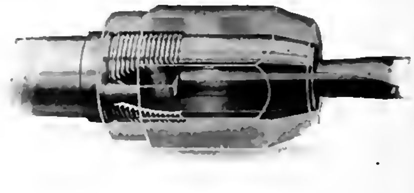

Fig. 3. Drill in Chuck, showing Long Grip in the Grooves

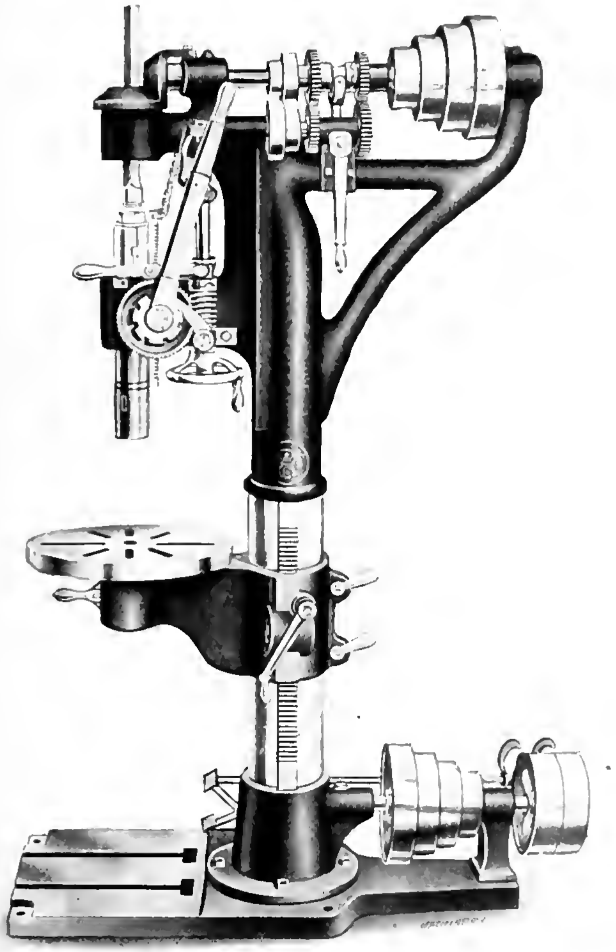
ROBERTSON 21-INCH UPRIGHT DRILL

The Robertson Drill & Tool Co., 1848 Niagara St., Buffalo, N. Y., is completing the drilling machine illustrated herewith, which combines a number of new features while retaining standard constructions which have proved their value by long use. Special attention is called to the spindle drive and to the back gearing. Instead of keying the spindle to the driving gear as usual, the spindle is made of square section, accurately fitting a corresponding hole in the gear. This obviates all danger of cramping, met with in the older construction. Its efficacy is especially noticeable in tapping. It is common, for instance, in drilling even the heaviest work, to have it raised from the table by the action of the tap, this being made possible by the side thrust or cramping

of the keyed spindle in the gear. With the square spindle drive the same piece requires no clamping, thus showing that less power is required and that friction has been eliminated to a large degree.

The back gears can be thrown in or out, or the spindle stopped, by the back gear handle shown. This can be done while the machine is running at full speed without danger of excessive shock. While the drive in general follows the lines of the standard drill press, this machine has been built throughout from original patterns and designs. No attempt has been made to meet competition by furnishing a tool which is too light and weak for the size of work it is intended to perform. A 5½-inch diameter column is provided with this 21-inch drill, and the diameter of the spindle through the quill is 1 9/16 inch. The table is raised by a crank operated through a self-locking worm gear and pinion. All clamps are provided with attached handles, making the use of wrenches unnecessary.



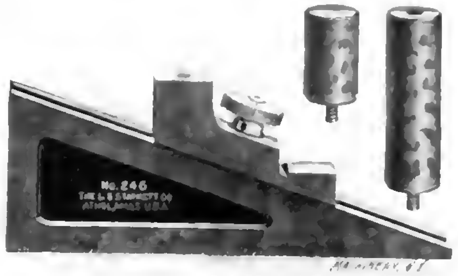
Heavy Duty Drill, with Power Feed and Automatic Stop

The following dimensions will give an idea of the capacity and rigidity of the machine: Diameter of the column, 5½ inches; total height of the machine, 60 inches, and net weight, 650 pounds. The counter-shaft runs 250 revolutions and has tight and loose pulleys 8 inches in diameter for a 2½-inch belt. The largest step of the cone pulley is 9 inches, and the smallest 4½ for the 2½-inch belt. The machine will drill to the center of a 21¼-inch circle. The table is 15¼ inches in diameter, and has a vertical travel of 40 inches. The vertical travel of the spindle is 10 inches; it has a No. 3 Morse taper hole. All parts are well ribbed and of good workmanship. The gears are cut from the solid, the racks and small pinions being cut from steel. The plain wheel and lever are power-fed, and automatic stop and quick return are provided.

STARRETT PLANER AND SHAPER GAGE

The L. S. Starrett Co., of Athol, Mass., has added to its line of machinists' tools, the convenient planer and shaper gage shown herewith. This gage is of the adjustable wedge type; it is made of drop-forged steel and is so constructed as to give a wide range of measurements. It can be set to any dimension from ½ to 5½ inches. As may be seen, gage surfaces of two different heights are provided, and the upper one is arranged to be extended by the use of the screw blocks shown, either or both of which may be used.

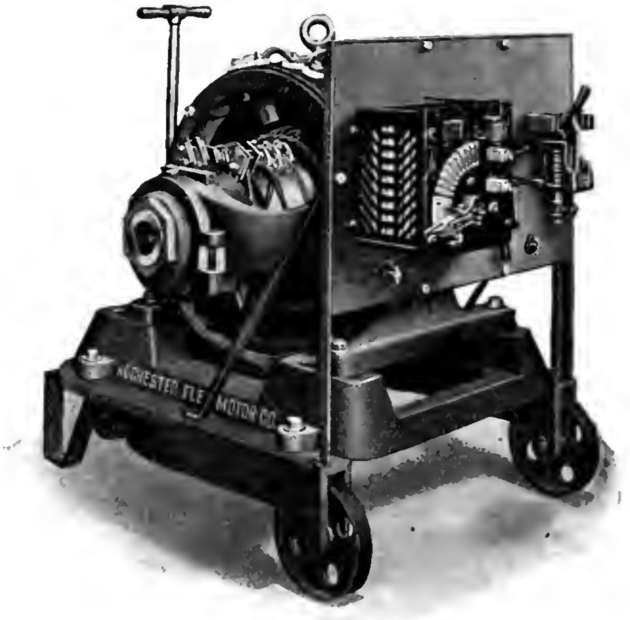
It will be found convenient on other work besides planing. It is very useful, for instance, on the miller, where slots are to be machined. The gage can be inserted in the slot and the blocks adjusted until a perfect fit is obtained. Then the tool may be removed and the exact measurement taken by the use of a micrometer. Where a close measurement is required, the tool can first be set by the micrometer and then used as a standard gage. It is case-hardened and carefully finished.



An Adjustable Gage for Setting Planer and Shaper Tools, etc.

ROCHESTER PORTABLE MOTOR

In shops where the individual drive has not yet been adopted, there are times when the shafting of a whole building or, at least, a whole department, has to be kept running in order to furnish power to a single tool on which overtime work has to be done. To meet the demands of one of its customers who was often in this predicament, the Rochester Electric Motor Co., Rochester, N. Y., designed the portable outfit illustrated herewith. It was so successful that a second was made for the same customer, and since then several have been made for others.



A Portable Motor for General Emergency Work in Machine Tool Driving

These outfits (see the accompanying engraving) comprise slow-speed motors mounted upon iron trucks, with permanent connections between motor, rheostat, switch and circuit breaker. Heavy clamping terminals permit the motor to be connected up to the service wires very quickly. The design of the truck is such that with the handle in a vertical position, the weight of motor is thrown upon the forward wheels, effectually blocking them. The wheels are mounted on an eccentric axle, so that lowering the handle for moving the outfit raises the weight from the wheels. The forward wheels

are located close together, making it possible to manoeuver the truck in cramped quarters.

The builders also furnish portable trucks with variable speed motors, to be used in case of breakdown of the motors on individually driven machines. One customer has a variable speed motor equipped with a back geared shaft, making it possible to connect quickly with almost any drive in the shop.

MORROW QUICK-RELEASING BALL BEARING CHUCK

As mentioned in a note in the New Tools department of the November, 1908, issue of MACHINERY, the Morrow Mfg. Co., of Elmira, N. Y., makes a ball-bearing drill chuck, so constructed that the knurled sleeve gives positive control to the jaws in all positions, and holds them square with the drill. The provision of the ball bearing makes it possible to get a very firm grip with the jaws with comparatively little effort on the part of the operator. The construction also is such that the driving force exerted on the drill tends to tighten it in place. This tool has recently been improved by the incorporation of a quick-releasing device which permits the loosening of the chuck jaws with a very light twist of the hand, even though the turning force applied to the drill may have tightened the jaws up very strongly. Fig. 1 shows a chuck made on this plan, while Fig. 2 is a sectional drawing illustrating the details of the design.

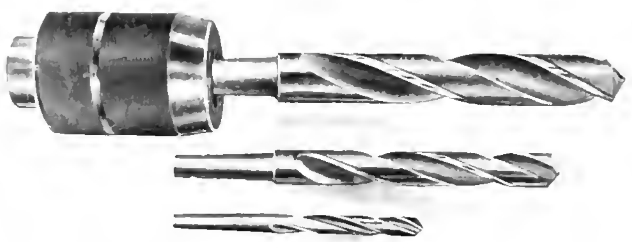


Fig 1. The Morrow Quick-releasing Ball-bearing Chuck

Referring to Fig. 2, which shows the construction most plainly, *A* is the body of the chuck, by which it is held in the spindle of the machine. On the nose of *A* is fitted a revolving sleeve *B*, held in place by the threaded collar *C*. A ball bearing and shoulder on *A* are shown, which serve to retain *B* and *C* in place and permit them to be turned easily in tightening the drill, as will be explained later. *B* is slotted radially to hold three jaws *D*. An outer sleeve *E* with an inner taper seat, threaded solidly onto *B*, furnishes the abutment surface by means of which jaws *D* are pressed down onto the drill. These jaws have dove-tailed slides machined on their inner faces, which fit radial dove-tailed slots in plate *F*. This latter has a shank with a short square thread fitting the bore of sleeve *G*. This sleeve is provided with a fine pitch square thread on the outside diameter, fitting a corresponding seat in body *A*. A slot milled across the face of sleeve *G* permits the insertion of a pin *H* in the shank of *F*, which is thus allowed a limited rotary movement with reference to *G*.

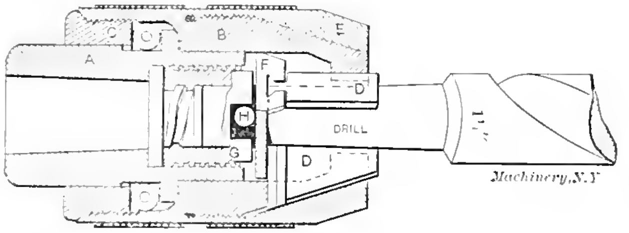

Fig 2. The Construction of the Morrow Chuck

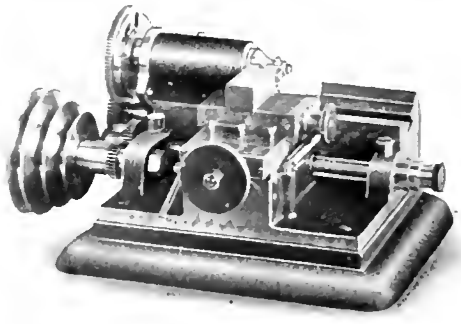
The action of the chuck will now be understood. The drill being inserted in place, the hand of the operator grasps the knurled periphery of sleeves *B* and *E*, which revolve together, turning jaws *D* and with them the plate *F* to which they are dove-tailed. This, in turn, by the action of the pin *H* in the slot in *G*, revolves the latter and screws it out to the right from its threaded seat in body *A*. This, in turn, forces *F* and jaws *D* outward to the right; forcing all the jaws against the inner conical seat of sleeve *E* simultaneously, thus strongly gripping the shank of the drill. The thrust of the outward pressure of jaws *D* is taken on the ball bearing between the sleeve *C* and the shoulder on body *A*.

In loosening the drill, the workman grasps the periphery of the chuck and turns it in the opposite direction. Parts *B*, *C*, *E*, *D*, *F*, *H* and the drill all revolve together. *G* remains stationary for the moment, however, since the slot in its face permits a slight free rotation of the pin *H*. This slight rotation screws inward the coarse threaded shank of *F* in the sleeve *G*, withdrawing it rapidly to the left, and loosening the chuck jaws. The lead of the coarse thread on the shank of *F* is so great that the hand readily screws *F* back and loosens the drill no matter how tightly the latter may have been held. In tightening the drill in place again, *G* remains stationary as before until pin *H* strikes the other side of the slot, when conditions are again as shown in Fig. 2.

This construction gives the greatest facility in handling a chuck of this type without the aid of a spanner or wrench even on sizes running over ½ inch capacity. The particular chuck illustrated (which is known as the makers' No. 5½) was designed to use up drills from which the tangs have been twisted. The body of the chuck is 3 inches in diameter by 4 inches long and will hold Nos. 1, 2, and 3 taper shanks, thus giving a range of drills from ¼ inch to 1¼ inch which may be rescued from the scrap heap. The chuck will safely hold a 1¼-inch drill to its full capacity without slipping, or straining the hand of the operator. The No. 4 chuck for straight drills takes from ¼ to ¾ inch, and No. 5 from ½ to 1 inch. All parts are hardened and ground accurately to size.

WALTHAM CUTTER TURNING AND BACKING-OFF MACHINE

The machine illustrated herewith is built by the Waltham Machine Works, Newton St., Waltham, Mass., and is intended for the work of turning and backing off minute precision formed cutters.



Lathe for Turning and Relieving Minute Formed Cutters

The machine consists, as may be seen, of a head-stock of the lathe, mounted on a base provided with a cross-slide for the forming tool. The backing off or relieving of the cutter teeth is obtained by a cam on the driving shaft connected to the lower cross-slide by means of a reducing lever. The driving shaft is connected with the work spindle by a train of gears. For the change gears regularly furnished, any number of teeth from 4 to 16 may be backed off. By the use of special gears it is feasible to back off cutters having as many as 20 teeth.

The depth of cut is gaged by a hand-wheel graduated to one-half of a thousandth of an inch, on the feed-screw on the upper cross-slide. The side adjustment of the tool is obtained through the longitudinal slide adjusted by a screw having a hand-wheel graduated to one-thousandth of an inch. Either circular or rectangular tools may be used.

An important feature of the machine is the provision for reversing the head-stock on the bed—that is to say, placing it either to the right or the left of the tool-slide. This permits the cutting of both sides of a cutter with a single tool, thus giving assurance of absolute symmetry in the finished shape of the cutter. As the profile of the bed to which the head-stock is clamped is an arc, having its center identical with that of the work spindle, the reversing of the position of the head-stock has no effect on the distance of the work from the tool. The second setting thus gives the proper

position and the proper diameter of cut to match with the first.

The machine can be used for turning cutter blanks or circular form tools, as well as for backing off teeth. By turning the lever at the left of the cross-slide, the cam becomes inoperative, and when the lower side is clamped by the lever on the right, the two remaining slides can be used the same as a compound rest on the lathe. The machine will hold rectangular forming tools up to ⅜ inch square and circular tools from 1 to 1¼ inch in diameter. Although of small size, the machine is very stiff. The base measures 11 by 14 inches and the net weight is about 100 pounds. The work spindle, cam-shaft bearings, etc., are made of hardened steel, and the finish and workmanship are intended to meet the highest requirements of watch machine construction.

GERSTNER PORTABLE TOOL CASES

H. Gerstner & Sons, 871 Germantown Ave., Dayton, O., are manufacturers of a line of tool-chests and cabinets particularly adapted to the needs of skilled mechanics. They have recently perfected a line of portable tool-cases made in a number of styles and sizes, of which one is here illustrated. Particular features of these tool-cases are their neatness and careful finish, and their compactness. Every inch of available space has been utilized in them, and the tools may be placed in separate drawers where they can be kept in good condition and easily picked out when needed. This gives a much more orderly and systematic arrangement than is afforded by the older style of chests. A convenient feature of style No. 31, shown herewith, is a patent self-hinging lid with a felt-lined tray, which will slide in under the bottom drawer and out of the way if desired, leaving the case in the form of a chest of drawers. When, however, the drawers are closed and the lid is brought up and fastened, the case is safely locked, permitting it to be carried from one job to another with a full kit of tools.

A Leather-covered Portable Tool Case for Machinists' and Toolmakers' Use

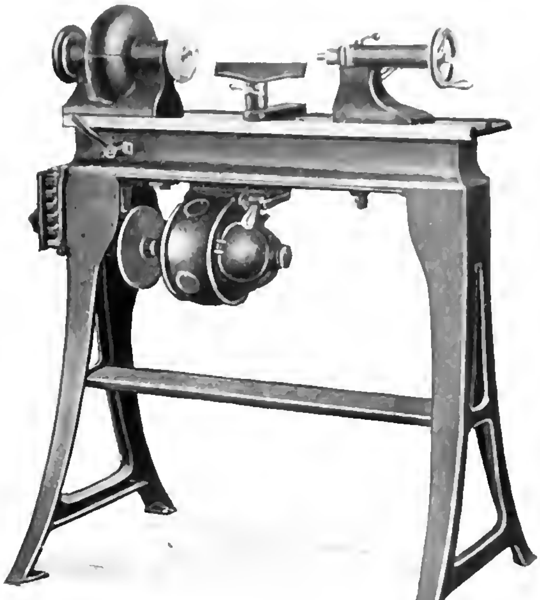
These cases are substantially constructed, of seasoned lumber, and are either lock-cornered or dove-tailed, with all parts that are liable to warp well paneled. They are finished in quartered oak, or are covered with the genuine or the best quality of imitation black seal leather. When covered, these cases are also finished in cherry or mahogany if desired. Drawers are lock-cornered and glued, with sheet metal bottoms covered with the best quality of heavy green felt. They are finished with shellac throughout. The trimmings are in harmony with the design, and of sensible construction. They are of highly polished brass, either lacquered or nickeled.

Besides cases and chests for tool-makers and mechanics, this firm makes a line of cases for draftsmen, electricians, and metal-pattern makers. Orders are solicited for special tool-cases, which will be built as desired by the customer in matters of style, size, price, etc.

MOTOR-DRIVEN SPEED LATHE

In the department of New Machinery and Tools in the April and May, 1908, issues of MACHINERY, we described two friction-driven sensitive drill presses manufactured by the Washburn Shops of the Worcester Polytechnic Institute. The satisfactory operation of these tools has led to the adaptation of the same principle to a speed lathe, intended for service on both wood and metals. This lathe is illustrated in the accompanying engraving. The advantages of this particular type of friction drive are the instant control of the speed variation, the starting and stopping of the lathe independent of the motive power, the automatic control of the power transmitted from the driving shaft, whereby the power consumed varies directly as the work requires, and the use of a constant speed motor so that the full efficiency of the motor is available for the slower speeds.

The illustration shows the motor-driven type. The motor is hung from the lathe bed at such an angle that it does not project in front of the bed, and is never in the way of the operator. The power is transmitted from the motor to the main spindle by means of a double roll and disk friction The pressure of the disks on the rolls is controlled automatically by means of a cam clutch. This cam clutch acts as a positive drive or tightener, and increases or decreases the pull of the disk on the roll directly as the work requires, the pressure between the disks and rolls being very slight except when turning. This construction is the same as used for the drill presses previously described.



Variable Friction Drive Speed Lathe, built by Washburn Shops of Worcester Polytechnic Institute

The variation of spindle speeds is obtained by throwing the lever near the head-stock. This lever is attached to a segment gear which meshes into a rack cut in the roll carrier, the extreme movement of the rack being only 2 inches to obtain a range of speeds of over 4 to 1. This sliding of the rolls across the disk is easily accomplished, as there is slight normal pressure on the rolls except when the machine is working. The motor is run at 1,800 R. P. M. and the drive is so designed that a speed variation of the spindle is obtained ranging from 600 to 2,650 R. P. M. The spindle is stopped, without stopping the motor, by throwing the speed lever to its extreme position. When in this position, the driver disk is out of contact with the rolls, the disk being recessed for this purpose. This also permits starting the motor without load. The disk on the spindle is wholly enclosed by the head-stock and a moveable cap, and a hand wheel is provided on the end of the spindle for use as a brake and for placing the work. A noticeable feature is the smoothness of operation due to the entire elimination of belts.

The lathe is fitted with either a direct current or induction motor, or a special single-phase motor may be used whereby the lathe can be run from the ordinary lighting circuits. This makes the lathe of special value for house or garage use. The

lathe may also be fitted to run at slower speeds for metal work and in this case is provided with draw-in chucks and a side rest.

INGERSOLL COMBINED HORIZONTAL AND VERTICAL SPINDLE MILLING MACHINE

Our readers will remember that we published, as a leading article of the New Tools department in the June, 1908, issue of MACHINERY, a description of a combined horizontal and vertical spindle milling machine built by the Ingersoll Milling Machine Co., of Rockford, Ill. Since putting out this first design, the makers have added certain improvements in mechanism and structure which materially increase the stiffness and convenience of the machine. It is now also furnished in two sizes, thus covering a wider range of usefulness. Figs. 1 and 2 illustrate the two sizes of these machines, while Fig. 3 shows quite plainly the mechanism of the larger of the two.

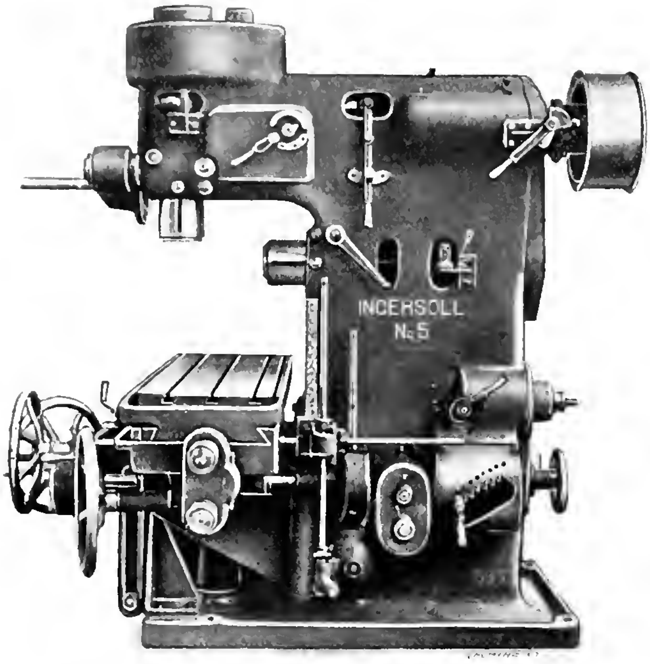


Fig 1 The Largest Size of the Ingersoll Combined Vertical and Horizontal Column Type Miller

General Construction

A brief general description of the tool will not be out of place before calling attention to the particular points of improvement in the new design. Below the horizontal spindle the machine is similar in appearance to the ordinary column-and-knee type milling machine. Above the horizontal spindle, the column has been brought forward to furnish a housing for the vertical spindle, which is as solidly supported as in any approved type of regular vertical milling machine. This spindle is well out from the face of the column, and a long knee is provided, thus giving a large cross-feed movement. To prevent this from weakening the machine, heavy knee supports are provided on the No. 5 size.

The machine is gear driven throughout, both as to speeds and feeds, the latter being taken (as required by modern practice) from a constant speed driving shaft. Longitudinal, cross and vertical power feeds are provided, all reversible and all controlled by automatic stops.

Changes in the Drives

Perhaps the most radical change in the new design is in the spindle driving mechanism. This, as may be seen in Fig. 3, provides for 16 changes of speed, applicable alike to the vertical and horizontal spindles, the final or "back-gear" change for the two spindles being independent. Fig. 3 shows a motor-driven machine. In the belt-driven machines, such as shown in Figs. 1 and 2, the driving gear *A* is replaced by a constant speed pulley. The inner surface of the flange of this gear or pulley (as the case may be) forms a seat for the conical clutch member *B*, which is pressed into engagement by a spring as shown, and is thrown out of engagement by lever *C*. This clutch and spring furnish a safety device to limit the driving power to a point which the machine will safely stand. Four gears *D* on the constant speed driving shaft mesh with four mating gears *E* on the variable speed shaft *F*. This latter is shifted axially by a lever having four positions, as shown just at the right of the vertical spindle in Fig. 1. It carries clutch teeth engaging corresponding internal clutch teeth on extensions of gears *D*, so that each of its four positions gives the corresponding one of four changes of speed.

On shaft *F* are also keyed the double gears *G*, which engage corresponding gears *H* on shaft *J*. Shifting gears *G* by the lever shown entering an opening at the top of the column in Fig. 1, doubles the four speeds previously obtained. Shaft *J* is connected by bevel gears as shown with the back-gearing *K* on the vertical spindle, where the eight speeds previously obtained are doubled to 16 by the shifting of the clutch sleeve *L*, to engage either upper or lower gear *K* with the vertical spindle. In a similar way shaft *J* is connected by a train of spur gears with similar back-gears *K* and sliding sleeve *L* on the horizontal spindle. The handles for throwing the back-gears are plainly shown in Fig. 1, and this back-gear mechanism is the same as described for the earlier machine; as is, also, the axial adjustment provided for each of the two spindles and the form of spindle bearings used.

The older machine gave four changes of speed only from the driving shaft instead of the 16 here provided. The new design thus obviates the necessity of speed changes in the counter-shaft, and permits the use of a constant speed motor drive.

The Feed Mechanism

Instead of being driven by a chain, the feed mechanism is connected with the constant speed shaft by a vertical shaft *M* and bevel gears. The same frictional spring driving device *N* is used to prevent breakage of the feed mechanism. The gear box, which is inclosed within the column of the machine, is of the familiar tumbler gear type, with added changes by means of shifting gears and clutches giving 16 variations for the No. 3 machine and 32 for the No. 5 machine.

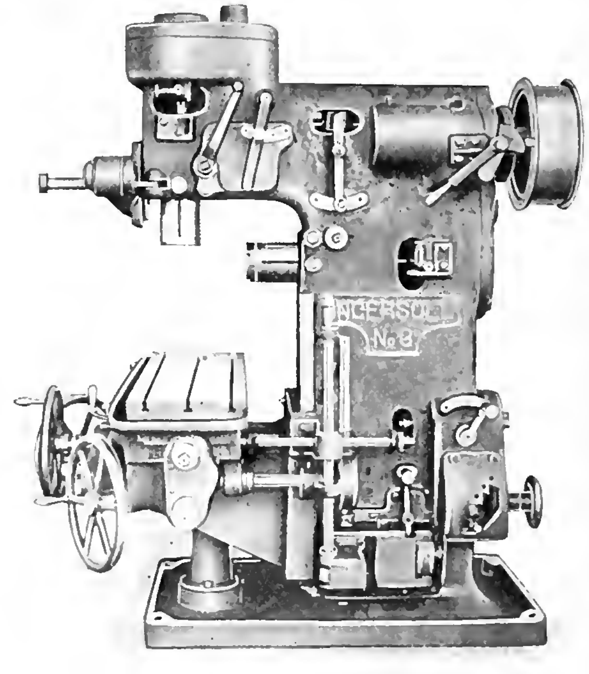

Fig. 2. The Smaller, or No. 3, Size

All the feeds are reversed from the bevel gear reversing mechanism at *O*. The reversing clutch at this point is operated by the vertical rock shaft *P* which is geared with the horizontal rock shaft *Q*, and connected by a reach rod with the reversing lever *R* at the front of the knee. The regular stop dogs on the front of the table operate this reversing lever for stopping the longitudinal feed in either direction. The stops for the automatic cross-feed are shown at *S* and *S*. They are adjustable on rock shaft *Q*, and by means of in-

clined cam faces acting on similar engaging faces on stationary support *T*, shaft *Q* is rocked at the extremes of the desired movement; this, through the connections described, throws the reversing clutch to the central or off position. Similar adjustable dogs *U* on the vertical rod *P*, engage corresponding cam faces on *T*, and furnish the automatic stop for the vertical travel of the knee. Slip clutches are provided at the various feed screws for connecting each of the feeds in the three directions, and hand-wheels are conveniently placed for operating them manually without interference with each other.

Minor improvements in construction that will be noticed are the more rigid design of the overhanging arm, the more compact arrangement for the machine as a whole in spite of the stockier design, and the convenient provision for motor driving when desired, as shown in Fig. 3. It should also be mentioned that a spring counterweight is provided for the knee of the No. 5 machine.

Dimensions and Range of Feeds

The following dimensions will give an idea of the capacity of the two sizes of this machine. The No. 3 machine has a table whose working surface is 14 inches wide by 48 inches long. The longitudinal feed is 39 inches, the cross-feed 11, and the vertical feed 15 inches. Sixteen changes of feed are provided ranging from ½ to 20 inches per minute. The spindle is of open-hearth crucible steel, running in phosphor bronze bearings, and has a No. 12 Brown & Sharpe taper hole. The 16 spindle speeds range from 13 to 350 revolutions per minute. The table will take in 23 inches under the vertical spindle, as a maximum, and 2 inches as a minimum. The distance from the center of the horizontal spindle to the top of the table ranges from 15 inches to 0. The distance from the center of the vertical spindle to the face of the column is 16 inches. The shipping weight of the machine is about 7,500 pounds.

The corresponding dimensions for a No. 5 machine are as follows: The working surface of the table is 20 by 60 inches, and the longitudinal, cross and vertical feeds are 59, 15 and 16 inches respectively. Thirty-two changes of feed, varying from ⅝ inch to 24 inches per minute, are provided. The spindle has a No. 16 Brown & Sharpe taper hole. The spindle speeds are the same as for the smaller machine. The capacity of the table under the vertical spindle ranges from 26 inches maximum to 4 inches minimum. The distance from the top of the table to the center of the horizontal spindle ranges from 16 inches maximum to 0 minimum. The center of the vertical spindle is 20 inches from the face of the column. The shipping weight is about 15,400 pounds. A circular table with automatic feed will be provided for either of these machines at an extra cost.

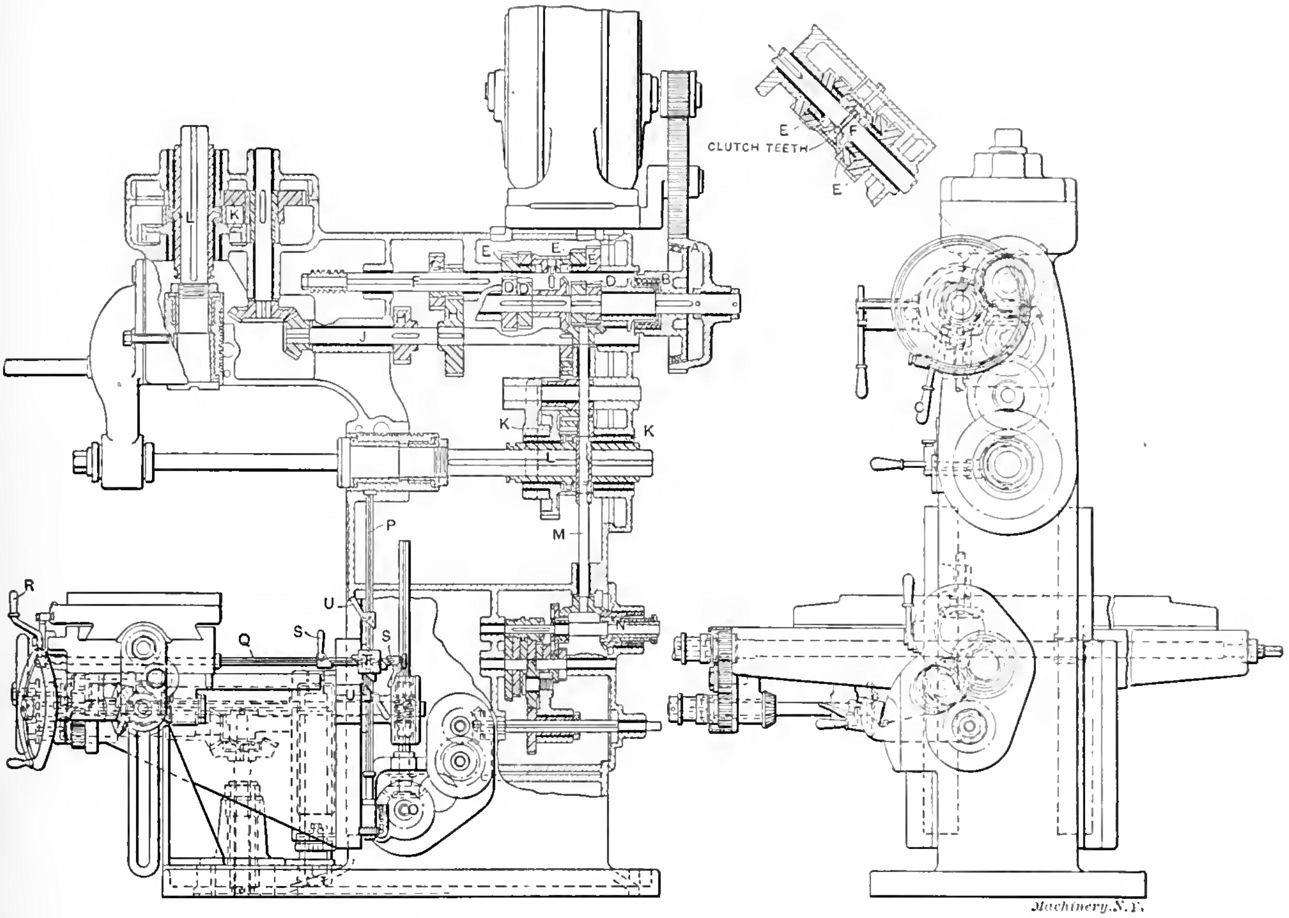

Fig. 3. The Feed and Drive Mechanism of the No. 5 Machine

OBERMAYER BLUE LEATHER BELLOWS

The ordinary bellows used by foundry men gives a great deal of trouble from the cracking of the leather which, being the most vulnerable part of the tool, shortens its period of usefulness. The Obermayer Co., of Cincinnati, O., has succeeded in producing a bellows with a specially prepared leather, which is unusually soft and pliable, thus doing away with most of the danger of cracking. The treatment which the leather receives gives it a deep blue color and this, in combination with a careful oil-soaking process, produces the required flexibility. The bellows is strongly made in all respects. It is fitted with a short steel spout which will not be crushed, broken or rusted, in the treatment ordinarily received around the foundry.

FRANKLIN MOORE CO.'S IMPERIAL HOIST

The Franklin Moore Co., of Winsted, Conn., has designed and placed on the market a chain hoist with a number of innovations which tend to increase its strength, efficiency and general handiness. Among other improvements is a new method of supporting the load sprocket from the hook, and an improved brake mechanism. The construction also permits a very compact design, requiring small head room, and gives a total weight for the apparatus which is considerably less than for older designs of the same capacity.

The general appearance of the Imperial hoist is shown in Fig. 1, while the details of its construction will be plain from the line engraving, Fig. 2. The hand chain wheel *A* is connected (through the brake mechanism) with shaft *B*, which has formed on it a pinion *C*, meshing with similar gears *DD* on a pair of similar intermediate shafts *E*. Shafts *E*, in turn,

carry pinions *F*, which mesh with the large gear *G* on the load sprocket shaft. This latter is supported on roller bearings in hangers *H*, to the upper end of which the hook *J* is pivoted. It will thus be seen that the load is supported from sprocket *K* through hangers *H* to the hook, without putting any strain whatever on the cast iron casing of the hoist. These hangers or yokes are made of steel. This avoids the possibility of an accident due to imperfect castings—a risk which is always taken where the top hook is fastened to the housing. The method of gearing employed effects a considerable reduction in friction loss as well, since the housing or casing is free from strain, permitting all the other shafts and gears to run freely. This, in combination with the ball bearing support of the load shaft, gives a high hoisting speed with comparatively little force exerted by the operator. The fact that the load is supported so directly also, without requiring a heavy, strong casing, explains the reason why the hoist can be made compact and of light weight.

Fig. 1. The Imperial 2-ton Chain Hoist

The operation of the brake will be easily understood from Fig. 2. In hoisting a load the direction of rotation of the sprocket wheel *A* is such that it is screwed on threaded shaft *B* toward the right, tightly clamping leather washer *M* between friction members *N* and *O*, so that *A*, *M*, *N*, *O* and shaft *B* revolve together as one member. If now the operator releases the hand chain, the tendency of the mechanism would be to run back, if the load is heavy enough. This is prevented, however, by the fact that friction plate *N* is provided with a ratchet mechanism (not shown in the engraving) which prevents it from rotating backward, and as *A*, *M*, *N*, *O* and *B* are all clamped together, the load is held stationary. If sprocket wheel *A* is rotated backward by hand chain

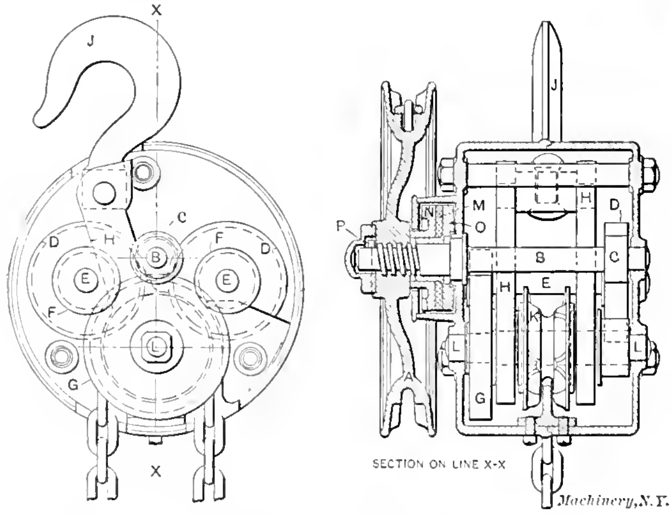

Fig. 2. Mechanism of the Imperial Hoist, showing Improved Brake and Suspension

to lower the load, it is first unscrewed to the left on the threaded shank of shaft *B*, thus releasing friction surfaces *M*, *N* and *O*, and permitting the work to descend in spite of the stationary disk *N*, as long as hand wheel *A* is revolved. When this is again left stationary the rotation of *B* under the influence of the load, screws it into the hub of *A*, thus again drawing the surfaces on *M*, *N* and *O* into tight contact, and stopping the rotation against the stationary disk *N*. Pin *P* prevents *A* and *B* from unscrewing more than is necessary to give a free but easily controlled descent. The load thus descends rapidly and smoothly and with perfect safety.

Great pains have been taken in the construction of this line of hoists in the matter of selecting suitable materials which would give satisfactory wear under the continued abuse to which chain blocks are subjected. The working parts are accurately made on high-class machinery, and are all thoroughly protected by the enclosed two-piece housing provided. The Imperial hoist is made in a number of sizes, ranging from ½ to 20 tons capacity.

BLEVNEY AUTOMATIC POLISHING MACHINE FOR FINISHING PUNCHINGS

John C. Blevney, 216 High St., Newark, N. J., has built for some years a form of polishing machine, which has come into extensive use for finishing metal surfaces of all kinds. The distinctive feature of this polishing machine is its use of two belts. The inner belt is usually made of leather, perforated and ribbed, as described later, to give a better grinding action. This inner belt does the driving. The outer belt is composed of emery cloth and rides over the lower belt, passing around one of the two pulleys on which the latter is carried, and then over an idler of its own, by means of which the proper tension is maintained on it irrespective of the heavier tension given to the driving leather belt. This construction, originally applied in the regular vertical machine of the builder, can easily be followed in the horizontal arrangement of the automatic machine illustrated in Figs. 1 and 2.

Arrangement of Driving Belts

In arranging this machine for the automatic finishing of punchings and other flat steel parts, the belts were arranged to run horizontally in order to design the feeding mechanism to the best advantage. The structure of the machine is of a light but rigid design, and carries stiff cylindrical bars on which the various idler and driving pulleys and other operating mechanisms are adjustably mounted. The driving belt from the main line-shaft is led to tight and loose pulleys at the right of the base of Fig. 1. The counter-shaft on which these pulleys are mounted is adjustable on the bar by which it is supported to give the proper tension to the driving belt; this latter extends diagonally upwards in Fig. 2 to the driving shaft of the polishing belts. The driving shaft is mounted on a fixed support clamped to the upper bar as shown, and it carries on its other end a pulley for driving the inner or leather belt of the double belt system. This passes over an idler at the right of Fig. 2. This idler pulley is mounted in adjustable bearings and the proper tension on the belt is maintained by the lever and weight shown, acting through the chain connection with the sliding journal support. The grinding belt proper, of emery cloth, lies over the leather belt and extends back to the idler at the left of Fig. 2. This idler is also mounted on a sliding journal in the upper bar, and is provided with a lever and weight arrangement for giving it the proper tension. This tension is less, of course, for the emery cloth than for the leather belt.

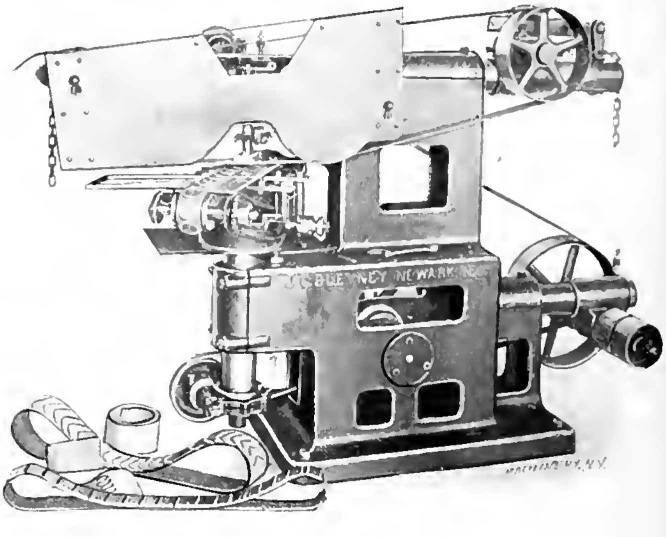

Fig. 1. Blevney Horizontal Grinding and Polishing Machine, with Automatic Belt Feed

Feed Mechanism

So far the general arrangement of the machine is identical with that for the original vertical design. The improvement consists in the addition of the automatic feeding mechanism shown. This consists of a holder provided with driving and idler pulleys so mounted as to rotate a leather feeding belt across the under surface of the grinding belt. The frame in which these feed belt pulleys are mounted can be adjusted so that the belts cross each other at any desired angle, thus giving an opportunity to cross the grinding marks when roughing and finishing cuts are taken. On the feeding belt are riveted suitable metal strips or pins for confining the punchings or other parts which are to be finished. The movement of the feeding belt is continuous, being driven by the chain and sprockets shown in Fig. 1, operated by bevel and spur gearing from a vertical shaft through the center of the column on which the mechanism is mounted. Connection with the counter-shaft at the rear of the machine is made, as shown in Fig. 2, by a pair of three-step cone pulleys, which provide means for varying the rate of feed.

The operator sits at the front of the machine (Fig. 1) and places the punchings in the holders on the constantly moving feed belt. The mechanism is carefully guarded on the operator's side, by the removable sheet iron guard shown. The machine has a capacity for finishing punchings of 1 square inch surface at the rate of 4,000 per hour.

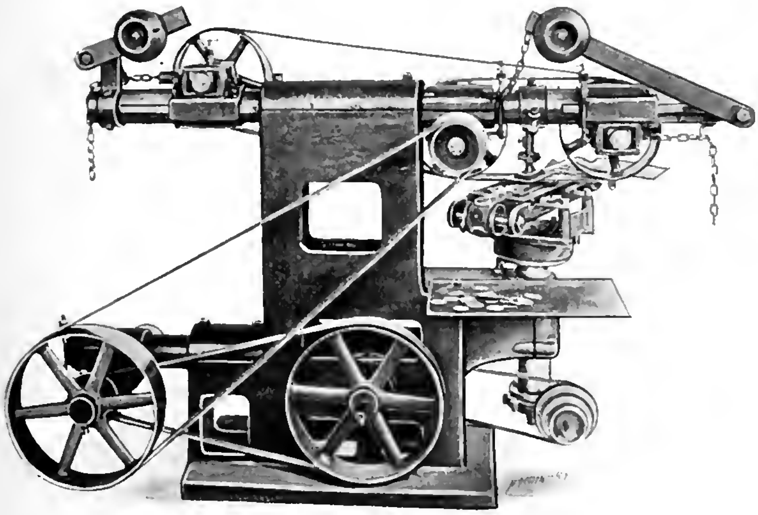

Fig. 2. Rear View of Machine, showing Drive and Tension Mechanism

Pressure for polishing is produced by the spring and weight controlled presser-plate, shown immediately above the belt in Figs. 1 and 2. A latch is provided for raising this plate off the belt when no work is beneath it and a stop is also furnished to limit the thickness to which the work is ground, and to prevent, as well, the grinding of the feed belt and its holders when no work is passing through the machine. The feed belt itself runs on a metal plate. The surfaces finished are thus true with each other, the belts being held between two flat metal surfaces.

Construction of Belts

The construction of the belts is interesting in a number of respects. The inner or driving belt is usually made of leather, ribbed as shown in the sample on the floor at the base of the machine in Fig. 1. This ribbing raises corresponding ribs in the thin emery cloth belt which runs over it, giving alternate grinding and relieving surfaces to the belt; this gives provision for taking care of the dust produced by the grinding, and prevents clogging with grains of emery, as would be the case if its surface were smooth and unbroken. In this respect the action of the ribbed belt is similar to that of the grooved surface so largely used for disk grinders, though it has the advantage over the latter that the ribs constantly change position, as the emery belt is constantly changing its position with relation to the leather belt by which it is driven. The dust which collects in the recesses between the ribs is easily thrown off on the revolving pulleys, and the belt is kept cool as well by its rapid motion.

For accurate flat grinding the inner leather driving belt may be replaced by an endless steel belt. This, however, does not give so good a cushion for polishing as leather. An improved form of joint is used in forming the light emery belts. This joint is shown in the section of belt on the floor in Fig. 1. It consists of a series of interlocking fingers cut from each other in the belt, inserted in each other, and then glued and dried under pressure. This results in a joint as strong as the original belt, and at the same time of the same thickness, if properly pressed. It is made without waste of stock. The belt in the foreground is a feed belt for plain washers of a considerable range of diameter; these are inserted between the tapering steel plates provided.

A Friction Roller Attachment for Making Fine Adjustments on the Beam Caliper

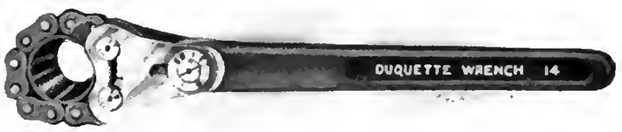
Besides the automatic features in this particular machine, this system of grinding offers evident advantages in the way of rapidity of action, simple use of the emery cloth, and provision for the rapid change of grinding material. The bearings are dust-proof and the machine is strongly driven. The maker is prepared to furnish machines of the same principle constructed for the hand or automatic finishing of almost any work for which polishing by emery cloth is adapted.

IMPROVED ADJUSTMENT FOR COLUMBIA CALIPERS

The E. G. Smith Co., 134 No. 3rd St., Columbia, Pa., maker of the well-known "Columbia" line of machinists' tools, has recently improved the standard beam caliper, as shown in the accompanying engraving, by the addition of an ingenious attachment for making fine adjustments. This new attachment, which the makers call the "fine roll," is exceedingly simple. It consists of a roller straddling the scale, and pulling the sliding head along forward or backward as required. It does this very smoothly, and delicate adjustments can be made with much greater rapidity and ease than with the old style adjusting screw. This attachment is furnished with any of the maker's calipers.

"DUQUETTE" TWO-WAY PIPE WRENCH

The chain pipe wrench shown herewith is made by the Toledo Wrench Co., 1507 Nicholas Building, Toledo, O., and is known as the "Duquette" two way pipe wrench. Three important improvements are offered in its design. First, it has a positive two way action. It works like a ratchet in either direction, grips the work instantly, and can be reversed immediately. The annoyance arising from a crossed thread in starting a jointed pipe is quickly overcome; no re-adjustment of the chain is necessary. The second advantage is that this



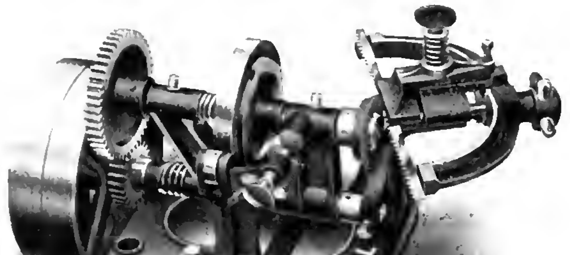
A Chain Pipe Wrench whose Action is Reversible

wrench has no teeth, yet it will take a tight grip on an oil covered nickel pipe without crushing or marring the surface. In the third place, being of the type in which pressure is applied practically throughout the whole circumference of the pipe, there is no tendency to crush rusty spots in old pipes, or to open new pipes at a seam, as sometimes happens. The head portion of the handle, in connection with the inner surface of the chain links, gives practically a true circular pressure about the work, exerting a uniform pressure. The wrench releases immediately when the pressure is removed, but will bite again and not slip so long as force is exerted. All parts of this tool are well made and are interchangeable. Being suited to a wide range of work, it should find ready appreciation with mechanics in general.

ROTARY FILE AUTOMATIC BAND SAW SHARPENER

The accompanying illustration shows a band saw filing machine made by the Rotary File & Machine Co., 589 Kent Ave., Brooklyn, N. Y. It is a new design of filing machine which has been built for some years, and which has met with a high degree of appreciation among users of band saws. The tool is chiefly remarkable for the simplicity with which it performs a somewhat complicated operation. The file itself is circular and revolves continuously. It has file teeth cut for about three-quarters of its periphery, the remaining part being smooth. The file teeth are cut at such an angle as to give very efficient action. The smooth portion of the file is used in feeding the saw, as will be described.

The machine is driven from the tight and loose pulleys at the left. The driving-shaft is connected by gearing with the cam-shaft above it, which is mounted in bearings on arms swinging about the driving-shaft as a pivot. The cam has acting surfaces on its periphery and on its face. The surface on its periphery bears against a roll on the stationary stand bolted to the base, so that the cam-shaft is thus rocked in toward and out away from the saw. The cam surface on the face bears against a similar roll pivoted on the stand, and gives the cam-shaft an axial movement. These axial and rocking movements are, of course, imparted to the file itself, which is mounted on the cam-shaft.



A Band Saw Sharpener of Noticeable Simplicity

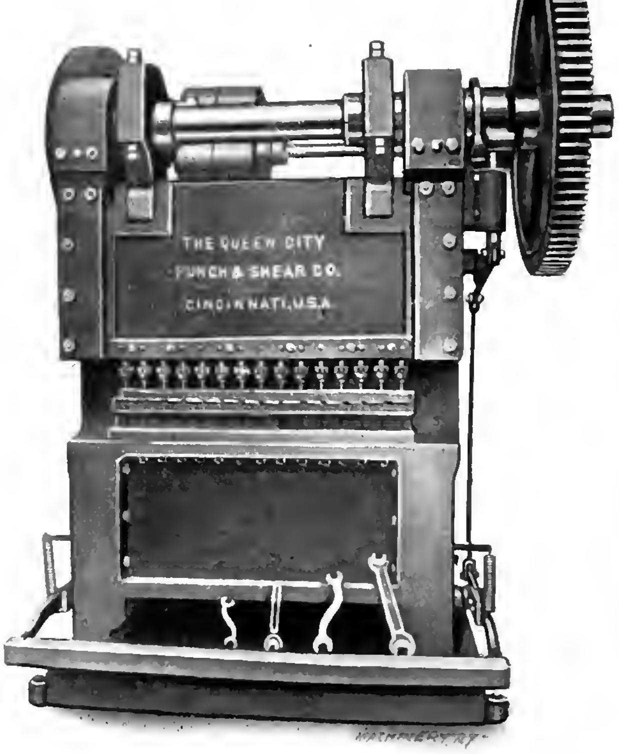
The saw is held in the frame shown, being guided by the ledges on which it rests. It passes through the adjustable friction clamp in the center of the frame, which gives the proper tension for holding the saw during the filing, and still permits it to be fed forward without binding. The holding frame may be swung about its pivot to change the angle of the tooth, and may be adjusted in and out to agree with the width of the saw blade.

The operation of the machine is as follows: Considering that the blade is in proper position, the file, as it revolves, is forced into the tooth, cutting the worn metal away and sharpening it to give a new cutting edge. The face and periphery cams then swing the file out and back, dropping it into the next tooth of the blade; by the continued action of the cams, the rotating file is properly placed in this tooth and the blade is pushed forward by the file until the position occupied by the preceding tooth is reached. This pushing of the blade is done on the smooth portion of the periphery of the file. The cutting does not commence again until the blade is fed forward as described. Suitable adjusting screws regulate the movements of the cams, which may be varied to suit saws of different width and pitches.

The concave face given to the tooth by the file is said to be much superior to the convex surface given by the hand operation, even when the latter is skillfully done. It is claimed, also, that the cost of files is reduced by the use of this machine.

QUEEN CITY MULTIPLE PUNCH

The accompanying illustration shows a multiple punching machine recently built by the Queen City Punch & Shear Co., of Cincinnati, O. It is well adapted to general work, owing to its large capacity and convenience of arrangement. The punches and dies are interchangeable, and can be spaced in any position required by the work to be done. The capacity of the tool permits the punching of fifteen ¼-inch holes in ¼-inch material, in one operation.



A Multiple Punching Machine with Adjustable Punches and Dies

The machine is built with any depth of throat, and any depth between the housings required. The engraving shows the machine with 48 inches between the housings, and a 3-inch throat. It can be either belt or motor-driven. Machine cut gearing is used, insuring smooth and noiseless operation; and the machine is equipped with a newly designed automatic speed stop clutch, which the builders have found to give unusually good service. This machine can also be used as a gap shear by removing the punching tools and attaching suitable blades for such work. The tool thus appears to be well adapted to general or special machine shop use.

TWENTY-ONE INCH SNYDER UPRIGHT DRILL

J. E. Snyder & Son of Worcester, Mass., have placed on the market the 21-inch drill shown in the accompanying engraving. As may be seen, it is a rugged and business-like appearing tool, and is capable of doing heavy work for a machine of its size. It has sufficient driving power to drill 1¾-inch holes in cast iron, or 1⅜-inch holes in solid machinery steel. It has a wheel and lever feed combined, and a power feed with automatic stop. The whole driving mechanism, including the bevel gearing and the belt area, has been designed for heavy service.

The following dimensions will give an idea of its size and capacity. The height from the floor to the upper cone pulley is 21 inches. The machine will take 26 inches between the

table and the end of the spindle, or 43½ inches on the base. The table is 17 inches in diameter, and the main column 6 inches. The driving pulleys are 11 inches in diameter for 2½-inch belt, and the cone pulleys range from 4¾ to 10 inches for the same width of belt. The spindle, in the sleeve, is 1½ inch in diameter. It has an automatic feed of 8 inches, and has a No. 3 Morse taper hole. The weight of the machine is about 900 pounds. It is shown here arranged for motor-drive, using a 1-H.P., 220-volt, General Electric direct-current motor. It is regularly furnished for tight and loose pulley drive.

A 21-inch Drill of Rugged Design

At the Mechanical and Electrical Exhibition recently held in Worcester, this tool attracted considerable attention. It was tested by drilling seven ⅝-inch holes in 1⅛-inch solid cast iron, doing this in 30 seconds with the lever feed. The operator was unable to stall the machine, though using his whole weight on the lever.

"VIXEN" HAND MILLING TOOL

In the department of New Machinery and Tools in the September, 1908, issue of Machinery, we described the "Vixen" patent milling file. The maker of this file, the National File & Tool Co., 110 Allegheny Ave., Philadelphia, Pa., has recently adapted this style of file to be used as a hand planing or surfacing milling tool for metal.

The "Vixen" Milling File adapted for use as a Hand Planing or Surfacing Tool

As may been seen in the engraving, the construction is very simple. A strip of hard wood is provided with a convenient metal handle, and a small projecting front hook to assist in guiding the stroke. Attached to the lower side of this wooden strip, by bolts as shown, is a "Vixen" milling tool or file blade. When so held, this blade is in convenient form to use on all sorts of surfacing operations on all sorts of materials, such as steel, iron, copper, tin, babbitt, aluminum, bronze, marble, etc. The peculiar shape and cutting actions of the teeth have been explained before. Suffice it to say that they are machined instead of being struck by a chisel, and that carefully shaped and very efficient cutting teeth are thus obtained. This surface milling tool is furnished in 8, 10, 14, 16 and 18-inch lengths.

TAYLOR & FENN TYPE C MANUFACTURERS' DRILL

The manufacturers' sensitive drill made by the Taylor & Fenn Co., of Hartford, Conn., is now furnished with a simple and effective design of power feed when so desired. The drill press provided with power feed is called by the makers the "Type C." It is illustrated in Figs. 1 and 2.

The general features of the Taylor & Fenn sensitive drill are well known. In the multi-spindle style shown in Fig. 1 the separate columns are adjustable on the top of the base to any desired center distance within the limits of adjustment required for the machine. Each separate column carries a complete driving mechanism, with a geared variable speed drive, operated by the lever seen projecting from the gear box at the rear in Fig. 2. A vertical variable speed shaft passes up through the center of the column, and is connected with the drill spindle by a chain and sprocket wheels at the top. This chain is shown provided with a guard.

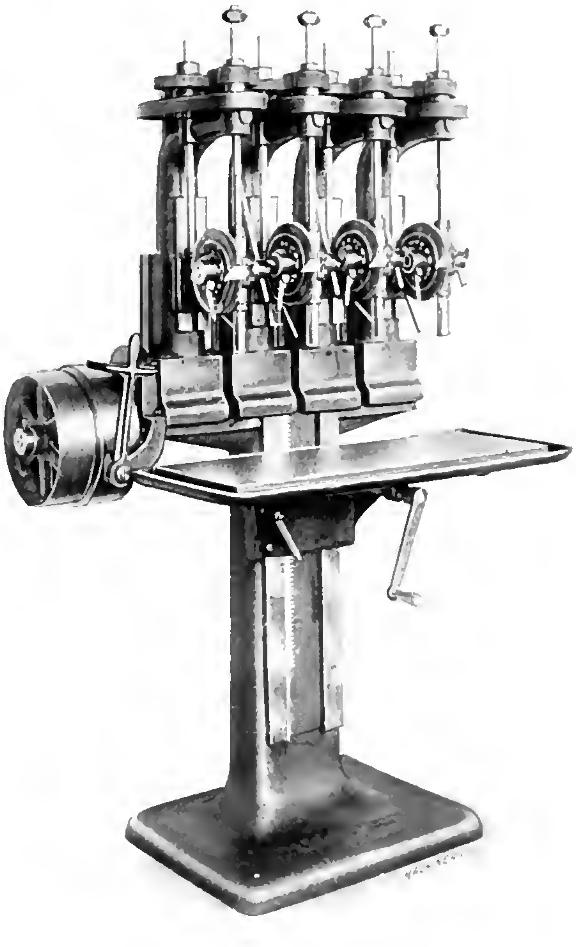


Fig. 1. Taylor & Fenn Multiple Spindle Sensitive Drill with Power Feed

The details of the automatic feed are best seen in Fig. 2. A vertical worm-shaft is geared with the spindle at the top of the column. Two rates of feed, one of 0.0071 and the other 0.0096 inch per revolution of the spindle, are provided by loosening the nut on the intermediate gear stud and reversing the compound connecting gear. The worm on the vertical shaft engages a worm-gear with a bronze rim and a hardened steel center, in which notches are cut to form a clutch ring for receiving the driving lever. The worm-wheel runs free on a bronze bushing when the driving lever is disengaged. It always remains in mesh with the worm, so that the wear is evenly distributed over all the teeth. The driv-

ing lever is fastened to a clamp collar that fits on the end of the feed pinion shaft, which is octagon in shape, permitting of eight settings of the feed lever. If it is desired to shorten or lengthen the range of feed, it may be quickly accomplished by loosening the binder screw on the clamp collar, slipping it off and replacing it into position so that the lever shall have minimum travel to the knock-off. The lever is disengaged from the clutch ring by means of a hardened knock-off, which has an adjustment greater than the distance between the notches on the clutch ring, and may then be set to drill holes of a given depth with great accuracy.

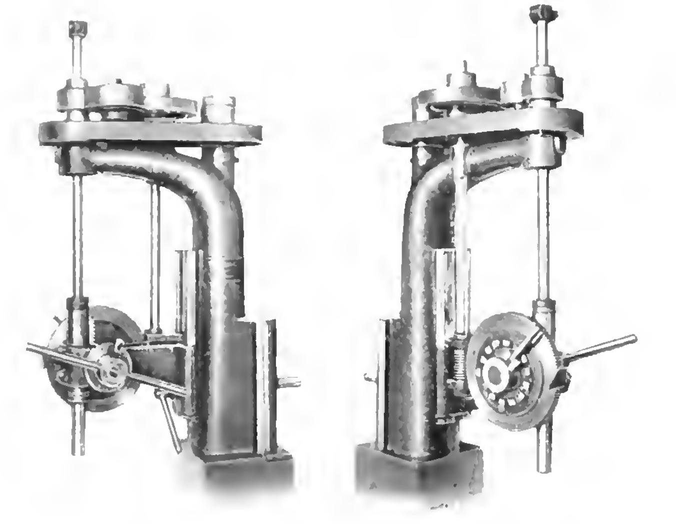

Fig. 2. The Mechanism of the Power Feed

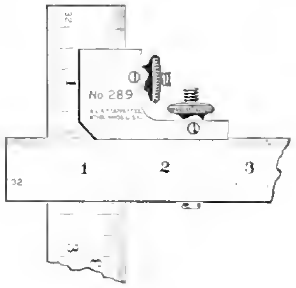
The "Type C" drill press illustrated herewith is the same as the regular "Type A" machine, with the addition of the automatic power feed. The separate spindle columns are interchangeable with all the other types, and may be used in combination with any of them on the same base. This same power feed may also be applied to one spindle of the "Type B" machine which was illustrated in the New Tools department of the January, 1909, issue of MACHINERY. By this means all the spindles are fed simultaneously. The power feed may at any time be disengaged and the same lever feed used as in the ordinary "Type A" machine.

AUXILIARY SCALE ATTACHMENT FOR STARRETT SQUARES

The attachment shown herewith is furnished by the L. S. Starrett Co., Athol, Mass., for use with the 12-, 18- and 24-inch blades of the No. 11, 23 and 33 squares. It can be used with any of the makers' regular rules up to 1 inch in width, or with the No. 21 flat steel square as well.



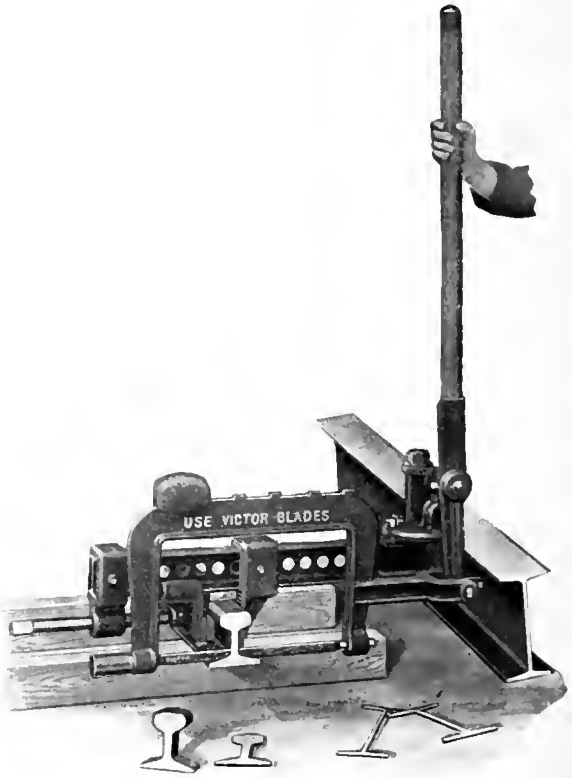
A Device for Clamping together Scales and the Blades of Squares

The ways in which it may be used will readily be appreciated. It is shown in the engraving holding two rules or blades together at right angles. Either of these may be adjusted in relation to the other for any dimension within their range. The blades are held squarely at right angles to each other. This device increases the usefulness of the combination square in laying out centers, or in scribing lines at right angles to each other, but at a given angle with a reference surface. They also convert the combination square into a height gage or beam caliper, and extend its usefulness in many other directions which will readily be appreciated by the mechanic who uses it.

M. S. W. PORTABLE HACK-SAW MACHINE

The Massachusetts Saw Works of Chicopee, Mass., has designed a portable hack-saw machine for use in cutting rails, I-beams and other steel shapes, in place. Such work hitherto has either been done by a portable circular saw machine, or by the ordinary hand hack-saw, generally operated by two men. The ordinary portable saw has the disadvantage of requiring two or three men to set it up and operate it, and it is troublesome as well in the matter of keeping the saws in the proper condition. The hand hack-saw is a slow and tedious device. It takes experienced men to cut through an ordinary rail or I-beam without breaking several blades, and it takes conscientious men to work on such a job without doing more or less loafing.

The attachment shown in the accompanying engraving uses the hack-saw under the best conditions. The clamp is universal, and may be easily adjusted to any steel shape, or to almost any kind of miscellaneous work it may be desired to saw. The saw is operated by a long handle, so that the workman stands or sits in the position most convenient for protracted exertion. This handle is mounted on a pivoted base, so that cuts may be taken at any desired angle. The frame itself is solid and substantial, and is provided with an adjustable weight for giving a suitable and even rate of feed.

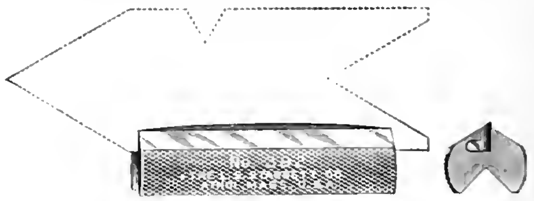


A Portable Hand-operated Hack-saw Machine

The whole apparatus, set to run, weighs about 90 pounds. One man can easily cut through a 9-inch I-beam in from twenty-five to thirty minutes, without resting. Saws in this machine make clean straight cuts, and the danger of breakage is reduced to a minimum. Fourteen-inch blades are used. The makers sell a grade of blade which they call the "Victor Special P" blade which has been found to give unusual satisfaction on I-beam and rail work.

STARRETT CENTER GAGE ATTACHMENT

The center gage attachment shown herewith is made by the L. S. Starrett Co., Athol, Mass. It consists of a V-block, with a slot containing a flat spring to hold the center gage, by friction, parallel with the V-surface. By placing the block against the lathe spindle or face-plate, a threading tool can



A V-block Holder for the Center Gage

be adjusted in proper alignment to cut both sides of a thread to the exact angle, for either external or internal work. The V-block will be found convenient for lining the attachment on arbors or other cylindrical pieces. The attachment is adapted to holding the gage either by the side or end, in any position required for the work in hand.

FOSDICK MOTOR-DRIVEN HORIZONTAL BORING, DRILLING AND MILLING MACHINE

In the October, 1908, issue of MACHINERY, in the department of New Machinery and Tools, we illustrated the No. 0 horizontal boring, drilling and milling machine made by the Fosdick Machine Tool Co., of Cincinnati, O. Provision has recently been made for equipping this boring machine with constant speed motor drive, as shown in Fig. 1. The speed box used is of the tumbler gear type, and is equipped with steel gears throughout. There are four changes made through the tumbler gears, and two changes made through the back gears in the speed box, making a total of eight changes of speed. The slow speed change is made through a pair of tool steel clutches, 4 inches in diameter, and the high speed change through a powerful friction clutch, 5½ inches in diameter. These changes are controlled by a lever shown running to the front of the machine, which can also be used for starting and stopping. A 5 H.P. constant speed motor, 1,000 R.P.M., is used, geared direct to the drive shaft through a pair of spur gears, the pinion of which is of rawhide, brass mounted.

In using a variable speed motor, the equipment is similar to that shown, with the exception of the speed box and the controller. A drum type of controller is used on the variable speed motor drive, mounted on the head, where the speeds can be easily controlled from the front of the machine. The lever for starting, stopping or making the back gear changes, is in the same position as shown for the constant speed drive.

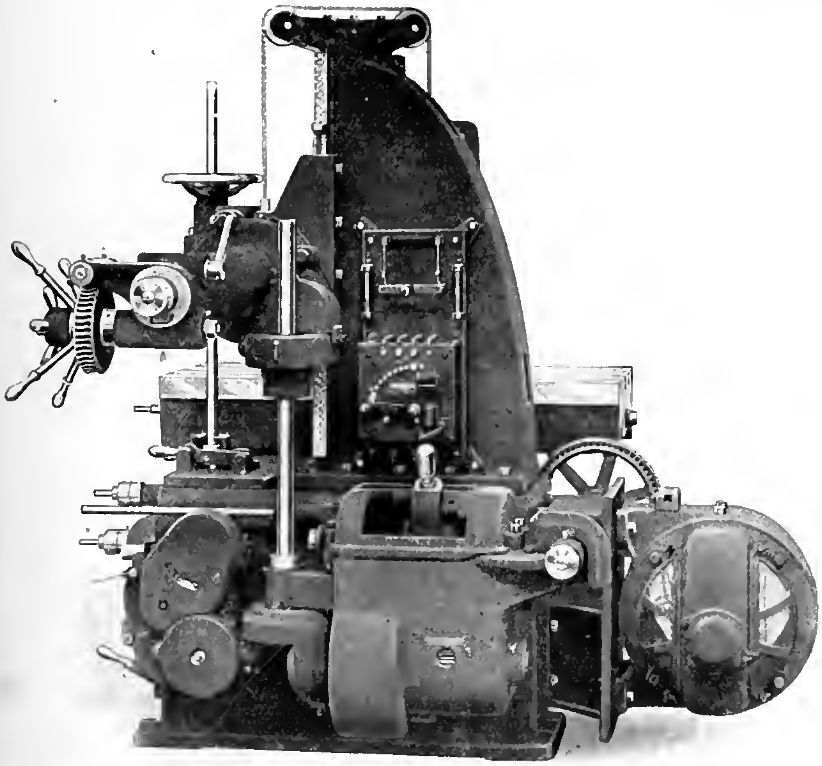


Fig. 1. Arrangement of Drive on Fosdick Boring Machine, for Use with Constant Speed Motor

Fig. 2 illustrates three recent attachments provided for this machine. The star feed facing attachment can be bolted directly to the spindle sleeve, or clamped in any desired position on the spindle itself. It will face work up to 18 inches in diameter. The auxiliary table is used for overhanging parts of any kind, which may be bolted to it, or allowed to slide on it with the adjustment of the main table. It is 8 inches wide and 48 inches long, and is provided with a T-slot for its full length. The swiveling table shown may be revolved by hand or by worm-wheel movement as desired; the worm and its hand-wheel may be withdrawn, leaving the table free. Four tightener bolts are provided for securely fastening the rotary platen to the base-plate when the adjustment has been made. The base-plate in turn is tongued and bolted to the cross-table of the machine. This table is graduated to ½ degree. It is 24 inches in diameter and 6 inches high, with an accurately bored center hole for arbors and plugs. Four cored T-slots are provided in the top surface.

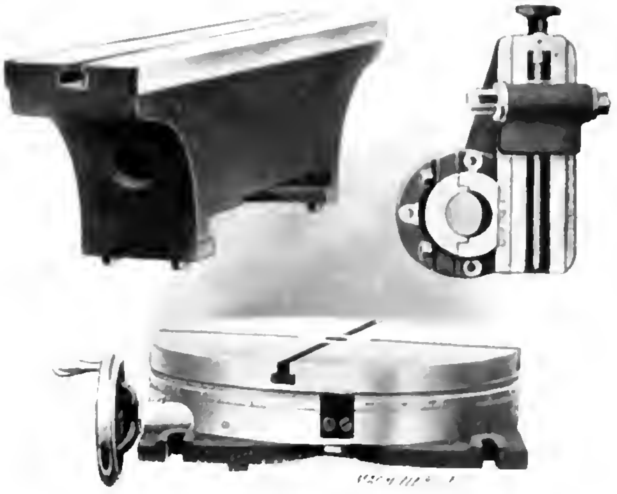

Fig. 2. Auxiliary Table, Facing Attachment, and Revolving Table for Boring Machine

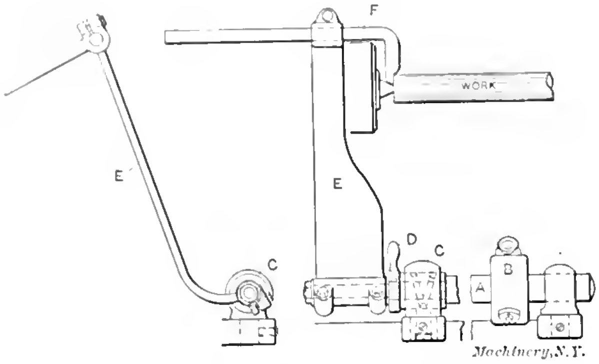
COMPENSATING AUTOMATIC STOP FOR "LO-SWING" LATHE

The well-known "Lo-Swing" lathe built by the Fitchburg Machine Works, Fitchburg, Mass. (see description in the November, 1905, and September, 1907, issues of MACHINERY, has recently been equipped with the improved stop motion illustrated herewith.* The particular point of advantage in the construction of this stop motion is its provision of means for stopping all the cuts taken on the machine at a desired distance from the head-stock end of the stock, no matter what the depth of the centering may have been; or the desired shoulder distances may all be cut to dimensions measured from the deepest point of a rough or irregular end; furthermore, the mechanisms makes provision for stopping the cuts automatically at desired distances from shoulders turned in previous operations, on cuts taken from the opposite end of the stock.

In the illustration, *A* is a stop rod, mounted on fixed brackets on the base of the machine, and carrying stops *B*, which may be adjusted to any desired position to throw out the feed mechanism in the carriage of the lathe. The left-hand support *C*, of this bar *A*, contains a sleeve in which the bar is journaled. This sleeve has cut in its periphery a coarse thread, as indicated by the dotted lines, and is provided with a handle by which it may be rocked. A cone pointed screw, fast in support *C*, enters this groove. It will be seen that the rocking of handle *D* will thus move the sleeve axially, and will likewise shift the axial position of bar *A* and the stops *B*, which are mounted on it. To the left end of bar *A* is clamped arm *E*, carrying index finger *F*.

The operation of this device is as follows: The first piece of work of a lot having been placed on the centers, ready for turning, arm *E* is swung up to the work, and handle *D* is rocked until the end of finger *F* just touches the end of the work. *E* is then swung back again with *D* remaining in place. Bar *A* has now been set to a position depending upon the position of the end of the stock being turned; stops *B* next are set to give the required shoulder distances as meas-

ured from that end. If the next piece put in the machine is centered too deeply, *F* is swung up again opposite the end of the work, and *D* is rocked until the end of the finger again matches. This shifts *A* to the right as may be required to give the same dimensions as before, measured from the end of the new bar of stock. In the same way, for very rough work, the end of finger *F* is placed a trifle inside the position where the end of the stock will just clean off in machining. In second operation work, finger *F* is similarly set to agree with the position of the shoulder from which it is desired to take measurements.

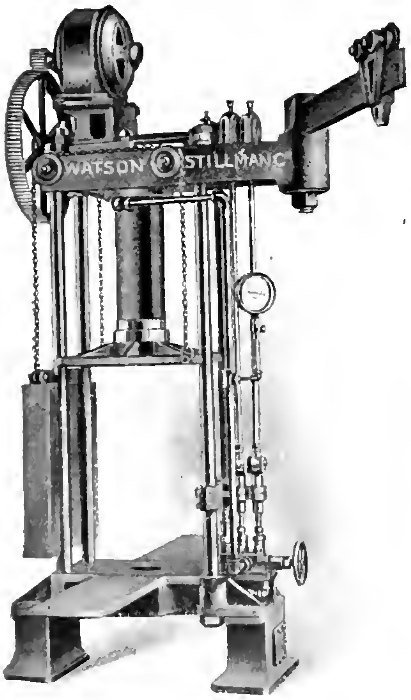


Compensating Automatic Feed Stop for Lathe

The operation of this stop is practically instantaneous, and adds greatly to the accuracy and convenience of the machine.

WATSON-STILLMAN REVERSED CYLINDER PRESS

A recent addition to the line of presses made by the Watson-Stillman Co., 50 Church St., New York City, is shown in the accompanying engraving. This is a reversed cylinder forcing press especially adapted for pressing on bearings and for miscellaneous shop work. As will be seen from the illustration, a crane bracket and beam, extending from one end, enables the operator to swing a heavy piece of work onto bracket shelves extending out from each side of the bottom platen. These shelves, 30 inches long by 12 inches wide, are detachable, can be lifted off, on jobs where they would be in the way, and are sufficiently strong to support any work that will go into the machine. They will be appreciated by those who have had to push castings or parts into place on the ordinary small platen.



A Press for General Shop Use in Pressing on Bearings, etc.

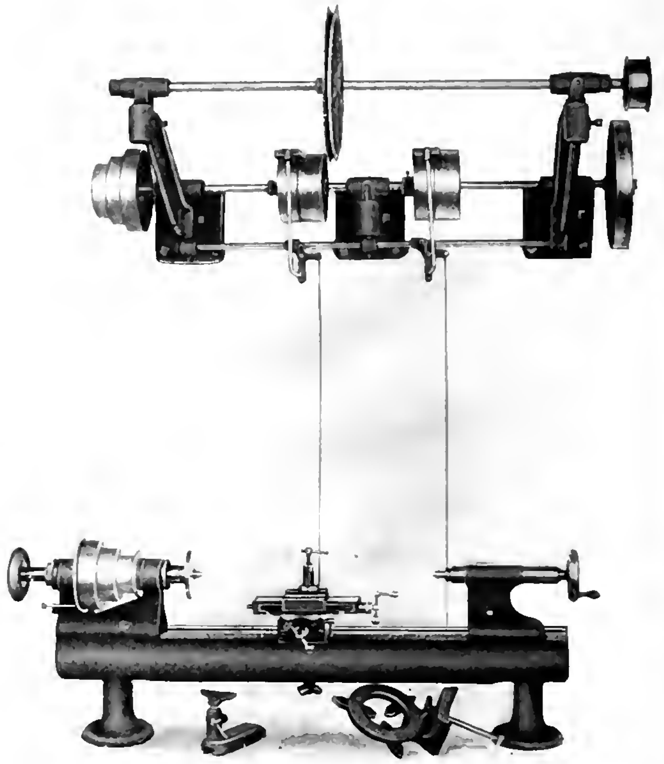
The motor, mounted upon pedestals on top of the press, drives the pump shaft through single gearing. A hand or belted drive is furnished if desired instead of the motor. On the other end of the pump shaft are two eccentrics, each driving one of the pistons of a ¾-inch by 2-inch twin pump, for which the pedestal legs act as reservoirs.

The operating valve is of the single screw stem type, and connected to release the pressure from the work when opened, and start the ram down when closed. It will not retain the pressure unless the motor is stopped or the liquid driven through the safety valve. Other types of valves may be substituted to meet special conditions. A gage is furnished to read in tons or pounds per square inch, as desired.

ROCKFORD MACHINE & SHUTTLE CO.'S PRECISION BENCH LATHE

We illustrate herewith a precision bench lathe made by the Rockford Machine & Shuttle Co., of Rockford, Ill. It is designed for small tool work, jigs, etc., or wherever accurate lathe operations are required, though it is well adapted for the finer grades of manufacturing purposes as well.

The collet has capacity for stock up to ½ inch in diameter. The lathe swings 7 inches over the bed and 4½ inches over the slide rest, and takes 16 inches between the centers.



Rockford Precision Lathe, with Wall Countershaft

A carefully designed thrust bearing is provided. The head and tail centers are ground to No. 1 Morse taper, and the rear end of the spindle is fitted to the standard size for indexing plates. The cone pulley flange is provided with two rows of index holes. The counter-shaft shown is intended to be screwed to the wall. It is provided, as may be seen, with a second shaft for driving grinding and other attachments.

STANDARD DESIGN FOR NEWTON HORIZONTAL MILLING MACHINE

The Newton Machine Tool Works, Inc., of Philadelphia, Pa., has persistently re-designed its line of horizontal milling machines, to keep pace with the capabilities of modern, inserted tooth, high-speed cutters. The changes that have been made have related mostly to the general stiffness of the machine, and to the power of the driving mechanism. It has been found that the rate of removal of metal is about 1¼ cubic inch per minute per H.P., the volume removed being proportionate to the size of the machine. This high rate of removal results in cuts so rapid, that the time of setting the work and adjusting the cutters has become the important factor on most work, rather than the time required on the cut itself. For this reason the builders have found it advisable to redesign the mechanism of their horizontal milling machines from the standpoint of convenience and rapidity of handling.

The machine shown in Figs. 1 and 2 has the controlling levers all mounted within convenient range of the operator, so that any movement except the clamping of the rail can be

obtained instantly. This latter adjustment offers no difficulties, however, since the use of roller thrust bearings at the top and bottom of the elevating screws permits the rail gibs to be tightened to a stiff running fit, and be so used for heavy cuts. Lever *A*, shown attached to the rock-shaft at the bottom of the bed in Fig. 1, passes through to the opposite side as shown in Fig. 2, and is there connected with a bevel gear reversing clutch by means of which all the feeds and fast traverse movements are stopped, started and reversed. Lever *B* operates the table locking mechanism. Lever *C* operates the clutch engaging the rapid power adjustment for the cross-rail. Lever *D* engages a clutch which throws in either the fast travel or feed for the table, as desired. The levers on the feed-box operate change gears, which give nine changes of feed through the different combinations. The hand-wheel may be slipped forward or back on its shaft to give l and vertical adjustment to the rail or to the table as required

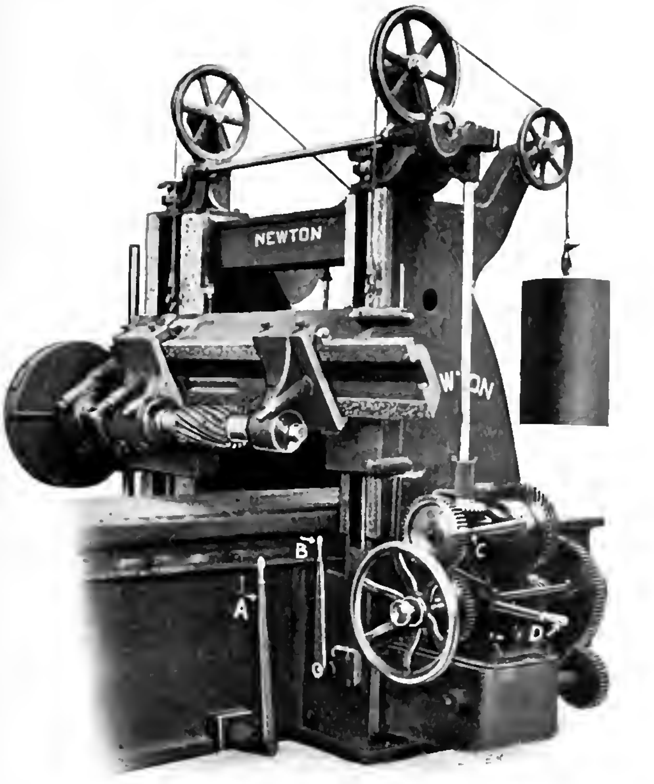


Fig. 1. The Operating Side of the Newton Standard Horizontal Miller

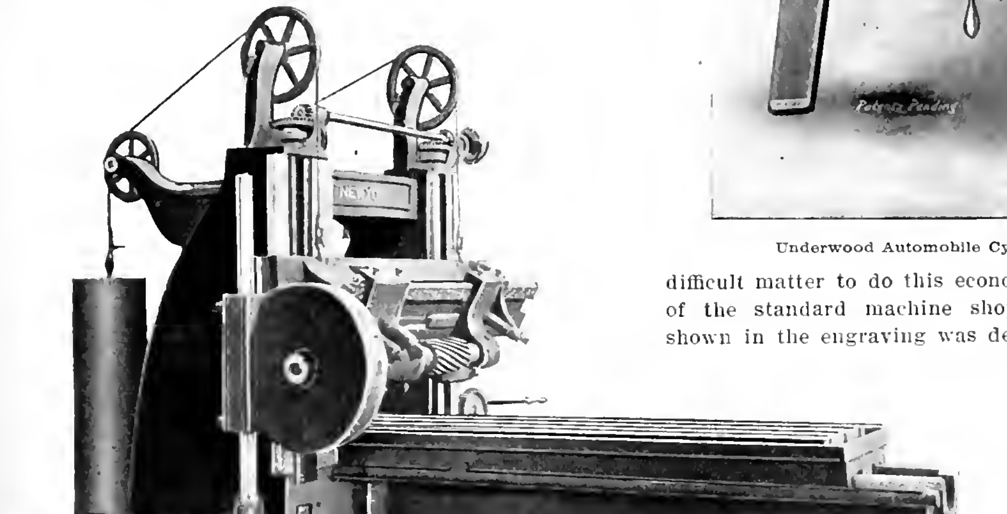

Fig. 2. Arrangement of the Drive and the Controlling Mechanism of the Newton Miller

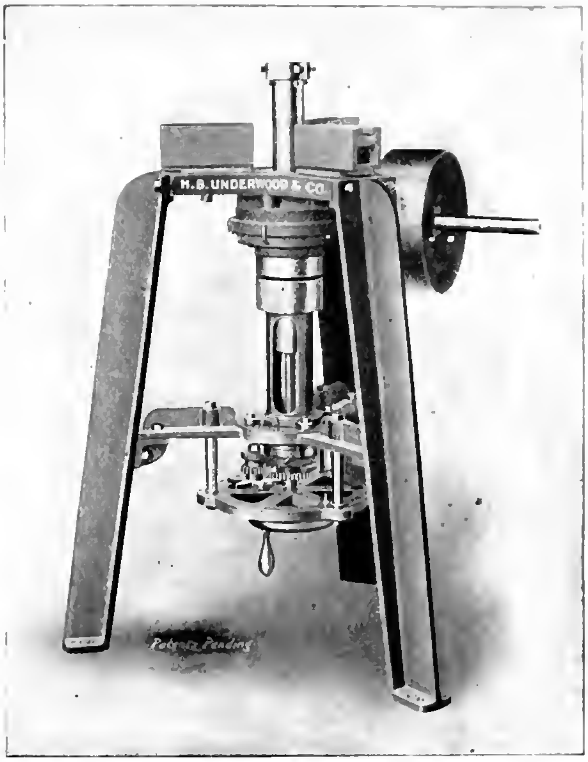
It will be seen that the operator has all the required controlling levers within easy reach of his working position

This line of machines is complete in all sizes from the smallest (having a table 11 inches wide with 20 inches between the uprights) to the largest, having a table 60 inches wide and 70 inches between the uprights. On the machine illustrated, the makers have been able, in their own shop, on cast iron brackets, to take cuts 9 inches wide, 5/16 inch deep and 15 inches long, in one and one-half minute. Another cut which was taken was 11¼ inches wide and 3/16 inch deep with a table feed of 11½ inches per minute. The machine here shown will be supplied with either a 15 or a 20-horse-power motor, according to the work to be done. The average removal of metal is 1¼ cubic inch per minute.

UNDERWOOD AUTOMOBILE CYLINDER RE-BORING MACHINE

H. B. Underwood & Co., 1024 Hamilton St., Philadelphia, Pa., in the regular run of shop work has been frequently called upon to re-bore automobile cylinders. Finding it a difficult matter to do this economically and efficiently on any of the standard machine shop tools, the special machine shown in the engraving was designed. This tool follows the general mechanism of the regular portable cylinder boring machine made by the builders. It is provided, in addition, with such changes in mechanism and such arrangements for mounting and holding the work, as suit the special operation of re-boring automobile cylinders.



Underwood Automobile Cylinder Re-boring Machine

The tool operates in a vertical position, and thus requires but little space. The boring mechanism is supported on a stout tripod as shown. The cylinder to be re-bored rests on three adjustable sliding blocks, planed true and at right angles to the spindle. Suitable clamps hold the cylinder in place after it has been centered; since it rests on the face by which it is bolted to the engine base, accurate alignment is insured. This method of holding applies equally well to

single and multi-cylinder castings, either of which styles are held without distortion. As the work is done in a vertical position, the chips fall out without clogging the cutters or interfering with the work.

The driving pulley shaft is connected with the cutter spindle by worm-gearing. The spindle or boring bar has about 15 inches travel, with a variable automatic feed operated by a star wheel engaging one or more knockers, as required. A special adjustable head is mounted on the spindle for centering the cylinder. After centering, this is removed, and the cutting tool substituted. The cutter head carries four tools which may be adjusted simultaneously to the depth of the cut by screwing down a taper seat in the center of the head. A 1-horse-power motor is sufficient to drive the machine.

This tool is also capable of boring as well as re-boring, and several of them may be set to work in a space which one large machine tool would occupy. The tool is easy to operate and does good work. Only one cut is required, and this may be taken in a remarkably short time.

HYATT HIGH-DUTY ROLLER BEARING

The roller bearing made by the Hyatt Roller Bearing Co., of Newark, N. J., is well-known to mechanics and engineers. It employs a flexible roller, which is formed of helical coils of steel, having a rectangular section. These rollers are confined in a cage which locates them properly between an inner and outer hardened shell, of which the former is made fast to the shaft and the latter to the bearing. For hardened shafts the inner bushing is omitted. In the high duty bearings here described, this inner bushing is omitted only for hardened, heat-treated shafts and rolls or coils.

Hyatt High-duty Roller Bearing

This high duty type of the Hyatt roller bearing has been designed to meet conditions of service which can not be met with the commercial type. To make this increase in capacity, the carbon steel parts of the commercial type have been replaced with alloy steel, properly heat treated; also as explained above, hardened and ground inner and outer surfaces have been provided for the bearing of the rollers. The increase of capacity of the bearing thus obtained may be employed either in getting the same capacity in a smaller space than in the original form, or in getting an increased capacity in the same space. This bearing is particularly adaptable for automobile transmissions, rear axles, and other applications where the duty required of the bushing is great, while the space available for it is limited.

Two designs are made, one of them narrower than the standard to meet the first conditions mentioned, and the other considerably wider for the heaviest service. The light series is made for shafts from ¾ to 2¾ inches in diameter, and for safe loads of from 460 to 3,030 pounds; the corresponding sizes for the heavy series have a capacity of from 1,200 to 6,890 pounds. The length of the smallest size is 2 inches over the bearing, while that of the largest is 3½. These loads give the amount of radial load that a bearing can be subjected to under a maximum speed of 1,000 revolutions per minute. The flexible nature of the roller permits the safe absorption of a reasonable amount of shock. The loads given are the results of actual tests by the mechanical inspection department of the makers, who stand always ready to assist customers in every way in the proper choice of bearings and in their proper installation.

* * *

Switzerland imports machinery to the value of about $10,000,000 yearly. Seventy-six per cent of the machinery imported is of German manufacture.

NEW MACHINERY AND TOOLS NOTES

Brazing Compound: Universal Fluxine Co., Urbana, O. This compound may be used for fusing together cast iron and other metals. It is adapted also to the brazing of high-speed steel cutters to soft steel bodies.

Name Plate Machine: Roovers Mfg. Co., Brooklyn, N. Y. This instrument is adapted to the making of embossed letters for use on patterns, machine tools, in stock rooms, etc., and for general use in numbering and classification about manufacturing plants.

Roller Thrust Bearing: Reeves Pulley Co., Columbus, O. This bearing was developed by the makers to fill the requirements for their variable speed transmission. It is carefully machined, and provided with thrust rollers of large diameter, held in the position required for proper action.

Water-Cooled Rolling Mill: Atlas Machine Co., Waterbury, Conn. This is a rolling mill for small, accurate work; it is provided with a water circulation through the rolls for carrying off the heat generated by the work performed on the metal. The rolls are 6 inches in diameter by 2½ inches face.

192-Inch Plate Shear: United Engineering & Foundry Co., Pittsburg, Pa. A heavy plate shear of the guillotine type, with a capacity for shearing ⅜-inch plate 192 inches wide. The crank-shaft is supported by four bearings on a heavy truss connecting the tops of the housings. A cam-operated plate holder is provided.

Combination Square: W. F. Dissell, 9700 Gibson Ave., Cincinnati, O. This combination square consists of two steel rules, provided with suitable surfaces and clamps for engaging each other firmly in the various positions required for a tool of this kind. It may be set up for use as a depth gage, try square, hook rule, T square, vernier caliper, etc.

Geared-Drive 20-Inch Shaper: Mark Flather Planer Co., Nashua, N. H. This firm has recently added to its line a 20-inch gear-driven shaper made on practically the same lines as the 16-inch shaper described in the November, 1907, issue of Machinery. The design avoids the use of the cone pulley, and is particularly adapted to direct connection with a constant-speed motor.

Portable Drill: Coates Clipper Mfg. Co., Worcester, Mass. This portable drill is intended to be driven by the Coates flexible shaft from any convenient motor power, preferably from a portable motor. It is in the form of the ordinary breast drill. The breast-plate, however, may be removed, and the tool used with the regulation "old man."

"Cito" Cut Meter. Schuchardt & Schutte, 90 West St., New York City. This is a development of the makers tachometer, arranged for giving direct readings in linear velocity. A friction wheel is provided which is placed against the surface whose speed is to be measured. The readings are made from a dial graduated in meters per minute, or feet per minute, as required.

Combined Punch and Shear: Jannell Machine Co., Rumford, Me. This is a small tool, standing a little over 3 feet high. It will punch ⅝-inch holes in ⅜-inch iron, and has sufficient gap capacity and driving power to shear ⅝-inch stock 6 inches wide. The tool has a distinctive appearance, being mounted on a heavy base with all the gearing and other mechanism below the dies.

Heavy Five-Spindle Milling Machine: Niles-Bement-Pond Co., 111 Broadway, New York City. This is a heavy milling machine provided with two facing heads on the cross-rail, a side facing head on the front of each housing and a horizontal slab milling spindle. The vertical spindles are both counterweighted. The table has a working surface 14 feet long, and the clear width between the uprights is 38½ inches.

Shop Transit: H. W. Brown, 63 Canal St., Waterbury, Conn. This tool is a modification of the engineer's transit, omitting every adjustment and piece of mechanism that is not required for shop use. It will be found useful in connection with the modern practice of laying out large work by sighting through the telescope, as well as for running line shafts, setting foundations, etc.

Automobile Cylinder Boring Machine: Newton Machine Tool Works, Inc., Philadelphia, Pa. This is a double-head boring machine with spindles driven by worm-gearing, so arranged that the center distances may be adjusted without disturbing the drive. The machine is arranged for either open or closed cylinders, as may be required. Four changes of feed are provided.

Portable Boring Machine: Beaman & Smith Co., Providence, R. I. This machine has unusual capacity for a portable tool. It is of the type in which the column, carrying a vertical traveling spindle head, is adjustably mounted on ways on a horizontal base. It is provided with all the movements and conveniences of the ordinary stationary machine, though intended for portable use. It weighs about 15 tons.

Steam Hammer Having Anvil Solid with the Frame: Niles-Bement-Pond Co., 111 Broadway, New York City. The anvil is mounted directly on the base. The side housings are lipped over bearings on the top of the base, and are held to it by bolts provided with heavy springs to allow a slight vertical movement from the rebound of the blow. This is an 8,000-pound hammer of the double housing type.

Special Lathe for Billet Turning: Pacific Iron Works, Bridgeport, Conn. This is a lathe designed especially for turning billets of copper, brass or other alloys for the purpose of cleaning off the scale and other imperfections before putting them through the rolls. This operation also serves to reveal flaws which might otherwise remain hidden. Special holding devices for supporting the billets are provided. The machine weighs about 7,000 pounds.

Angle Drive: Max Ams Machine Co., Mt. Vernon, N. Y. This drive is adapted to the transmission of power through shafting set at right angles. It consists of two short pulley shafts connected by sprockets and a special chain running over sprocket idlers. The chain is so constructed that it will bend and run over sprockets in all four directions. This device is built to transmit various amounts of power as required.

Double-End Lathe Tool: Taylor Mfg. Co., Hartford, Conn. This tool-holder has a provision for clamping a round shank blade at either end, one of the blades being held horizontally and the other at an angle. The blades may be easily ground as turning tools, parting tools, threading tools, etc. The round shank arrangement gives the edge an adjustable cutting angle, and permits tipping the threading tool to agree with the angle of the thread.

Press for Shallow Drawing and Forming in Heavy Plate: Ferracute Machine Co., Bridgeton, N. J. This press, being designed for large work in heavy metal, has been given the form of the coining press made by the same builders. The lower bed or "ram" is operated by a toggle joint mechanism. The blank holder in the upper member is supported by heavy springs, grouped in a casing at the top of the frame. The ram is capable of exerting a maximum pressure of 450 tons.

Motor-Driven Vertical Spindle Milling Machine: Newton Machine Tool Works, Inc., Philadelphia, Pa. This vertical spindle milling machine is of large capacity and heavily built. Work 10 inches in height can be taken between the table and the end of the spindle. The distance from the center of the spindle to the face of the column is 33 inches. The length of the in-and-out feed and the length of the cross-feed are also of the same dimension.

High-Speed Steam-Hydraulic Flanging Press: United Engineering & Foundry Co., Pittsburg, Pa. This is a form of rapid action, horizontal press, built on Davy patents, whose principles were discussed in an article entitled "Rapid Action Hydraulic Forging Press," in the May, 1907, issue of Machinery. The makers have acquired the right to this important machine for the United States. This press is intended to take the place of the steam hammer in ordinary machine forging, doing the work as quickly and more effectively.

Slab Miller with Auxiliary Vertical and Horizontal Spindle: Ingersoll Milling Machine Co., Rockford, Ill. This tool is one of the builders' regular slab or horizontal spindle milling machines, provided with an auxiliary head, carrying two spindles at right angles to each other, on either of which milling cutters may be mounted. The attachment is particularly adapted to face milling in either the horizontal or vertical plane, simultaneously with the use of a regular milling cutter for the main arbor.

Independent Chuck with Differential Screw Mechanism: Carter Chuck Co., St. Louis, Mo. This is an independent chuck, with a neatly designed differential screw mechanism for setting down the jaws on the work. This gives, of course a much greater gripping power than can be obtained with an ordinary screw. The construction is such that most of the wear comes on an easily renewed member, making repairs simple and inexpensive. The matter of durability, however, has been carefully considered in the design of the tool.

Crank-Shaft Grinding Machine: Tindel-Morris Co., Eddystone, Pa. This is a grinding machine specially designed for multiple throw crank-shafts. These shafts are driven from each end by geared head-stocks, provided with face plates which hold the work without requiring special fixtures of any kind. Counter-balances are provided on each face-plate to insure steady running. Suitable back-rests, truing stands, etc., are furnished, so that the grinding is effected as conveniently as for ordinary cylindrical work.

Armington Electric Hoist: Armington Electric Hoist Co., Wickliffe, O. These hoists are made in various styles, either for single point suspension, with plain or geared trolley, or in the trolley form with both power hoist and travel. They are made in sizes from 1 to 10 ton capacity, with a standard hoisting speed of from 1 to 12 feet per minute. An improved brake mechanism is employed; it is of the coil type, and of practically one-piece construction. The mechanism is very compact, though accessible. Careful attention has been given to lubrication.

Nelson Combined Ratchet Wrench and Drill: L. H. Brown Mfg. Co., Carlinville, Ill. This reversible ratchet drill is provided with adjustable chuck jaws, which may be used for holding nuts, bolt heads, etc., as well as for holding drills. By removing the feed-screw, a free hole is left through the center of the tool, so that it may be slipped over a long threaded bolt. The ratchet mechanism is entirely enclosed, making the tool more durable than with the ordinary open construction. The head room is unusually short, adapting it to use in confined places.

Draftsmen's Protractor: L. S. Starrett Co., Athol, Mass. This is a protractor intended especially for use in the drafting-room. It is made of sheet steel, nickel-plated and is graduated in degrees to read from either left or right. The vernier provided gives accurate readings to within 5 minutes. The straight edges of the protractor are graduated in inches and 16ths, the adjustable edge being graduated to 6 inches in length. Angles can be reversed without resetting by simply turning the instrument 90 degrees around on the T square or straight edge.

Tool-Holder for Turning and Threading: G. R. Lang Co., Meadville, Pa. The idea incorporated in the locomotive and car wheel tire turning tool made by this firm, and mentioned in a note in the December, 1908, issue of Machinery, has been applied to a general tool-holder for turning, threading, etc. The threading blades and the smaller turning blades are made from triangular drawn stock. Larger tools are milled from stock to fit the dovetail in the holder. The lock-bolt in the latter supports the blade against a solid abutment, and at the same time clamps it tightly in place by frictional means.

* * *

In a paper read before the *Société de Ingenieurs Civils de France*, it was stated that in the Messina earthquake, reinforced concrete proved itself to be the safest building material for regions thus afflicted. One typical example is cited of a house now standing in the center of a section where all the other buildings were reduced to fragments. This house sheltered a family the members of which are now the sole survivors within a large adjacent area. The one million-gallon reinforced concrete reservoir supplying the city with water suffered no damage.

PRESENTATION OF THE JOHN FRITZ MEDAL TO CHARLES T. PORTER

The National Engineering Societies, comprising the American Society of Civil Engineers, The American Institute of Mining Engineers, The American Society of Mechanical Engineers, and the American Institute of Electrical Engineers, conferred the John Fritz medal for 1908 on Mr. Charles T. Porter for his work in advancing steam engineering and his improvements in engine construction. The medal was presented in the presence of a distinguished company on the evening of April 13th, in the auditorium of the Engineering Societies' building at 29 West 39th St., New York.

The John Fritz medal was established by the professional associates and friends of John Fritz, of Bethlehem, Pa., on August 21, 1902, his eightieth birthday, to perpetuate the memory of his achievements in industrial progress. (See MACHINERY, September, 1902.) The awards are made annually by a board of sixteen, appointed or chosen in equal numbers from the membership of the four societies named. The awards up to date have been as follows:

First award, January 20, 1905, to Lord Kelvin for his work in cable telegraphy and other scientific attainments.

Second award, January 19, 1906, to George Westinghouse for the invention and development of the air brake.

Third award, January 18, 1907, to Alexander Graham Bell for the invention and introduction of the telephone.

Fourth award, January 17, 1908, to Thomas Alva Edison for the invention of the duplex and quadruplex telegraph, the phonograph, the incandescent lamp system of electric lighting, etc.

Fifth award, January 16, 1909, to Charles T. Porter for his work in advancing the knowledge of steam engineering and in improvements in engine construction.

Mr. Henry R. Towne, chairman of the board of award, presided at the meeting, and Dean W. F. M. Goss, of the University of Illinois, read a paper entitled "The Debt of Modern Industrial Civilization to the Steam Engine as a Source of Power." After the presentation of the medal to Mr. Porter letters of salutation were read from societies and prominent engineers in the United States and Europe, and then followed a paper by Prof. F. R. Hutton, of Columbia University and honorary secretary of the A. S. M. E., "The Debt of the Modern Steam Engine to Charles T. Porter." Robert W. Hunt followed with "The Debt of the Era of Steel to the High-Speed Steam Engine," and Frank J. Sprague concluded with "The Debt of the Era of Electricity to the High-Speed Steam Engine."

Professor Hutton spoke in detail of the pioneer work of Mr. Porter, and gave him credit for first seeing the great possibilities of the high-speed engine. In analyzing the debt we owe to the work of Mr. Porter, stress was laid on the following:

"First, the reciprocating engine owes to him the first vision of the advantages that come from making the crank-shaft turn at a high number of revolutions whereby the weight of the motor per horse-power is reduced; and second, for raising the standard of mechanical construction because of the necessity of such in the high-speed engine. We owe to Mr. Porter many engineering details which are commonplaces of modern practice. He created a condenser air pump that was directly connected to the engine and capable of running at high speed, and a highly sensitive governor in two forms."

Among those present on the rostrum were: James C. Brooks, Charles L. Clarke, W. F. M. Goss, C. W. Hunt, F. R. Hutton, George W. Melville, Alfred Noble, C. A. Parsons (England), W. H. Pegram, Charles T. Porter, Charles B. Richards, Henry R. Towne, Jesse M. Smith, E. G. Spilsbury, Frank J. Sprague, Ambrose Swasey, John E. Sweet, E. Swenson, G. G. Ward, S. S. Wheeler.

* * *

A record in long-distance telegraphy has been achieved by the Indo-European Telegraph Co., which has succeeded in transmitting messages direct from London to Calcutta, a distance of 7,000 miles, with no intermediate re-transmissions. A speed of forty words a minute was maintained.

NEW STEAM-ENGINE VALVE MECHANISM

On April 6 the Rothchild Engine Company, 102 Center Street, New York, gave a public demonstration of a new and novel form of valve mechanism which the company expects to apply to both stationary engines and locomotives. The engine which has been built for the purpose of trying out the new valve has four cylinders which are cast integrally in pairs. The steam chest for each set of cylinders is located at the top and contains a single valve which is in the form of a cylindrical bushing. These valves are connected by a shaft which is rotated from the main shaft below, by a chain, and sprockets so proportioned that the crank-shaft makes three revolutions while the valves are making one. Three steam ports, 120 degrees apart, are cut into the valve for each cylinder. Each set of three ports is in line with a larger main port opening into the cylinder, and as the valve turns one-third of a revolution, while the crank-shaft makes a complete turn, obviously, one port will be at the point of admission at the beginning of each stroke. The live steam which is within the cylindrical valve would be admitted to the cylinder while the port in the valve was passing the larger main port were it not for a half-round cut-off valve which fits inside of the cylindrical valve. This cut-off valve closes the port and cuts off the steam at a point depending upon its angular position which is varied by the movement of a lever. The point of release occurs when the port through which steam was admitted opens into the exhaust port which is located in the lower side of the cut-off valve. By changing the position of this valve so that its opposite edge controls the point of cut-off, the reversal of the engine is effected.

* * *

The Queensboro, or Blackwells Island bridge, joining Manhattan Island and Queens County, New York, was opened to traffic March 30. This bridge is of the cantilever type and is one of the three great cantilever structures in the world, completed or in construction, the other two being the Firth of Forth bridge and the Quebec bridge, one section of which fell in process of construction last year. The Queensboro bridge is 8,600 feet long, including the approaches. The bridge proper is 3,746 feet long, made up as follows: Anchor span, 460 feet; channel span, 1,182 feet; island span across Blackwells Island, 632 feet; span over the east channel of the river, 984 feet; and anchor span on the Long Island shore, 459 feet. The approaches are 4,854 feet. The roadway is 135 feet above mean high water mark and the towers are 185 feet above the bottom chord. The height of the trusses of the island span is 118 feet. This is the heaviest part of the bridge, weighing 10,400 tons or 16½ tons to the linear foot. The steel superstructure was furnished by the Pennsylvania Steel Co. and weighs 52,000 tons. The width between the railings of the lower floor is 86 feet and of the upper floor 67. The total cost of the bridge is about $20,000,000. Ground was broken for the bridge in 1893, but active work was not begun until January, 1901. Following the fall of the Quebec bridge, an investigation was made of the plans for the Queensboro structure, and it was deemed unadvisable to subject it to the load for which it was originally designed. It was designed to carry four elevated railway tracks, but only two will be laid. Provision is made for four trolley tracks and one 34-foot roadway on the lower deck and two rapid transit tracks and two 14-foot walks on the upper deck.

* * *

PERSONAL

Percy Reston has been promoted to the position of chief draftsman in the office of the Cincinnati Planer Co.

John W. Freeman has been appointed manager of the Sprague Electric Co.'s Pittsburg office to succeed Mr. F. W. Parry, who recently resigned.

James Hartness, president of the Jones & Lamson Machine Tool Co., Springfield, Vt., sailed for Europe April 14 on the steamer *Mauretania*.

E. E. Brosius, Alliance, Ohio, has been made sales manager of the Pawling-Harnischfeger Co., Milwaukee, Wis., builders of traveling cranes.

H. W. Bridge is now president of the Buckeye Equipment Co., Cincinnati, O., having succeeded J. S. Nowotny, who retired from the company some time ago.

At the last meeting of the directors of the firm of John Steptoe Shaper Co., Cincinnati, Ohio, G. K. Atkinson, superintendent, was elected secretary-treasurer.

H. M. Wood, formerly with the Niles-Bement-Pond Co., has joined the Lodge & Shipley Machine Tool Co., Cincinnati, Ohio, to act as publicity and advertising manager.

J. B. Baker of the Safety Emery Wheel Co., Springfield, Ohio, sailed April 1 for a two months' business trip to England, Germany, Holland, Norway and Sweden.

H. L. Clark, formerly superintendent of the Dominion Coal Co., Glace, Cape Breton, has recently been appointed superintendent of the Chester Park shops of the Cincinnati Traction Co.

M. E. Dewstoe, First National Bank Building, Birmingham, Ala., has been appointed selling agent of the Bullard Machine Tool Co., Bridgeport, Conn., in the Alabama and Tennessee territory.

W. Robertson has severed his connection with the Robertson Mfg. Co., Buffalo, N. Y., and is now with the Robertson Drill & Tool Co., manufacturers of a line of power hack saws and drill presses.

H. W. Kreuzburg, president of the Champion Tool Works Co., Cincinnati, O., recently returned from a business trip which included San Francisco, Denver, Salt Lake City and other large cities in the West.

Philip Fosdick, president, and R. K. Le Blond, vice-president of the Cincinnati Chuck Co. Cincinnati, Ohio, are in Europe on a business-pleasure trip. They expect to return to this country about May 1.

John R. Kempf, secretary and treasurer of the Star Corundum Wheel Co., Detroit, Mich., sailed for Europe April 16 on the steamer *St. Paul*, to make an extensive business tour of England and the Continent.

C. G. Hafley, formerly advertising manager for the Buffalo Forge Co., Buffalo, N. Y., and later with the Keuffel & Esser Co., is now with the Vechten-Waring Co., 92 John St., New York, acting as assistant in the advertising service department.

W. H. Smead, mechanical engineer, has moved his office from Greenboro, N. C., to 207 Prudential Building, Atlanta, Georgia. Mr. Smead will continue his general engineering business, making a specialty of designing power and heating plants.

Frank Wells Hall has been appointed manager of the Philadelphia office of the Sprague Electric Co., New York. Mr. Hall formerly was connected with Sprague Electric Co. both in the New York and Chicago offices in an engineering and sales capacity.

F. O. Hoagland, who for twelve years past has been connected with the Pratt & Whitney Co., Hartford, Conn., the last eight years of which as department foreman, has been made chief mechanical engineer with the Remington Arms Co., Ilion, N. Y.

W. S. Rogers, president of the Bantam Anti-Friction Company, Bantam, Conn., sailed for Germany April 29, on the invitation of several German makers of balls and ball bearings, to make close connections for the handling of their goods in this country.

D. B. Clark, master mechanic of the Chester Park Shops of the Cincinnati Traction Co., has been appointed master mechanic of the Columbus shops of the Ohio Electric Railway Co. Mr. Clark will continue to hold his position as master mechanic of the Chester Park shops.

Hermann Hill, 437 Columbus Ave., Boston, Mass., has invented machinery for the manufacture of expanded metals and will organize a company called the Steel Fire Proofing Co., for the manufacture of expanded metals for all classes of service. The factory will be located in Pittsburgh, Pa. His temporary shop is at 82 Purchase St., Boston, Mass.

George Taylor, for the past three years connected with the testing and construction department of the General Electric Co., of Schenectady, N. Y., lately resigned to become a partner in the Taylor Machinery Co., 8 Oliver St., Boston, Mass., a concern recently organized by Thomas I. Taylor, as noted in the March number of MACHINERY.

P. V. Vernon, chief designer of Alfred Herbert, Ltd., machine tool builder, Coventry, England, has sent a communication to the American Society of Mechanical Engineers, of which he is a member, proposing that the British Institution of Mechanical Engineers and the American Society of Mechanical Engineers cooperate to secure the adoption of a standard for involute gearing.

P. E. Montanus, president of the Springfield Machine Tool Co., Springfield, Ohio, returned from a two months' business trip in Europe, March 27. Mr. Montanus reports that the outlook for the sale of standard American machine tools in foreign markets is not promising and that foreign manufacturers are rapidly developing imitations of American machines, which are sold at lower prices than the American tools.

Frank P. Peters has been promoted from the position of general foreman of the Sodemann Heat & Power Co., St. Louis, Mo., to that of superintendent of the entire factory. Mr. Peters went from the United States Heater Co., Detroit, Mich., in January, 1908, to take charge of the machine department, and was soon promoted to general foreman. He has had about ten years' experience in the manufacture of radiators and heating apparatus, and is a practical machinist.

Edwin C. Thurston, who has been with the Gould & Eberhardt Co. for the past four years, in their machine designing department, and who was formerly with the Brown & Sharpe Mfg. Co. for a period of over ten years, having had experience and charge of work in the various machine tool and sewing machine departments, has associated himself with Mr. J. C. Blair, expert tool maker, machine builder and manufacturer of metal specialties. Messrs. Thurston and Blair will take up special small machinery and tool designing and building, metal specialties, model and experimental work, pattern making, drawings, tracings, blue-printing, etc., and also developing and perfecting ideas for inventors. They are located at 78 Clinton St., Newark, N. J.

James R. Anderson, sales manager of the Lunkenheimer Co., Cincinnati, Ohio, recently returned from a business trip through South America. In an interview he laid much stress on the bad results on American commerce caused by poor packing of goods. He said that American manufacturers, including those in all lines, do not pack their goods strong enough for rough handling. As a consequence, packages are frequently broken and goods of all kinds are lost or damaged in transit. Another serious fault is that American manufacturers do not cater to the size, kind, quality and weights of packages that South Americans want. It appears that it will be necessary for American manufacturers who desire to develop a South American trade, to send a trustworthy representative who will spend some time in making the acquaintance and learning the peculiarities of the inhabitants. There are many prejudices to overcome and ideas to be conformed to. The custom house regulations of various countries are complex and a great deal of attention must be given to meeting these regulations to avoid loss and trouble.

OBITUARIES

G. Charles Connor died March 27 of blood poisoning following an operation for intestinal abscess. Mr. Connor was manager of the Philadelphia office of the Sprague Electric Co., which position he had held since February, 1903. He leaves a widow and son.

Nathan P. Towne, chief engineer of the Cramp Ship Building Co., Philadelphia, Pa., and formerly an engineer of the United States Navy, died at his home in Philadelphia, April 23. Since 1893 Mr. Towne designed and superintended the construction of the engines of nearly all the battleships, cruisers and vessels built at Cramp's.

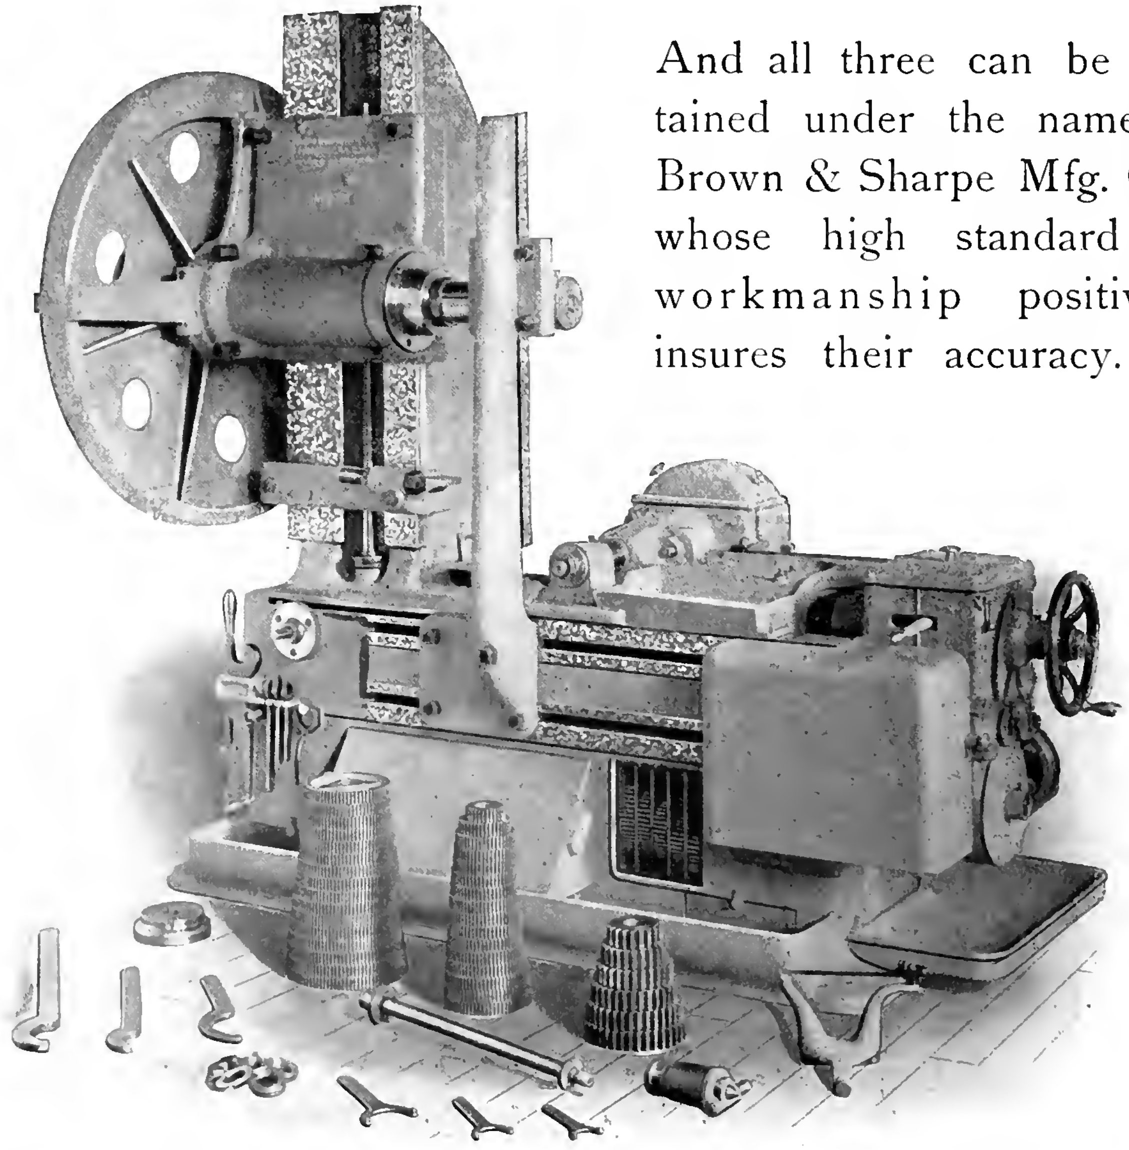
John Hall, a prolific inventor, died of pneumonia at St. Luke's Hospital, New York, April 20, aged eighty years. He was the inventor of the Hall car coupler, and while chief engineer of the A. Coburn Co., Philadelphia, Pa., manufacturers of thermometers, he made many improvements which greatly reduced the cost of thermometers, and made possible the cheap thermometers now in common use.

MATTHEW MORTON

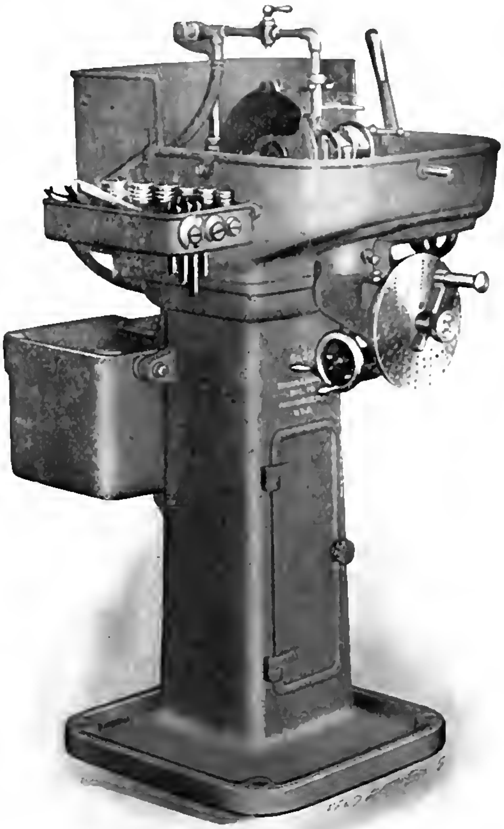
Matthew Morton, president and founder of the Morton Mfg. Co., Muskegon Heights, Mich., died at his home in that city, March 10, from an attack of pneumonia, in the seventy-third year of his age. A passion for mechanics and development of new ideas and improvements in machinery characterized Mr. Morton's life, and he was actually engaged in his business pursuits up to the Saturday noon preceding his illness.

Mr. Morton was a native of Scotland. He was born in Ayrshire, May 5, 1836. His father and mother, James and Margaret Morton, moved their family to America in 1844, and settled on a farm in Armada Township, Macomb Co., Michigan. Mr. Morton lived on the farm until he attained his majority. He frequently would go to Romeo, a distance of seven miles, to market and generally spent a little time at a machine shop there in making parts for a foot lathe. These parts he took home and stored in the woodshed, and one rainy day, when they were all ready, he assembled the lathe, quite to the displeasure of his parents, who did not take kindly to mechanical pursuits, but the lathe served its purpose and helped do the repair work in the community to general satisfaction. This incident clearly shows the trend of Mr. Morton's mind in early years.

After becoming of age, Mr. Morton moved to Armada village and with his foot lathe started in business, and a year later moved to Lapeer, Mich., at that time a frontier lumber town, and engaged in the steam engine business under the name of the Lapeer Engine Works. In 1861 he constructed his first steam engine, making the patterns and molding them and melting the iron in a home-made cupola. He machined the parts and assembled the engine unassisted, and did the entire work himself. He made a reputation for building engines of



Providence, Rhode Island, U. S. A.



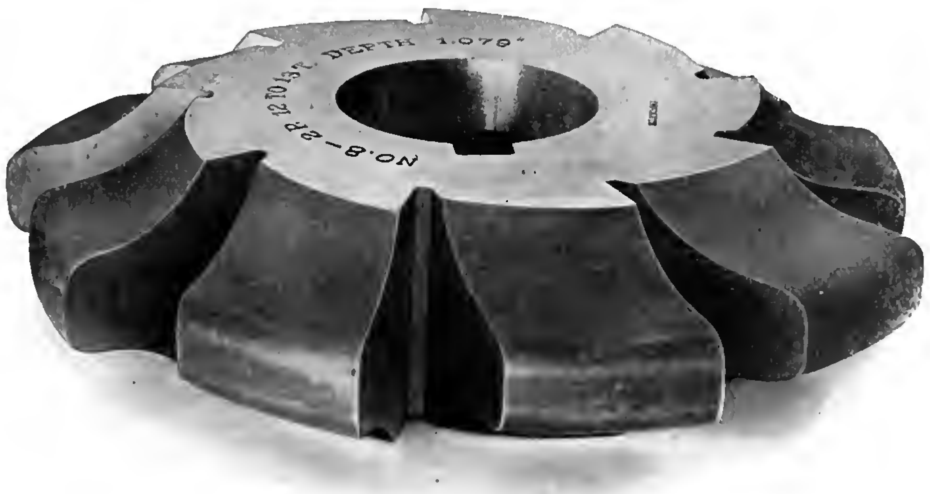
ACCURACY is a part of the machines because of their rigid construction, large index wheels, accurate indexing mechanisms, and long and wide bearing surfaces.

ACCURACY is established in the cutters because their forms are carefully laid out from original curves which are the standards of modern gearing practice.

ACCURACY in the grinding is made possible because the machines grind every cutter radially and equidistant, which is the only way the original forms of the cutters can be maintained.

By means of such a combination of B. & S. Machines and Cutters, accurately cut gears are obtained.

Write for circulars of the machines and cutter list.



Matthew Morton

very low steam consumption, and a prosperous business was established.

In 1866 he formed a co-partnership with the late William McDonald, which lasted for about five years. In 1871 he disposed of his interest in Lapeer to Mr. McDonald and moved to Romeo, where he again started the business of building engines. While in Romeo he built his first marine engine which operated with such economy and was so satisfactory that the user made him a present of $100. He also built a portable machine for boring cylinders and with it by hand bored out four locomotive cylinders in twenty hours.

From 1875 to 1878 he was engaged in building and repairing marine and stationary engines with Mr. A. H. Hamblin in St. Clair, Mich. The partners returned to Romeo where they began manufacturing agricultural machinery, but depression in business and financial reverses overtook them and Mr. Morton again started at the foot of the ladder with his foot-power lathe, and then founded the present business. He built the first successful key-seater that cut with a single tool, which proved to be constructed on the best principle for cutting key-ways. The developments of this line were such that machines were required to be built to cut key-ways up to six feet long and six inches wide.

In 1887 Mr. Morton developed the Morton portable slotter and planer, which was the first machine used in the Pittsburg district for planing the feet and windows of roll housings. The machine proved to be a valuable tool for heavy work and has since been largely sold to builders of heavy machinery in America and foreign countries. In 1891 Mr. Morton and the other members of his company moved to Muskegon Heights, a suburb of Muskegon, where in the same year the Morton Mfg. Co. was incorporated with Matthew Morton, president; A. T. Morton, vice-president; and William Rowan, secretary and treasurer, who have since been officially connected with the company. From this time on the draw-cut shaper was developed for general machine shop work, railroad work, steel foundry work, etc. The first machine built was of 26-inch stroke, from which start machines have been developed up to the traveling head planer and shaper, the largest in the world, having a stroke of seven feet. The machine stands 22 feet high and weighs 35 tons complete.

Mr. Morton was original in his ideas and constructive methods. He never looked at the catalogues of other machine tool builders to see what he should make. During his life he took out over forty patents, which nearly all have proved to be useful and valuable. He is survived by his wife, a daughter and two sons.

SOCIETIES AND COLLEGES

Beloit College, Beloit, Wis. Sixty-second annual announcement and catalogue for 1909-10. 159 pages, 5¼ x 7⅝ inches.

University of New Mexico, Albuquerque, N. M. Bulletin of the university containing catalogue for 1908-09 and announcements. 126 pages, 5⅝ x 7½ inches.

The Massachusetts Institute of Technology, Boston, Mass., has made fuller provision for advanced study relating to the higher degrees of Master of Science, Doctor of Philosophy, and Doctor of Engineering. During the present year, graduate students were awarded $5,100 for scholarships and graduate scholarships. The library received accessions aggregating 5,163 items for the year of 1908.

The executive committee of the Museum of Safety and Sanitation, of 29 W. 39th Street, N. Y., has detailed Dr. Wm. H. Tolman, the director, for field work, and he will start May 1 on a lecturing tour. Chambers of commerce, manufacturers' associations, engineering, insurance and architectural societies, railway and other clubs, may avail themselves of this illustrated exposition of devices and methods for reducing damage suits and preserving efficiency for the cost of the lantern operator ($10) if not too far removed from the itinerary.

The National Metal Trades Association held its eleventh annual convention in the Hotel Astor, New York, April 14 and 15. Nearly 200 were registered in attendance, and the association was welcomed by Hon. Patrick H. McGowan, president of the New York Board of Aldermen. A number of valuable papers were presented and discussed. Among them was, "Profit Sharing," by R. T. Crane, Crane Co., Chicago, Ill., and N. O. Nelson, N. O. Nelson Mfg. Co., St. Louis; "The Premium System of Paying for Labor," by F. C. Blanchard, works manager, The Ashcroft Mfg. Co., Bridgeport, Conn.; "Industrial Peace," by Hon. C. P. Neill, United States Commissioner of Labor; "What the Workingman Wants from the Employer," by James Wilson, president Pattern Makers' League of North America; "Employers' Liability Insurance," the Hon. Epaphroditus Peek, of Yale University; "Industrial Training Through Apprenticeship Systems," by E. P. Bullard, Jr., of the Bullard Machine Tool Co., Bridgeport, Conn., "The Labor Question," by David Gibson, editor "Common Sense," Cleveland, Ohio. The officers elected for the coming year are: H. P. Eells, president; J. H. Schwacke, first vice-president; H. W. Hoyt, second vice-president, and William Lodge, treasurer.

The charter members of the Museum of Safety and Sanitation met on Tuesday evening, March 30 and elected the following officers: Acting president, Philip T. Dodge; vice-presidents, Charles Kirchhoff, T. C. Martin, Prof. F. R. Hutton, and R. W. Gilder; treasurer, Robert A. Franks; plan and scope committee, Prof. F. R. Hutton, William J. Moran, Dr. Thomas Darlington, B. D. Whitfield, and P. T. Dodge; director, Wm. H. Tolman. The Museum of Safety and Sanitation has its office at the United Engineering Societies' Building, 29 West 39th Street. The objects of the museum are to study and promote means and methods of safety and sanitation and the application thereof to any and all public or private occupations whatsoever, and of advancing knowledge of kindred subjects; and to that end to establish and maintain expositions, libraries and laboratories and their branches, wherein all matters, methods and means for improving the general condition of the people as to their safety and health, may be studied, tested and promoted, with a view to lessening the number of casualties and avoiding the causes of physical suffering and of premature death; and to disseminate the results of such study, researches and tests, by lectures, exhibitions and other publication.

COMING EVENTS

May 4-7.—Spring meeting at Washington, D. C., of the American Society of Mechanical Engineers. Calvin W. Rice, 29 West 39th St., New York City, secretary.

May 5-7.—Joint convention of the Southern Supply and Machinery Dealers' Association and American Supply and Machinery Manufacturers' Association, Chattanooga, Tenn. Alvin M. Smith, Richmond, Va., secretary and treasurer of the Southern Supply and Machinery Dealers' Association, and F. D. Mitchell, secretary and treasurer, American Supply and Machinery Manufacturers' Association, 309 Broadway, New York.

May 12-14.—Annual meeting of the National Supply and Machinery Dealers' Association, at the Fort Pitt Hotel, Pittsburg, Pa. Secretary-Treasurer, A. T. Anderson, 41 Wade Building, Cleveland, Ohio.

May 18-20.—American Foundrymen's Association convention, Cincinnati, Ohio, Hotel Sinton, headquarters. Richard Moldenke, secretary, Watchung, N. J.

May 25-26—Spring convention of the National Machine Tool Builders' Association at Milwaukee, Wis. Plankington House, headquarters. P. E. Montanus, president of the Springfield Machine Tool Co., Springfield, Ohio, secretary.

May to November, 1910.—International Exhibition of Railway and Land Transport, Buenos Ayres, Argentine Republic, commemorating the first centennial of the Argentine Independence. The officers of the exhibition are, Alberto Schneidweind, general director of Argentine Railways, president; H. H. Loveday, general manager of Argentine Railways, and Dr. H. H. Trays, local director of Central Argentine Railways, vice-presidents; Juan Pelleschi, commissioner general; Eduardo Schlatter, secretary.

June 1.—Opening of the Alaska-Yukon-Pacific Exposition in Seattle, Washington, which is designed to call the attention of the world to the importance of Seattle as the western gate-way to the United States, and to its rapidly growing commercial importance. The exposition will include many working exhibits, among which are meat packing, watch making, jewelry, silk-making, rope-making, telephoning, printing, etc.

June 1-5.—Annual meeting of the International Railway General Foremen's Association at Chicago, Ill. E. C. Cook, Royal Insurance Building, Chicago, Ill., secretary.

June 7-19.—Cleveland Industrial Exposition, under the auspices of the Cleveland Chamber of Commerce, Cleveland, Ohio. It is estimated that 125,000 different articles are manufactured in Cleveland's 3,500 shops, and it is proposed to display to the world at this exposition the wonderful industrial facilities of the city. The products comprise steel ships, heavy machinery, hardware, twist drills, reamers, milling cutters, wire nails, bolts, nuts, vapor stoves, malleable castings, automobiles, paints and oils, etc. William G. Rose, Cleveland, Ohio, secretary.

June 9-11.—Joint convention of the Southern Hardware Jobbers' Association and the American Hardware Manufacturers' Association at Hotel Shenley, Pittsburg, Pa. F. D. Mitchell, 309 Broadway, New York, secretary and treasurer.

June 16-18.—Annual convention of Railway Master Mechanics' Association on Young's Million-Dollar Pier, Atlantic City, N. J. Joseph W. Taylor, Old Colony Building, Chicago, Ill., secretary.

June 21-23.—Annual convention of the Master Car Builders' Association on Young's Million-Dollar Pier, Atlantic City, N. J. Joseph W. Taylor, Old Colony Building, Chicago, Ill., secretary.

June 22-24.—National Gas and Gasoline Engine Trades Association convention, South Bend, Ind. Headquarters, Oliver Hotel. Albert Stritmatter, Cincinnati, Ohio, secretary.

September 25-October 2.—Hudson-Fulton celebration of the three-hundredth anniversary of the discovery of the Hudson River by Hendrick Hudson in 1609, and the one hundredth anniversary of the successful application of steam to the navigation of the Hudson River in 1807. The headquarters of the commission are in the Tribune Building, New York City, General Stewart L. Woodford, president, and Mr. Henry W. Sackett, secretary. The commission solicits the loan of collections of machinery, models, books, etc., having a bearing on the history of early steam navigation in the United States.

NEW BOOKS AND PAMPHLETS

New Method of Gas Manufacture, by Henry I. Lea. Pamphlet of 16 pages, 6 x 9 inches. Paper read before the Illinois Gas Association, Chicago, Ill., March 17, 1909. Henry I. Lea, The Rookery, Chicago, Ill.

Social Engineering. By W. H. Tolman, with introduction by Andrew Carnegie. 364 pages. Published by the McGraw Publishing Co., New York. Price $2, instead of $5 as given in the review in the April number.

Annual Report (49th) of the Superintendent of Insurance of the State of New York, Part 4. Assessment or Cooperative and Fraternal Insurance. 271 pages, 6 x 9 inches. Published by the State of New York, Albany, N. Y.

A Study of Roof Trusses, by N. C. Ricker, and Lighting Country Homes by Private Electric Plants, by T. H. Amrine, published by the University of Illinois, Urbana, Ill., have been issued in a new edition in response to the demand. These are known as Bulletins Nos. 16 and 25 respectively.

Supplement to MACHINERY, June, 1909

Operations for the Article in this number entitled "Machine Shop Practice—Twist Drill Grinding"

SHOP OPERATION SHEET NO. 100.

Franklin D. Jones. MACHINERY, June, 1909

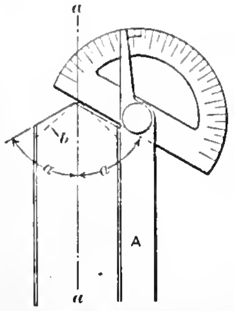

Fig. 1

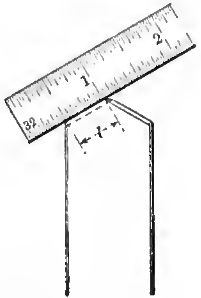

Fig. 2

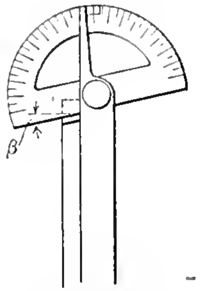

Fig. 3

Machinery, N.Y.

Grinding a Flat Drill.

NOTE.—A drill should be ground so that the two cutting edges make the same angle, *a*, with the axis *a-a*. When these angles are not equal, one side will have more work to do than the other. The angle of clearance β should also be equal for both cutting edges. For general work this angle should be about 12 degrees, but if the material to be drilled is soft and the feed is to be heavy, it may be increased to 15 degrees. The length *l* of each cutting edge should also be the same, as otherwise the hole drilled will be larger than the drill diameter.

1. Set a protractor *A* (a tool used for measuring angles) to an angle of 59 degrees, and test the angularity of the cutting edges of the drill to be ground. If these edges should, for example, be as indicated by the dotted lines *b*, when grinding, more metal would, of course, be removed from the point of the drill. Thus it will be seen that this preliminary test saves time.

2. When grinding, support the drill on the tool rest, and move it slowly back and forth in order that any unevenness in the wheel face will not affect the straightness of the cutting edge. Use, preferably, the face of the emery wheel in order to derive benefit from the cooling water, and grind slowly so that the temper of the tool will not be affected. The position of the tool in relation to the face of the emery wheel should be such that the angle *a* which the cutting edges make with the axis *a a*, and the angle of clearance β will be ground as nearly correct as can be judged.

3. Test the angularity of each cutting edge with the protractor, as shown in Fig. 1, and continue grinding until each edge is at an angle of 59 degrees with the axis of the drill.

4. With a scale measure the length *l* of each cutting edge as shown in Fig. 2; if they are unequal correct by grinding, being careful not to change the angle of the cutting edge.

5. Set the protractor to an angle of 12 degrees; test the clearance angle β and, if necessary, regrind until the clearance is approximately 12 degrees on each side.

NOTE.—When grinding a drill by hand it should, of course, as far as possible, be made correct with the first grinding. The operation has been somewhat separated in the foregoing in order to make the requirements more clear.

SHOP OPERATION SHEET NO. 101.

Franklin D. Jones. MACHINERY, June, 1909.

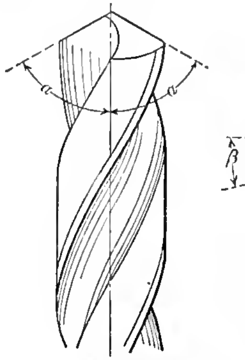

Fig. 1

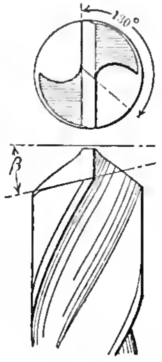

Fig. 2

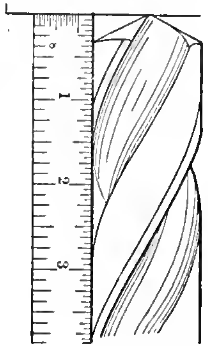

Fig. 3

Machinery, N.Y.

Grinding a Twist Drill.

NOTE.—The cutting edges of a twist drill should, as with the flat drill, be equiangular, of the same length, and have the same clearance. When both the cutting edges of the drill are ground to the same angles *a*, one cutting edge supports or counteracts the tendency of the other to spring from the cut (providing the clearance is also correct), but when the angles *a* are different, one edge will do more work than the other, thus subjecting the drill to an unbalanced twisting or torsional strain.

1. Grind each cutting edge to an angle *a* of 59 degrees (see Fig. 1), using the face of a wet emery wheel, and proceeding the same as if a flat drill were being ground, as described in paragraph 2 of the preceding sheet. The end of the drill will then appear as shown in Fig. 2. The clearance angle will be approximately correct when the line joining the cutting edges is at an angle of 130 degrees as shown.

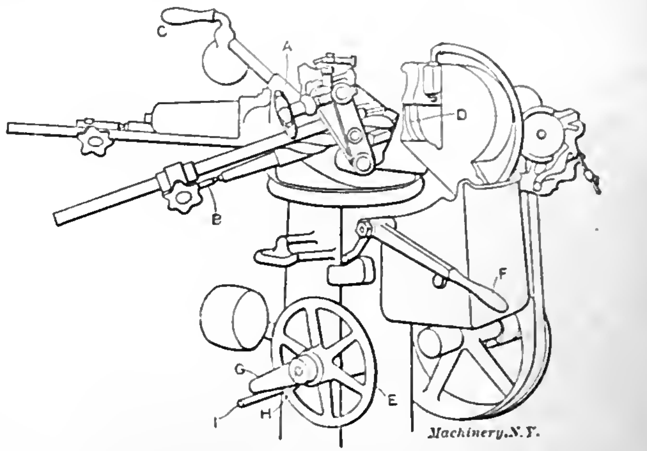
NOTE.—There is a difference of opinion as to the best angle *a* of the cutting edge. As this angle is decreased the pressure required to force the drill through the metal becomes less, but the length of each cutting edge is increased with the result that more power is required to turn the drill. An included angle of 118 degrees is thought by some to equalize the thrust and torsion to the best advantage, while others advocate much more acute angles.

2. Grind away the metal back of each cutting edge, indicated by the shaded portion (Fig. 2), by moving the outer end of the drill, which is fulcrumed on the tool-rest, up and down with the right hand. Continue grinding until a surface, which should be approximately conical in form, is blended into the flat part previously ground. The backing or clearance of the cutting edges should be of such a form and angle as to allow the drill to cut freely and without binding as it is fed into the metal.

3. The clearance for each cutting edge may be tested by placing the drill point against a flat surface, and then slowly revolving it close to a scale held in the position shown in Fig. 3. If the clearances are not approximately alike, this will be shown by their relative positions to the graduation marks upon the scale, as the drill is turned.

SHOP OPERATION SHEET NO. 102.

Franklin D. Jones. MACHINERY, June, 1909



Grinding a Twist Drill in a Sellers Grinder.

NOTE.—As it is impossible to grind drills theoretically correct by hand, at least in a reasonable length of time, special grinders are used for this purpose in which the movement of the drill in relation with the wheel is automatically guided so that its end is correctly formed. The way in which a Sellers grinder is operated is explained in the following:

1. Open the jaws of the chuck by operating the hand-wheel *A* and insert the drill from the back, letting the end rest on the lower jaw with the cutting edge just touching the end-stop. Close the jaws and bring up back-center *B* and clamp it; then release the jaws, hold the drill against center *B* with the left hand and, at the same time, rotate it against the two side-stops on the jaws. Then clamp the drill tightly by hand-wheel *A*, using the right hand.

2. Turn handle *C* part way back and feed up the emery wheel *D*, by hand-wheel *E*, until it just touches the drill. Turn handle *C* forward, feed in the wheel and pass it back and forth over the face of the drill by lever *F*, moving handle *C* back a little every other cut. When the entire end has been ground, hold lever *F* stationary and rotate the drill, taking a finishing cut over the surface just ground.

3. When one side of the drill is finished, loosen the jaws of the chuck, and turn the drill half way around. Press its lips, as before, against the side-stops on the jaws and at the same time hold the drill firmly against the back-center *B*; then tighten the chuck and grind the second lip without adjusting the stone.

NOTE.—When considerable metal has to be removed, and it is necessary to adjust the emery wheel for two or more cuts, mark its final position by clamping the lever *G*, by the nut *H*, against the stop-pin *I*. When the second half of the drill is being ground, feed the emery wheel forward until lever *G* strikes the stop-pin, thus bringing the wheel to the position it occupied when grinding the first half. When this side is finished, turn the drill again, and re-grind the first half to insure having both sides alike.

KNURLS AND KNURLING OPERATIONS—1

PRACTICE FOR THE BROWN & SHARPE AUTOMATIC SCREW MACHINES

DOUGLAS T. HAMILTON[*]

Douglas T. Hamilton[†]

In designing a set of cams for knurling operations on the Brown & Sharpe automatic screw machines, it is desirable that as little experimental work as possible be required. The following formulas and data have been derived and collected by the writer for use in work of this kind, and are here presented with the hope that they will prove of value to others. Before taking up the data and formulas, the different tools and appliances necessary for knurling will be briefly reviewed.

Rear Cross-slide Knurl-holder

A very solid and rigid rear cross-slide knurl-holder is shown in Fig. 1. It is held by means of the cap screw *B* on the outside face *A* of the cross-slide tool-holder. This screw also holds the circular cut-off tool in position. The holder allows the knurl to pass over the work, and returns it after the piece has been cut off. The holder is simple and cheap, and covers a wide range of work, as the distance *C* to the circular cut-off tool can be changed so that the work will be cut off closer or further away from the knurl, as desired. The set-screw *D* supports the knurl-holder rigidly, and also provides means for adjusting. The oil hole *E* permits a good supply of oil to reach the knurl for removing all chips. This holder, however, can be used only on the tool-holder which carries the cut-off tool, because the finished piece must be severed from the bar before the knurl can return.

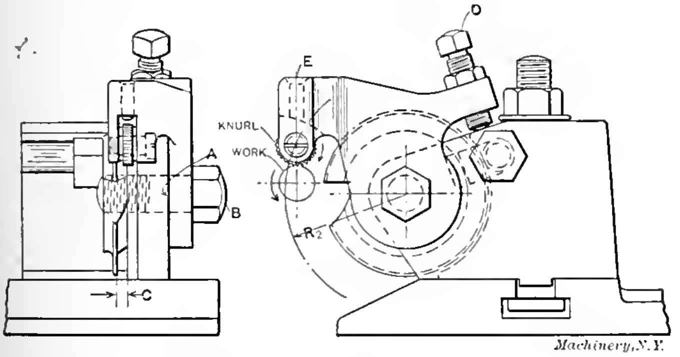

Fig. 1. Rear Cross-slide Knurl-holder

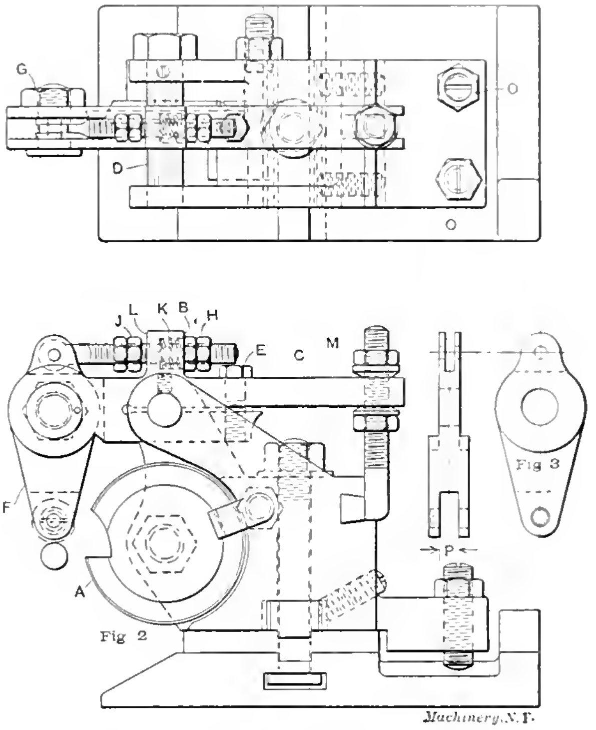
Universal Cross-slide Knurl-holder

The knurl-holder shown in Fig. 1 is limited in its range, but the one shown in Fig. 2, while more expensive and complicated, is also more efficient and universal. This holder eliminates the cross-slide tool-post, and carries the circular cut-off tool *A* in the same way as it would be held in the ordinary tool-post. It can also be used in conjunction with either circular form or cut-off tools on the front cross-slide. The knurl can operate at any desired position on the work by moving the arm *C* along the bar *D* and then clamping it by means of the cap screw *E*. The holder *F* which carries the knurl can be moved in or out to any position to suit the different diameters of stock being knurled, and is adjusted by means of adjusting nuts *H* and *J*. The nut *G* is adjusted to insure a good working fit of the holder, and also prevents side movements. When the knurl passes over the stock the nut *H* is brought up against the face *B* of the arm *C*, and also puts a tension on spring *K*, so that when the knurl has passed over the work and the pressure on the spring is released, the spring forces the nut *J* up against the face *L* and permits the knurl to clear the work when passing back over the stock. The nuts *M* permit the arm *C* to be raised or lowered for different diameters of stock. The washers are convex as shown so that the arm is held firmly even when at an angle to the face of the nuts *M*. Screws *O* tend to steady the holder.



Figs. 2 and 3. Universal Cross-slide Knurl-holder

In Fig. 3 the knurl-holder proper is shown in detail. It will be seen that knurls of different widths may be used by making the distance *P* to suit.

Straight Knurls

Straight knurls, as shown in Fig. 4, are generally cut in the milling machine with a cutter of the desired angle. The greatest difficulty is met with in selecting a suitable angle for the teeth for knurling different materials. A blunt knurl will work better on soft materials than one with a more acute angle. The writer has found by experiments that the following angles are satisfactory for the materials specified:

Materials	Angle
Brass and hard copper	90 degrees.
Gun screw iron	80 degrees.
Norway iron and machine steel	70 degrees.
Drill rod and tool steel	60 degrees.

When laying out a set of cams for knurling operations, it is necessary to know the depth of the tooth in the knurl.

If $d =$ depth of tooth in knurl,

$p =$ circular pitch of knurl,

---

[*] Address: Northern Electric & Manufacturing Co., Montreal, Can.

[†] Douglas T. Hamilton was born in Brownsburg, Province of Quebec, Can. He received a high school education and completed a correspondence course in mechanical engineering. He served an apprenticeship with the Dominion Cartridge Co., Brownsburg, and has since worked for the Montreal Watch Case Co., Eaves Bros., jewelers; the Linotype Co., and the Northern Electric Co., as die-sinker, tool-maker and designer of screw machine tools. His specialty is designing automatic machinery and machine tools. He has had a wide experience in designing jigs and fixtures, punches, and dies and other special tools.

P = "pitch of knurl" = number of teeth in one inch of the circumference $= \frac{1}{p}$,

a = included tooth angle of knurl,

then, for all practical purposes, the depth may be calculated as follows: When

$$a = 90 \text{ degrees, } d = \frac{p}{2},$$

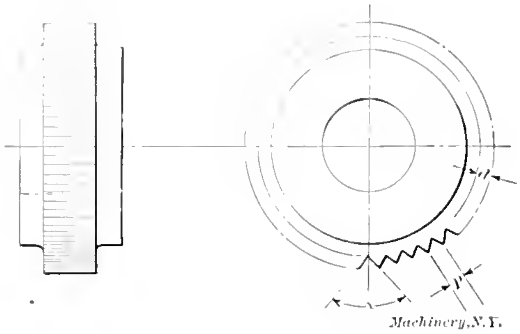


Fig. 4. Straight Knurl

$$a = 80 \text{ degrees, } d = \frac{p}{2} \times \tan 50 \text{ degrees,}$$

$$a = 70 \text{ degrees, } d = \frac{p}{2} \times \tan 55 \text{ degrees,}$$

$$a = 60 \text{ degrees, } d = \frac{p}{2} \times \tan 60 \text{ degrees.}$$

The values of d for different pitches ranging from 16 to 62 teeth per inch of circumference have been calculated from these formulas and are given in Table I.

Concave Knurls

The designing of a concave knurl which will work satisfactorily is, in most cases, a difficult problem, as the radius of the knurl cannot have the same radius as the piece to be knurled. It will be seen in Fig. 5 that if the knurl and the work are of the same radius, the material compressed by the knurl will be forced down on the shoulder A and will consequently make a poor looking job. The writer, having met with this difficulty, finally devised an empirical formula which gives satisfactory results.

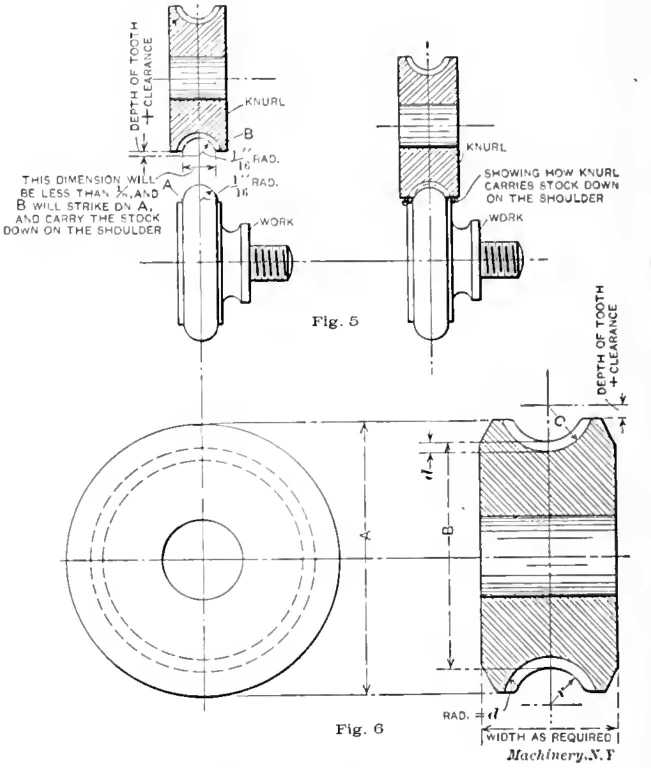
A design of a concave knurl is shown in Fig. 6, and all the important dimensions are designated by letters. To find these dimensions, the pitch of the knurl required must be known, and also approximately the throat diameter B. This diameter, of course, must suit the knurl holder used, and be such that the circumference contains an even number of teeth with the required pitch. When these dimensions have been decided upon all the other unknown factors can be found from the formulas given in the following.

Let R = radius of piece to be knurled,
r = radius of concave part of knurl,
C = radius of cutter or hob used for cutting the teeth in the knurl,
B = diameter over concave part of knurl (throat diameter),
A = outside diameter of knurl,
d = depth of tooth in knurl,
P = pitch of knurl (number of teeth per inch circumference),
p = circular pitch of knurl.



Figs. 5 and 6. Concave Knurls

Then $r = R + \frac{1}{2} d$,

$C = r + d$,

$A = B + 2r - 3d + 0.010$ inch.

As the depth of the tooth is very slight, the outside circumference will be accurate enough for all practical purposes for calculating the pitch, and it is not necessary to take into consideration the pitch circle as is done when calculating gears.

Example:—Assume that the pitch of a knurl is 32, that the throat diameter B is 0.5561 inch, that the radius R of the piece to be knurled is 1/16 inch, and that the angle of the teeth is 90 degrees; find the dimensions required for making the knurl.

Using the same notation as above, we have:

$$p = \frac{1}{P} = \frac{1}{32} = 0.03125 \text{ inch,}$$

$d = 0.0156$ (see Table I) inch,

$$r = \frac{1}{16} + \frac{0.0156}{2} = 0.0703 \text{ inch,}$$

$C = 0.0703 + 0.0156 = 0.0859$ inch,

$A = 0.5561 + 0.1406 - 0.0468 - 0.010 = 0.6399$ inch.

Straight concave knurls, when very small, are generally made with a master convex knurl. When the knurls are large enough, a milling cutter with the proper radius is used for cutting the teeth. As it is very difficult to make a concave knurl when the radius is very small, and as the knurl in most cases is not required to be absolutely straight, the

method described in the following for spiral knurls, can be used for making straight concave knurls on the milling machine with teeth in planes practically parallel with the axis of the knurl.

Spiral Concave Knurls

It is, in general, very difficult to cut spiral concave knurls, especially when the radius of the knurl is very small. In Fig. 7 is shown a method which has worked very satisfactorily, and which is also easily accomplished. A hob as shown in Fig. 8 is used, the included angle of the threads of which is made to suit the material to be knurled. The hob is fluted similar to a master tap, excepting that the flutes are not as deep and a greater number of flutes is used. If the hob has more than a triple thread, for instance, the width of the lands should be to the width of the flutes in the ratio 2 to 1. The lead of the hob governs the angle of the spiral on the knurl, and the angle formed by cutting hobs with different leads can be derived, approximately, by means of the following formula:

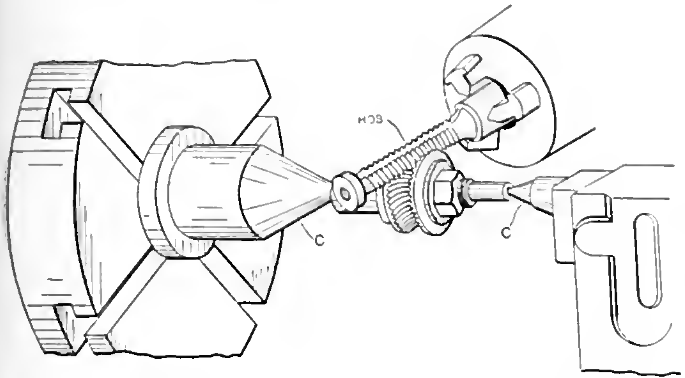


Fig. 7. Cutting a Concave Knurl by a Hob in the Milling Machine

Let α = angle required,
B = one-half the lead of the thread of the hob,
D = diameter of the hob.

Then $$\frac{B}{1.5\,D} = \tan \alpha.$$

Example:—If a hob has a double thread, the lead of which is ⅛ inch, and the diameter of the hob is ¼ inch, find the angle α.

B = ½ of the lead = 1/16, and therefore $\tan \alpha = 1/16 \div 3/8 = 0.1667$; $\alpha = 9\frac{1}{2}$ degrees.

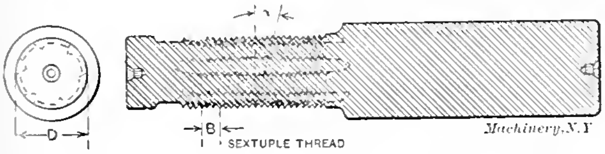

Fig. 8. Hob used for Cutting Concave Knurls in the Milling Machine

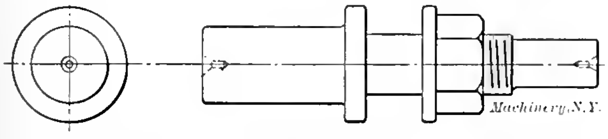

Fig. 9. Arbor for Cutting Concave Knurls in the Milling Machine

Cutting a Spiral Concave Knurl in the Milling Machine

It will be seen from Fig. 7 that when cutting a concave knurl in the milling machine, the knurl is held on an arbor shown in detail in Fig. 9. This arbor rotates freely on the centers C, the knurl being held tightly against the shoulder on the arbor by the nut shown. When the knurl has been tightened, the arbor is put between the centers and the table of the milling machine is raised so that the hob comes in contact with the knurl. The machine runs slowly at the start so that the hob will not be forced, but will space the teeth equally. The speed can be increased after the hob has started to cut properly. The hob is held in a chuck provided with a shank fitting the socket in the milling machine spindle. The work should be fed slowly at first, and care should be taken that the arbor rotates freely on the centers, as otherwise the knurl will not follow the lead of the hob properly, and a well-shaped teeth will not be produced. Care should also be taken to have the diameter of the concave knurl the correct size so that it will contain an even number of teeth, as required by the circular pitch. When the knurl has been cut, the corners should be removed as shown in Fig. 6, then no ragged edges are left on the work, as is the case if the corners are not removed. The table of the milling machine should not be set over when cutting knurls in this manner but should be left straight.

Designing and Cutting Diamond Knurls

The general methods of using diamond knurls are as follows:

1. When a knurl-holder, as shown in Fig. 10, can be used a pair of spiral knurls are used, one right- and the other left-handed.

2. When a cross-slide knurl-holder, as shown in Fig. 1, is used, only one knurl can be used, being cut both right- and left-handed. A knurl cut in this manner would produce a female knurl on the work; so if a male knurl is required on the work, the first knurl is used as a master knurl in cutting the second knurl which will produce a male knurl on the work.

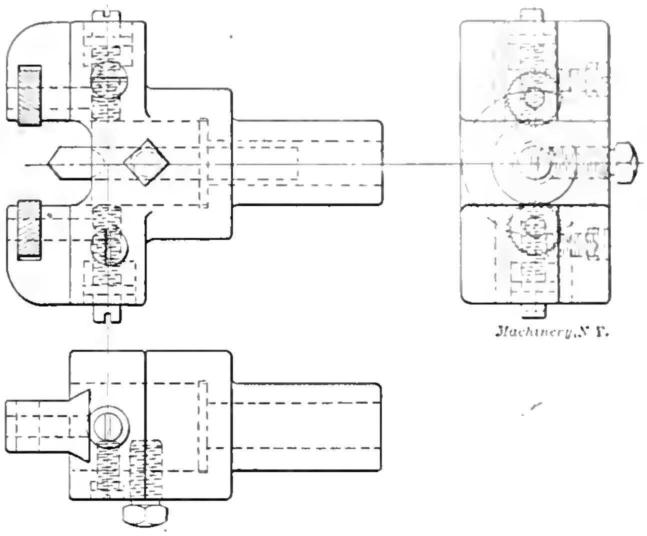

Fig. 10. Turret Knurl-holder for Brown & Sharpe Automatic Screw Machines

When only the pitch of the knurl required and the angle at which the teeth are cut, as indicated in Fig. 11, are known, then the number of teeth in the knurl must be found and also the spiral lead, as this governs the selection of the change gears used when cutting the knurl.

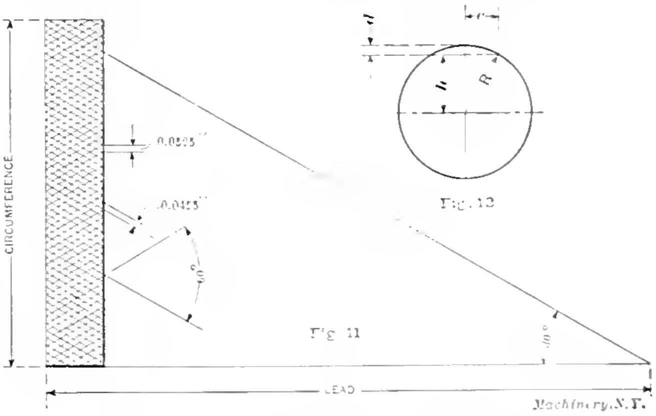

Fig. 11. Diagram for Finding Circular Pitch and Lead of Spiral Knurls.
Fig. 12. Diagram for Calculations Relating to the Feeds of Knurls

To Find the Number of Teeth on the Circumference of the Knurl

When the knurl is to form diamond shapes, as shown in Fig. 11, and the included angle is 60 degrees, the number of teeth can be found in the following manner. Let 22 be the normal pitch of the knurl. Then the circular pitch will be 0.0455 inch ÷ cos 30 degrees = 0.0525 inch, and the outside circumference divided by 0.0525 inch will be the number of teeth of the knurl.

To Find the Lead of the Spiral

To find the lead of a spiral of the knurl above, multiply the circumference of the knurl by the cotangent of 30 degrees. Assume that the knurl is 0.752 inch in diameter. Then the circumference equals 0.752 × 3.1416 = 2.3625 inches. The knurl has a circular pitch of 0.0525 and the number of teeth therefore equals 2.3625 ÷ 0.0525 = 45 teeth. The lead equals 2.3625 × cot 30 degrees = 4.09 inches.

THE RELATION OF DEPTH TO SPAN OF A GIRDER

FRED NEWELL*

In designing a girder or cantilever for any purpose where one is not tied to a particular depth by conditions or specification, it is often a matter of trial and error by those whose work or experience does not lead them to a knowledge of what will most surely be the best proportions of depth to span for a given deflection and stress. Even where one's knowledge of these proportions is of the best, the following table will prove a help in the first considerations of a design. It must, however, be remembered that the table is only of use where the girder is symmetrical in section about its neutral axis, and for a modulus of elasticity of 29,000,000, which is very general for structural shapes. The deflections used for calculating the table are those in most general use, being 1 inch per 100 feet span or $\frac{L}{1200}$, and 2 inches per 100 feet span or $\frac{L}{600}$, L being in inches. The lower limit is used where stiffness is necessary, and the higher limit where stiffness is not of primary importance.

If the modulus of elasticity is other than that taken in these calculations, the divisor of the expression in the last column of the table will be directly proportional to the value of the modulus. For each condition of loading, the divisor is inversely proportional to the assumed safe stresses.

To arrive at the results the writer has combined the bending mement formula $M = \frac{fI}{y}$, with the deflection formula $\delta = K\frac{WL^3}{EI}$, where

M = bending moment,
f = safe allowable stress,
I = moment of inertia of section,
d = depth of girder or cantilever,
y = distance of neutral axis from outer fiber = $\frac{d}{2}$ for symmetrical sections,
W = total load,
L = length of span,
δ = deflection,
K = constant depending on loading and support.

All dimensions are in inch-pound units. For example, take the simple case of a cantilever loaded at one end, and let $\delta = \frac{L}{1200}$, and $f = 10{,}000$ pounds per square inch.

$$M = WL = \frac{fI}{y} = \frac{2fI}{d};$$

$$\delta = \frac{WL^3}{3EI} = \frac{2fIL^2}{3EId} = \frac{2fL^2}{3Ed};$$

$$\text{but } \delta = \frac{L}{1200}; \text{ therefore } \frac{2fL^2}{3Ed} = \frac{L}{1200};$$

$$\text{and } d = \frac{2400fL}{3E} = \frac{2400 \times 10{,}000 \times L}{3 \times 29{,}000{,}000} = \frac{L}{3.625}$$

$$d = \frac{L}{3.625} = 0.276\,L.$$

Having arrived at the required depth for a given deflection, it is an easy matter to find a suitable section for the given stress; but in all cases where exact work is required, the actual deflection and stress should be obtained after the design has been completed.

* * *

The United States government inaugurated a plan two years ago for the purchase of coal on its heating value. At the present time there are forty departmental buildings in Washington, the Panama Railroad, more than three hundred buildings throughout the United States, navy yards and arsenals buying coal on specifications, the prime element of which fixes the amount of ash and moisture. Premiums are paid for any decrease of ash below 2 per cent at the rate of one cent per ton for each per cent. Reductions are made at an increasing rate for each per cent of ash when it exceeds the standard established by two per cent. The advantages of buying coal on these specifications are: bidders are placed on a strictly competitive basis, as regards prices and qualities; the field for both the government and the dealers is broadened, as trade names are ignored and comparatively unknown coals offered by responsible bidders may be accepted; the government is insured against poor and dirty coal and is relieved of disputes arising from condemnation on the usual visual inspection; experience with the old form of government contract is not always expedient to reject poor coal because of the difficulty, delay and cost of removal. Under the present system rejectable coal may be accepted at a greatly reduced price.

CORRECTION

A transposition of the titles of Figs. 41 and 42 occurred in the article on the Chicago and Northwestern Railway shop practice, published in the May number of MACHINERY. It should also be stated that the practice referred to as the company's method of boring piston rings, is instead its method of boring bushings for cylinders.

INCREASING THE EFFICIENCY OF A HORIZONTAL DRILLING, TAPPING AND BORING MACHINE

ALFRED SPANGENBERG*

A machine tool may be installed to handle work of a specific character and for the sake of economy in first cost it is frequently deemed advisable to select a standard type of simple design, and embodying only such features as are necessary for the work intended. Subsequently, if occasion requires, aditional features can be provided that will adapt the machine for a variety of work. The accompanying engravings illustrate a motor-driven, horizontal drilling, tapping and boring machine, and show a number of features that were recently added by the writer. This machine originally was designed for a class of work that would require comparatively short adjustments of the column, and therefore was provided with a hand ratchet movement.

The changes made were: Substituting a rapid power traverse for the column to enable quick adjustments on long work; providing a power feed for the head so that the machine could be used for milling; a new clamping arrangement for the column and also for the head, thus discarding open end wrenches and facilitating the clamping and loosening; providing means for shifting the sliding feed gears while the machine is running; and attaching a brass speed index plate to the controller and a pointer on the controller lever. This used in connection with a table of cutting speeds and feeds stamped on the brass plate shown fastened to the resistance box, provides the operator with a standard guide and eliminates all guess work as to the proper speed and feed for cutters of various diameters. The problem of applying features which are not in the form of standard attachments to a machine, and therefore were not contemplated in the original design, accounts for some of the devices appearing rather crude. The chief interest, however, lies in the fact that very little expense was involved, since the gears, handwheels and levers were taken from stock parts belonging to other machines.

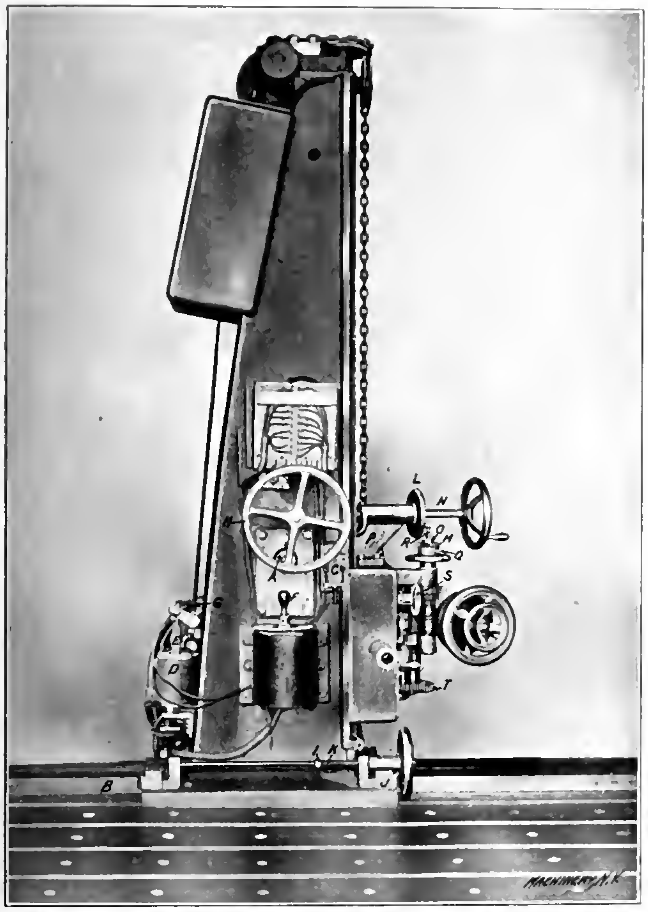

Fig. 1. Horizontal Drilling, Tapping and Boring Machine equipped with Power Traverse for the Column, Power Feed for the Head, New Clamping Devices for Column and Head, etc., to increase its Efficiency

A study of the engravings, Figs. 1 and 2, will make clear the application of the rapid power traverse for the column. Shaft *A*, Fig. 1, originally carried the ratchet wrench and transmits motion through bevel gears and a vertical shaft inside the column, to a rack pinion meshing with the rack *B*. For the purpose of deriving power from the motor, this shaft was replaced by a longer one that extends through the column and is also represented by the letter *A* in Fig. 2. Keyed to it is the spur gear *B* into which mesh the handwheel shaft pinion *C* and also the compound gearing driven by the pulley *D*. A belt that normally is loose, connects the pulley *D* with the motor pulley. The line engraving, Fig. 3, shows the method of fastening the latter onto the motor shaft. This was accomplished without removing the motor shaft by holding the drill in a ratchet wrench and feeding it in while the motor was running.

Fig. 2. Motor connected with Mechanism for the Column Traverse

When it is desired to traverse the column by power, the belt is tightened by closing the switch *C* (Fig. 1) which energizes the magnets *D* and they in turn bring the idler pulley *E* into position by means of the U-shaped magnet core, levers and shaft shown in the engraving. The column now can be run in either direction by operating the controller handle *F*. Spring *G* takes the weight of the magnet core and lever when the magnets are inactive. Final adjustment of the column is made with the hand-wheel *H*. The object of the belt drive was to avoid any accident, should the switch inadvertently be left closed and the motor started with the column clamped; and the sole reason for using the magnets was because they were a pair belonging to a discarded magnetic clutch planer drive. It will be observed that the idler pulley bracket cuts off some of the travel of the counterweight. This is of no consequence, however, as this particular machine never has to handle work requiring the head near the top of the column.

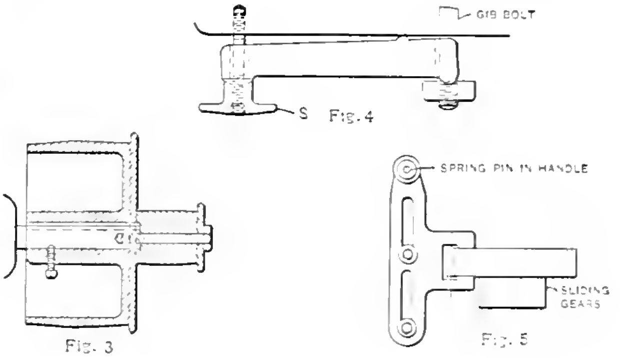

Fig. 3. Method of Fastening Rapid-traverse Driving Pulley on Motor Shaft. Fig. 4. Device for Clamping the Head without a Wrench. Fig. 5. Trunnion with Handle for Shifting the Feed Gears

The power feed for the head consists of the bevel gear *L* and sliding bevel pinion *M*. The axis of shaft *N* originally did not intersect with that of the vertical feed shaft *O*, and necessitated resetting the bracket *P*. A spring pin *Q* keeps the bevel pinion in mesh with the bevel gear when it is desired to feed the head by power. It was also necessary to

---

* Address: 951 W. Fifth Street, Plainfield, N. J.

lengthens the counter-shaft R. A crank wrench on the outer end of shaft N was superseded by the hand-wheel shown and the latter proved to be much more convenient. As stated previously, the primary object of a power feed for the head was to provide a feed for milling work, but when the spindle back gears are out, and the fast feed used, the adjustment of the head by power is quite rapid.

The clamping arrangement for the column is clearly indicated in Fig. 1. As will be seen, the clamping bolts are inverted and their heads beveled to fit the angle on the wedges *J*. Screwed on to the threaded end of each bolt is a block fitting the T-slot in the base plate. The hand-wheel sleeve is threaded to fit the tie-rod and the wedges act on the bolts by this means. Between the collar *I* on the tie-rod and the wedge *J* is a spring *K* which tends to keep the wedges loose when the hand-wheel is slackened off. Two turns of the hand-wheel is sufficient to clamp the column.

The line engraving, Fig. 4, shows the device for clamping the head to the column; the design is so simple that no explanation is necessary. The knob *S* is represented by the same letter in Fig. 1.

Means for sliding the feed gears *T* (Fig. 1) is shown in detail in Fig. 5. These gears formerly were shifted directly by band and held in place by a spring-pin that entered a groove in the shaft. The advantages of the new device at once are apparent.

An idea of the class of work this machine will handle to advantage is obtained from the half-tone, Fig. 6, which shows a 21-inch Pond rigid trurret lathe bed with the jigs in place ready to be drilled, bored and tapped. Four settings of the bed are necessary, as there are holes in both sides and ends. On work of this character the rapid power traverse is especially valuable. It will be of interest to note that this machine is also used to bore the head-stock for the bed just referred to. The head-stock and its jig was shown in Figs. 132 and 133 in the article on Jigs and Fixtures which appeared in the February issue of MACHINERY. For work of this character it is the practice to use universal joints for driving the cutter bars to avoid accurate setting of the jig; the machine only being used as a means for driving and feeding the bars and the jig acting as a guide. It must not be inferred, however, that this type of machine will not do accurate work without the use of jigs. As a matter of fact, the jig in question and nearly all of the jigs illustrated in the article above referred to were bored on a similar machine. For this work an adjustable outboard bearing is provided to support the end of the boring bar. These machines were built by the Pond Works of the Niles-Bement-Pond Co.

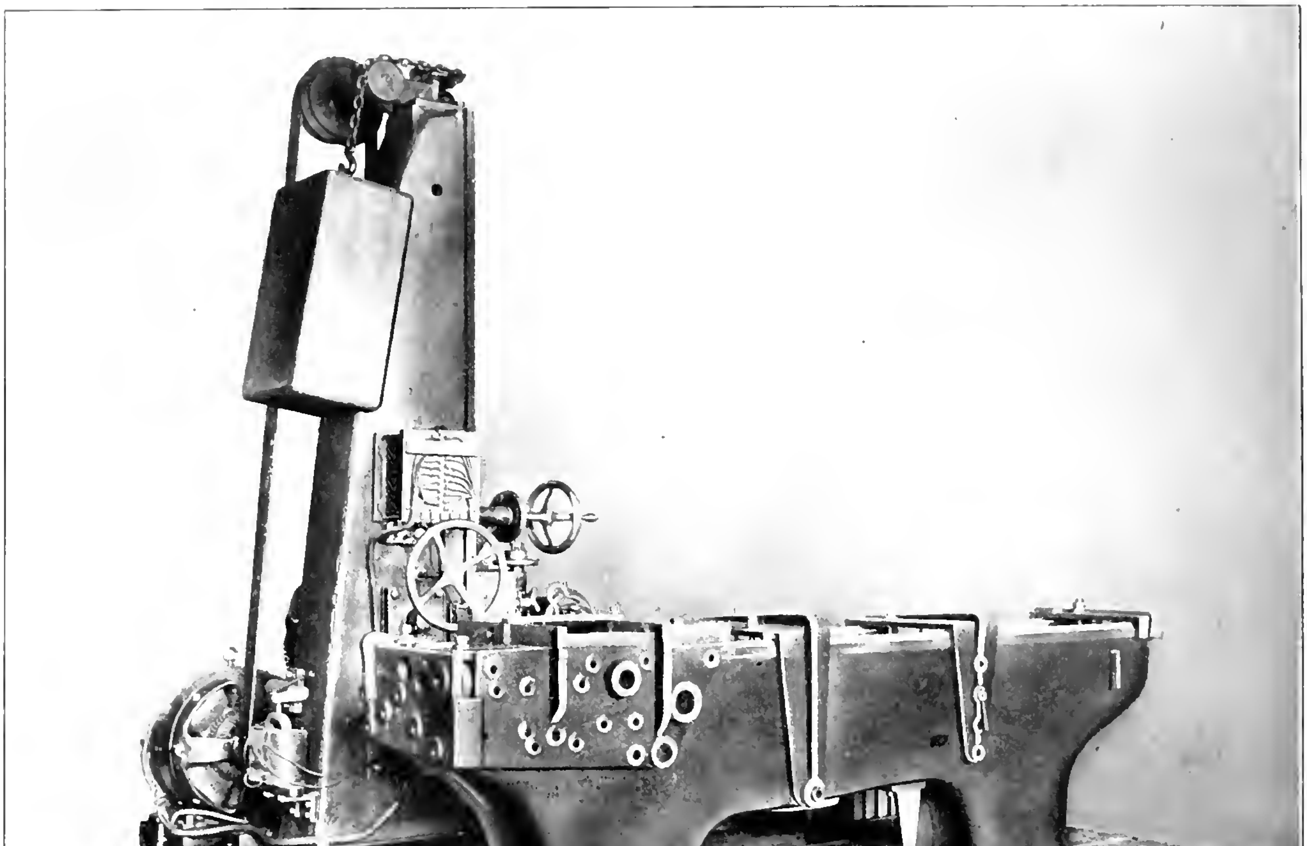

Fig 6. Twenty-one-inch Pond Rigid Turret Lathe Bed, with Jigs in Place, ready to be drilled

Recent correspondence in the *Engineering News* attributes the disintegration of concrete work in sea water to alternative freezing and thawing. It has been noted that this disintegration occurs only in that portion of the concrete which is between the high and low tide levels, being to this extent similar to the decay which takes place in piling under the same conditions. It has been found that this disintegration takes place in winter. At high tide the water penetrates the minute pores in the surface. As the tide lowers, this absorbed water freezes, expanding as it does so, and loosening the surface of the concrete. When it is again submerged, it again thaws, and a new supply of water enters the pores, so that the loosening process is repeated at the next tide. It is suggested that the concrete work be covered with a cement facing mortar; or better yet, that all the cement used in concrete laid below the watermark be thoroughly waterproofed, either by a patented compound or by the admixture of clay. Concrete which is not exposed at low tide is perfectly safe from disintegration.

An inventory of the resources of natural fuel represented by the peat deposits of the United States has been made by Prof. Charles A. Davis of the United States Geological Survey, who estimates that the bogs and swamps of the United States contain approximately 13,000,000,000 tons of peat, representing a value of $38,000,000,000.

LOGARITHMIC PAPER FOR DIAGRAMS

J. NORMAN JENSEN*

Engineers may be divided into two classes, *i. e.*, those who use diagrams to aid them in their work, and those who do not. The latter class will impatiently pass over any article or book in which a curve is used to express the relation between two or more variables. Some of these men detest a diagram more than they detest the curling tail of an integral sign. If diagrams are not too complicated they have, however, a certain place in business and in engineering. In most modern offices the fluctuation of prices in different commodities is shown graphically so that one can tell at a glance the general tendency of the market at any time. In the office of the manager, the shop foreman, or the timekeeper, diagrams showing the relation between wages and production are of great value as by means of them "leaks" can readily be discovered.

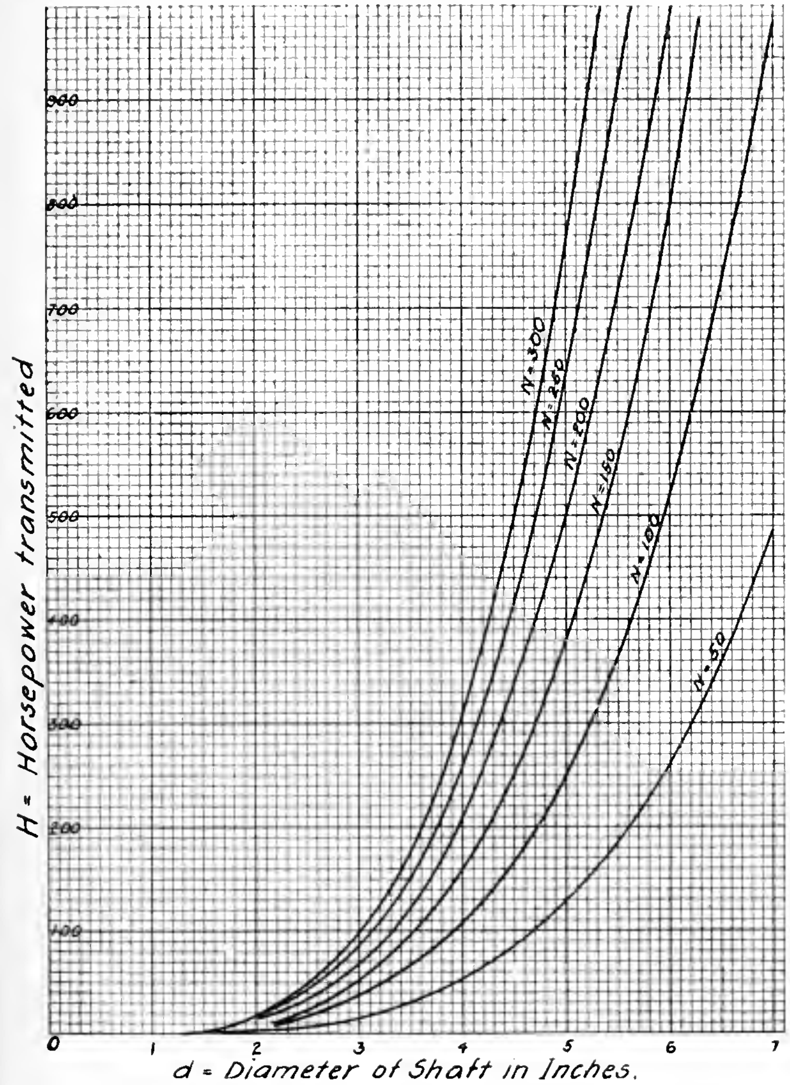

Fig. 1. Horse-power and Shafting Diagram Plotted on Regular Cross-section Paper

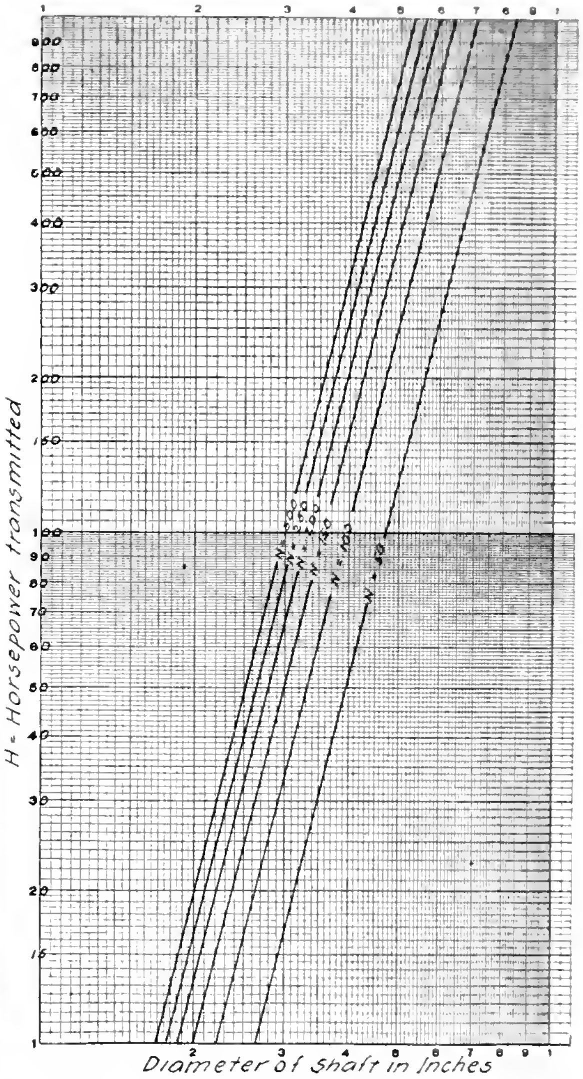

Fig. 2. The Same Diagram as in Fig. 1 laid out on Logarithmic Paper

It is the engineer, however, who uses and appreciates diagrams most. Oftentimes a row of figures does not tell very much, but when these same figures are plotted on cross section paper, a picture is obtained which clearly brings out the law of variation of the quantities involved. Another thing which may be said in favor of diagrams is that they are great time-savers. To the busy man this is the principal advantage.

The cross section paper on the market is ruled in the following ways:

1. Divided horizontally and vertically into centimeters and millimeters.

2. Divided horizontally and vertically into inches and eighths or tenths of an inch.

3. Divided horizontally into inches and tenths, and vertically, logarithmic, 1 to 10.

4. Divided both ways, logarithmic, 1 to 10.

5. Divided both ways, logarithmic 1 to 100.

In science and engineering the law of variation in quantities is usually expressed as an equation. When this equation is of the first degree, it is graphically plotted on cross section paper as a straight line. When the variable enters in any other power or root than the first, a curve results. On ordinary squared paper, plotting a curve is very laborious as a great many points must be found in order to obtain the shape of the curve. In tracing a curve through the plotted points it is difficult to obtain a draftsman's irregular curve which will "fit," and as a result the curve as drawn is only correct at the plotted points.

When the equation has the form $x = ay^{\frac{m}{n}}$, in which the exponents m and n are of any power or any root, logarithmic paper has a distinct advantage over ordinary squared paper. As its name implies it is divided logarithmically, that is, the distances of the abscissas and the ordinates from the origin are proportional to the logarithms of the numbers instead of the numbers themselves. The principle on which it is based will be readily understood by those familiar with the slide rule. In fact a slide rule can be made by anyone by merely setting the edges of two sheets of logarithmic paper in the proper position.

In order to compare logarithmic with ordinary cross section paper the accompanying diagrams were prepared. The curved lines are plotted on ordinary paper, the straight lines on logarithmic paper. The range of values is the same in both sets of curves.

The equation used is one in which the diameter of shafting is obtained by the formula $d = c\sqrt[3]{\frac{H}{N}}$ in which

$d =$ diameter of shaft in inches.

$H =$ horse-power transmitted.

---

* Address: Board of Trade Building, Louisville, Ky.

N = number of revolutions per minute.
c = a constant.

For long steel shafts c is usually 3.96. The equation which is to be plotted is $d = 3.96\sqrt[4]{\frac{H}{N}}$

For any particular curve N is a constant, so that all that is necessary to do is to solve for H with any given value of d. A numerical example may make this clearer. Take $N = 200$, $d = 2$ inches; then $H = 13$. Again, take $N = 200$, and assume $d = 5$; then $H = 508$.

On ordinary squared paper for any assumed value of N a large number of values of H and d must be found in order to obtain the true form of the curve. When completed, the curves thus plotted are unsatisfactory as they all approach the origin, so that they bunch together in a way that is annoying when calculations are involved wherein results near the origin are sought. In this particular instance the curves converge at the points where the diagram is most likely to be used.

Logarithmic paper reduces the labor of computation. All that is necessary is to plot two extreme points and draw a straight line connecting them. The equation is truly represented by this line and each point on this line is correct. To test the accuracy of the work an intermediate point may be calculated, and plotted on the diagram. If it falls on the line already drawn the work is correct. If it does not fall on this line, some mistake was made in calculating one or both of the end points.

To illustrate the use of logarithmic paper take the data previously calculated. Plot the point corresponding to $d = 2$, $H = 13$. In same way plot point $d = 5$, $H = 508$. Draw a straight line between the two points. This establishes the curve for $N = 200$. As a check it will be found that the point $d = 4$, $H = 208$ falls on the line drawn, showing that the end points were correctly plotted.

On plotting these different values of N on logarithmic paper it will be noticed that all the curves are parallel. This in itself is a check on the accuracy of the work, as a lack of parallelism in the lines indicates that something is wrong, so that the use of logarithmic paper in itself is a guard against inaccurate work. The directions given above are general for any equation of the form $x = ay^mz^n$. For any particular curve, y^m or z^n is a constant, and as a is a constant, the equation resolves into $x = ky^m$. Logarithmically expressed, the last equation becomes $\log x = \log k + m \log y$. This logarithmic equation is really the same as the equation $x = a + by$, an equation of the first degree, and explains why the curve becomes a straight line on logarithmic paper.

It will be readily seen that where a great many diagrams are to be made, this paper is a time-saver. It may be used for purposes of calculation in ways which will suggest themselves to the ingenious man. Among the more common uses to which it may be put are the following: Powers and roots of any and all indices; bending moment, shearing stress, or deflection of beams in terms of span or load; moments of inertia and radii of gyration in terms of a linear dimension; circumferences and areas of circles in terms of their diameters; sizes of bars, struts, shafts, etc., in terms of a linear dimension; hydraulic equations, etc.

* * *

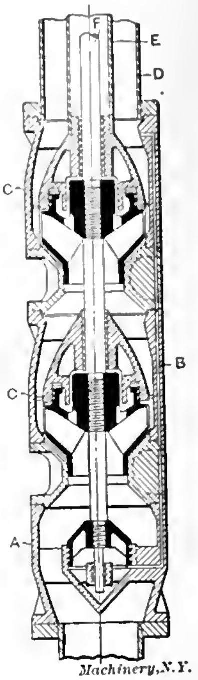
Consul William Bardel of Rheims reports that a new French plate glass has been brought out which is practically burglar-proof. While an ordinary plate glass, such as is usually put into jewelers' show windows, can be smashed by a single stroke of a metal-faced mallet, it is not possible to break this new plate glass in this manner. In an experiment made, a large piece of cast iron was thrown violently against the window, but the only effect on the glass was a small hole measuring one or two inches. Several shots of a revolver loaded with jacketed bullets were then fired at the show window, but the window suffered no damage except that the bullets entered to a depth of a fraction of an inch. The plate glass which will stand such usage is ordinarily made of a thickness of 7/8 to 1 inch. If desired, even a heavier glass can be made without diminishing the transparency.

CENTRIFUGAL PUMPS

JOHN B SPERRY*

Under the above title in the February issue of MACHINERY Mr. E. N. Percy writes as follows: "The common commercial volute pump seldom gives over 45 per cent efficiency, but can easily be designed to give 65 per cent and can be manufactured just as cheaply." This statement would have been true six years ago, but the manufacture of centrifugal pumps has improved greatly since then. Instead of using a rough runner in between the halves of a split casing, also without machined surfaces, and calling it a pump, the runners are machined thoroughly to gage and then accurately balanced to insure smooth running; the casing or volute is cast in one piece and machined to gage; the covers are also machined to gage. The bearings of the modern centrifugal pump are of the ring or chain oiled type, machined and babbitted to gage.

When Mr. Percy states that the volute pump seldom gives over 45 per cent efficiency, I think he is rather severe on that style of pump. I have copies of tests of five 4-inch centrifugal pumps of the volute type, no two of which were built by the same manufacturers. These tests were run at different speeds and covered heads ranging from 20 to 75 feet. The efficiency of all of the pumps was above 60 per cent and ran as high as 72 per cent. The maximum efficiency in these pumps varies according to the design. For one it comes at 25 feet, for another at 40 feet, and another at 60 feet. The efficiency on either side of this maximum decreases very slowly, and for this reason the patterns of these pumps are applicable to a wide range of heads, provided the speed is properly arranged. It might be of interest to add that it is customary by one manufacturer to guarantee at least 70 per cent on volute pumps 6 inches and larger; and 75 and 80 per cent on those 30 inches and larger. That he lives up to his guarantee is shown by his increasing business in pumps. Mr. Percy also states that European pumps give a higher efficiency than American pumps. In answer to this, I can cite instances where American pumps are taking the place of European pumps in Porto Rico and elsewhere. I also know of cases where pumps are being manufactured under European patents and the manufacturer does not dare to guarantee even as high an efficiency as that of some of the manufacturers of the volute pump, which type Mr. Percy considers low in duty.



A Two-Stage Pump for Deep-well Work

Mention was made of the electrically-driven, deep-well, multistage pumps which are now coming into use. The accompanying engraving illustrates a pump of this character that has been developed during the last two years by the American Well Works. The engraving shows a two-stage pump with a balancing chamber, or water step at *A*. This water step receives its pressure from the discharge side of the pump through the port *B*. The down thrust is still further relieved by the design of the runner, as shown at *C*. By this construction the suction pressure is admitted to the top of the runner, and the discharge pressure at the bottom; the difference in the two total pressures assists in floating the rotating member of the pump. Surrounding the shaft *F* is a tube *E* which forms a support for the guide bearings of the shaft and protects them from any sand that may be in the water. Outside of this and concentric with it is a larger tube that supports the pump from the top of the well. The annular space between the two tubes forms the discharge pipe. This type of pump is adapted for pumping from deep wells where a large quantity of water is required, such as city waterworks, factories, ice plants, railroads, mines and irrigation projects.

DESIGN AND CONSTRUCTION OF ELECTRIC OVERHEAD CRANES—6

BRACED GIRDERS

R. B. BROWN

Reference was made on page 669, May issue, to the three types of braced girders commonly in use, of which the Warren type is the most suitable for ordinary traveler work. The details of construction of this type differ somewhat according to the size and span of the crane, but the nature and magnitude of the stresses, which have to receive primary consideration, are found by the same methods in all cases.

In order to become thoroughly familiar with this type of girder, it is best to study its construction "anatomically." Fig. 28 shows the outline of the construction of a Warren girder consisting of a compression flange *AA'*, and a tension flange *ADD'*. These flanges are kept in position by the diagonal struts *BD*, *BE*, *CE*, *CF*, etc., which are subjected alternately to tensile and compressive stresses as the position of the load varies. Apart from the compression in the top flanges, due to the maximum bending moment, there is an additional force, due to the bending moment in the top flange caused by the load of the crab wheels. In order to minimize this quantity the vertical members *GD*, *HE*, *IF*, etc., are added, thereby reducing the effective spans in the top flange by one-half. Girders of this type are made either parallel (Fig. 28), or fish-bellied, as shown in Fig. 29. The former have a satisfactory appearance and do not need to be made so heavy at the ends as the latter; they are cheaper to make, owing to the fact that the lower flange does not need to be bent, and one set of templets will in some crabs suit all the diagonals. The fish-bellied form is, however, often preferred and is sometimes most convenient and will, therefore, be considered also.

The stresses in the various members may be found either by moments or by diagrams. The former method is somewhat tedious and not often adopted, except perhaps for finding the maximum flange stresses for comparison purposes, or to check the diagrams. If the stress diagrams are carefully drawn, the forces given will be sufficiently accurate for practical purposes. It is not within the scope of this article to prove the methods employed, since such can be done by referring to the various works on girder construction, the principal object being to take an example of each particular type and show the quickest methods of obtaining those results which directly concern the designer.

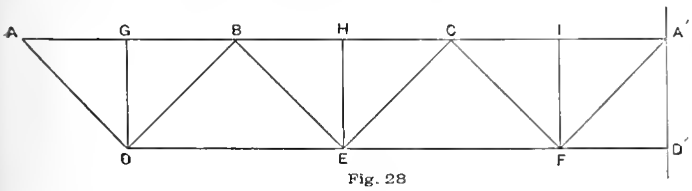

Fig. 28

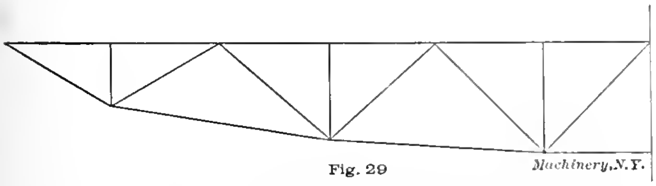

Fig. 29

Fig. 28. Warren Type Girder, Parallel Construction. Fig. 29. Warren Type Girder, Fish-bellied Construction

In designing girders of this type there are three distinct processes, as it were, to be gone through: 1. Draw an outline of the proposed girder, fixing the depth and number of bays; 2. Find the stresses which occur with the load in various positions in each member; 3. Select suitable sections to withstand the various stresses found.

Let Fig. 31 represent the outline of a Warren girder for a 15-ton crane of 72-foot span, weight of crab 5 tons, and centers of runners 6 feet. The most economical depth of these

Fig. 30. Enlarged Portion of Girder in Fig. 31

girders in relation to the span has been found to be about 1/12, so that in the present example the depth may be taken as 6 feet. It is preferable (but not essential) to divide the girder into an even number of bays on the top flange. No definite rule can, however, be given for the angle of the diagonals, which may be found to vary from 45 degrees in the case of light cranes to 60 degrees in those of heavier construction, but it is not economical to make the angle much *less* than 45 degrees. Other things being equal, the principal object is to have as few members as possible, and this result is generally gained by making the included angle of the diagonals as large as reasonable. There is, however, a limit to economy in this direction, which is reached when the span of the unsupported lengths of the top flange become so long as to require abnormally heavy sections to resist the combined bending moment from the crab wheels and compression in the girder itself. This quantity can only be settled by trial or comparison. In the example it will be seen that the top flange has been divided into six bays of 12-foot centers, the unsupported length being reduced to 6 feet by the insertion of the vertical struts. From the above figures it will be seen that the angle of the diagonals is 45 degrees, which represents a fair average for girders of this size.

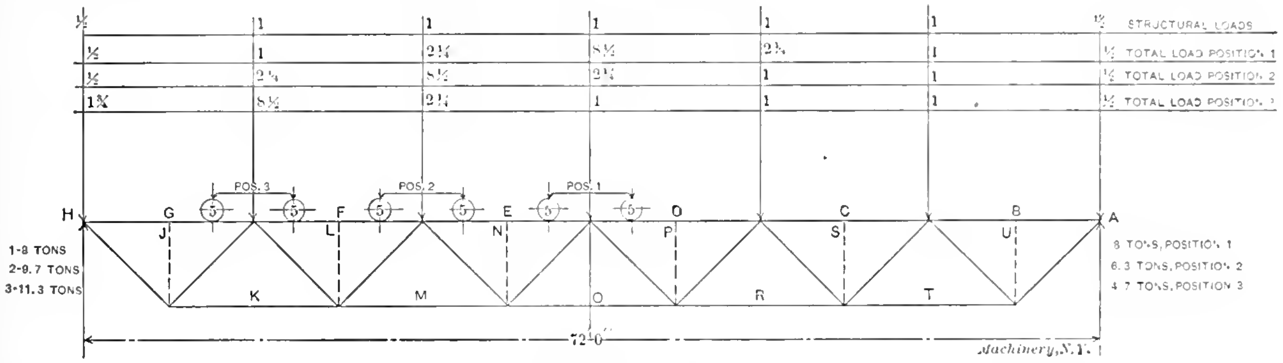

Fig. 31. Warren Crane Girder, 72-foot Span

The outline of the proposed girder is now complete, but before proceeding it is necessary to call attention to the fact that when possible the line drawn through the center of gravity of the various members should intersect at the same point, as in the case of the outline diagrams from which the stress diagrams are drawn. This precaution is necessary in order to minimize the secondary forces, which, although of no importance in small cranes, are sometimes considerable in heavy work; the girders and templets are also much more easily "set off" under these conditions. Before the stress diagram can be drawn, the loading of the girder must be considered, and it will be necessary to assume the weight of one girder together with its platform and cross-shaft.

In the present case this quantity may be taken at 6 tons, and since the girder will be of practically uniform construction, is equal to one ton per bay. The loading on the various bays from the crab wheels must be found by assuming the crab to be in the position shown in Fig. 30, where it would give the greatest reaction on any diagonals.

The effect of the above loads can be found from the skeleton diagram shown in Fig. 31. The first diagram is drawn for the loads as they occur when the crab is at the center of the girder. In reaching the loads from the crab wheels on to the apices of the various diagonals, no notice is taken of the intermediate vertical struts. This is not quite correct, since the vertical members convey part of the load direct to the bottom flange, but, as the inaccuracy is of little importance for small girders, it is simpler to eliminate the vertical struts from the diagrams altogether.

The first diagram for the load in the center is commenced by drawing the line *AH*, Fig. 32, which is the load or base line of the diagram. From *A* set off the distance *AB* equal to 0.5 ton at any convenient load scale, say, ¼ inch = 1 ton. This quantity represents the structural load acting directly over either abutment. Similarly, make *BC* = 1 ton, *CD* = 2.25 tons, *DE* = 8.5 tons, *EF* = 2.25 tons, *FG* = 1.0 ton and *GH* = 0.5 ton. Bisect *AH* at *V*, and draw a horizontal line through this point, as shown. The distance *VA*, or *VH* (8 tons) will be equal to the reactions at either point of support. The loads *AB* and *GH* are only set off on the load line to make the reactions complete, because, since they are directly over the abutments, they do not have any direct influence on the stresses of the structure itself.

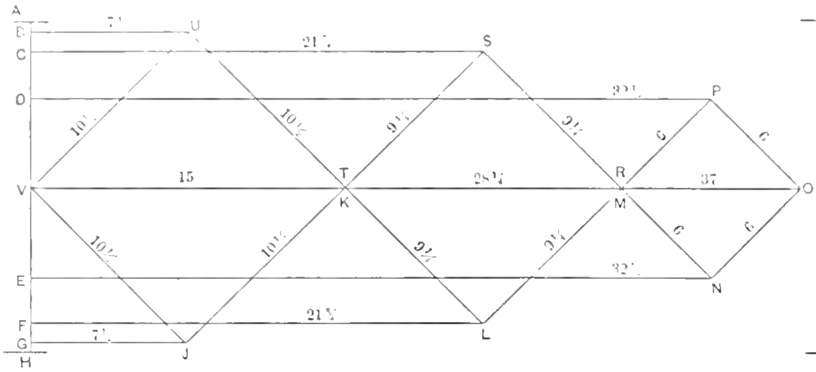

Fig. 32. Stress Diagram for Crane Girder in Fig. 31, Load in Center

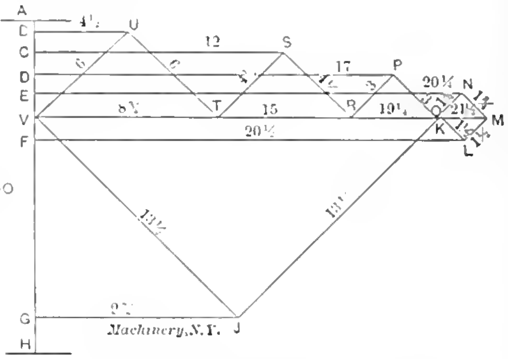

Fig. 33. Stress Diagram for Crane Girder in Fig. 31, Load in Position 3

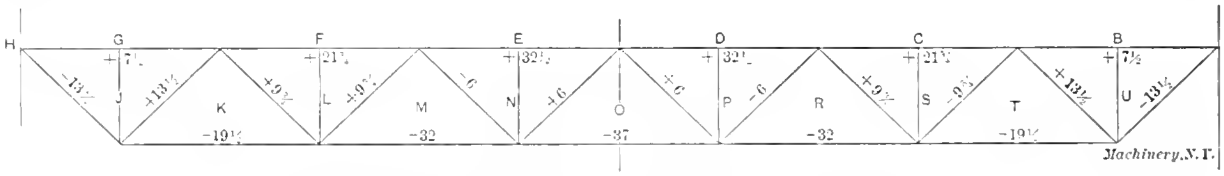

Fig. 34 Stresses in Crane Girder in Fig. 31, as determined by Stress Diagrams

From *V* draw a line *VU* parallel to the diagonal members in the skeleton diagram, producing same until it intersects a horizontal line drawn from *B* at *U*. Then the force in *VU* can be read off this line to the same scale as that adopted for the load line. Similarly draw *UT*, *TS*, *SR*, etc., parallel to their respective members in the skeleton diagram.

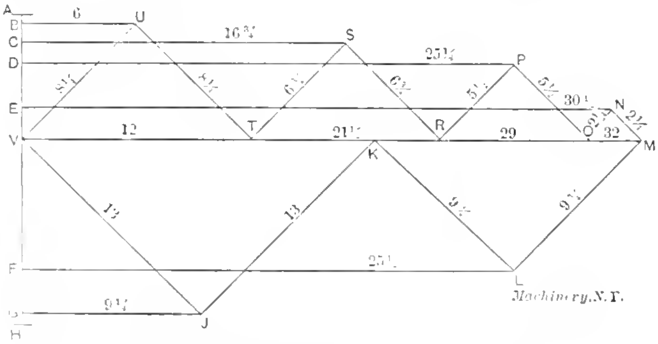

Fig. 35. Stress Diagram for Crane Girder in Fig. 31, Load in Position 2

When the diagram has been drawn on one side, the opposite side may be duplicated if required, since the loading is symmetrical. When the diagram is completed, the letters on the force diagram correspond to those given on the skeleton. Thus the maximum tension in the lower flange occurs at the center and is equal to *VO*, while the maximum force in the diagonals occurs at *U* or *J* and equals *VU*, *VJ*, *UT*, and *JK*. The various stresses occurring in each member have been scaled off and written in the skeleton diagram for reference.

In the case of small cranes, it will generally be found most economical in practice to make all the diagonals of one, or, at the most, two sections, since the difference between the maximum and minimum loads is not great, and when this is done, it is only necessary to draw one diagram in the center as shown in order to get the maximum flange stresses, and another with the load in a position near the end as shown in Fig. 33 to obtain the maximum diagonal stresses. When, however, the girders for cranes above 20 tons are being designed, it is better practice to find the maximum stresses occurring in each member and proportion the sections to suit; and this will be done in the present case, in order to show the method used.

In drawing the diagram, Fig. 35, for position 2, Fig. 31, the load line will be drawn as in position 1, with the order of loading, in accordance with the re-distribution of loads as in the skeleton diagram, Fig. 31. The reactions at the abutments from both the rolling and structural loads must be found in the usual way, and set off on the load line as shown. From *V* draw a horizontal line and then draw the diagonal stress lines as in the previous example. If the diagram is correctly drawn, the last force line will join at the starting point *V*, thereby checking itself, but it should be borne in mind that unless the position of *V* is exactly to scale, the diagram will not close and cannot be considered correct.

The stresses are found when the load is in position 3, as shown by the diagram, Fig. 33; this process could be repeated for any number of bays.

Since there is no definite relation between the centers of the crab wheels and the pitch of the diagonals, it is difficult to say beforehand whether the loads in the positions already considered give the maximum stresses on the diagonals; generally speaking, they do, but in heavy cranes it is better to make certain by drawing another set of diagrams for other positions. Having found the stresses arising from the loads in the various positions, it is convenient to record the highest stress found on any diagram for any particular member, on another skeleton diagram, as shown in Fig. 34.

Under certain conditions, it might have been preferable to make the above girder fish-bellied in form, as previously referred to, and, in order to make this treatise complete, the diagrams shown in Figs. 36 and 37 have been drawn to suit the altered design. The diagrams are constructed in precisely the same manner as in the previous example, the only exception being that the force lines for the lower flange must be drawn parallel to their corresponding members. By comparing these diagrams with those for the parallel girders, it will be seen how unsuitable, comparatively speaking, the fish-bellied girder is, for at the point where the diagonals have the maximum stress, they are inclined at the smallest angle, and consequently receive the greatest possible stress

which, generally speaking, is so heavy that sufficient rivets cannot be put into a suitable strut, and web plates, or very large gusset plates, must be used. The stresses in the end struts may be minimized by shortening the length of the bays at the ends, as shown in Fig. 37.

The corners or sets on the lower flange do not form a parabolic line as may be the case in a plate girder, but are more a question of practical judgment, the main object being to make the end bays as deep as possible. In details of construction this girder is practically the same as the parallel type.

When the stress sheet is finished, the designer may pass on to the first operation of selecting suitable sections to withstand the strains. There are four different types of girder sections commonly in use, as shown in Figs. 38 to 41. The type shown in Fig. 38 is suitable for cranes up to 3 tons capacity, and over 40 feet span, when no platforms are specified, as in the case of small cranes worked from the floor level. By placing the channel forming the top flange horizontal, as shown, the girder receives the necessary lateral stiffness in the right place, and, since the wheel pressures are light, there is always sufficient strength to resist bending in the other direction.

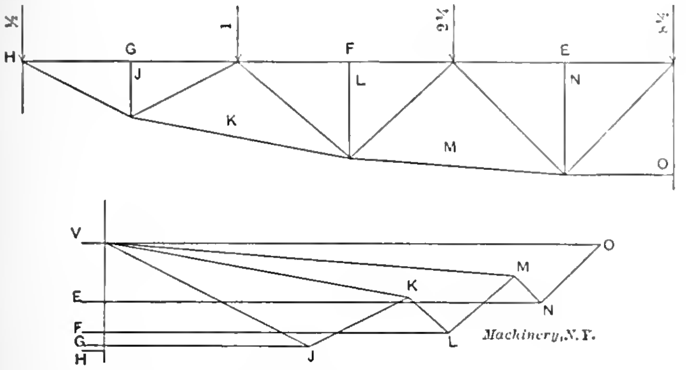

Fig. 36. Stress Diagram of Fish-bellied Girders

When platforms are required, and for all cranes above 3 tons and up to 20 tons, of more than 65 feet span, the construction shown in Fig. 39 has been found suitable. Lateral strength is given to this type by the addition of braced platform girders. For cranes of 25 tons capacity and upwards, and over 65 feet span, the box-latticed types shown in Figs. 40 and 41 are most suitable. The channel construction shown in the top flange of Fig. 41 generally becomes necessary for cranes of 40 tons capacity and upwards. When these types are used, it is cheaper to make the girders strong enough laterally, and attach ordinary platform brackets, as shown, although this arrangement is not suitable for high speeds. The type of girder used in the previous example will be the same as shown in Fig. 39.

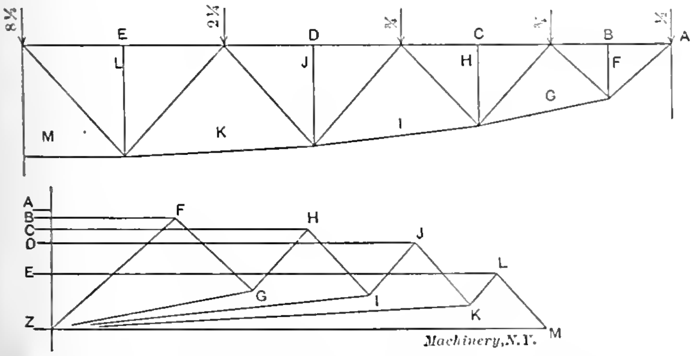

Fig. 37. Length of Bays at End of Fish-bellied Girders Shortened to equalize Stresses in Struts

The scantlings of the bottom flange can be determined without difficulty, since no lateral stiffness has to be provided for in the girder itself. The width of flanges becomes principally a question of convenience, adding a rail and web to suit the top flange, as shown in Fig. 42. It will be seen that in this case the rail has been riveted on continuously in such a manner that it can be regarded as a useful part of the section.

As a preliminary guide in assuming a suitable section the designer may select such sizes as will give an area which will correspond to not more than from 2 to 3 tons per square inch. The depth of the web varies according to the load, but is generally proportioned to suit the riveting of the diagonals. When the section has been assumed in this manner, the next step is to find the modulus in the usual way

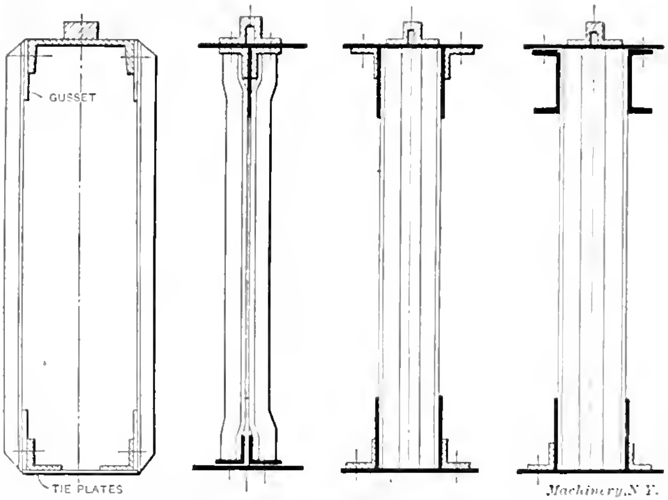
Draw the section full size, and from the vertical line *AB*, drawn parallel to the center of the section, set off the net section, as shown in Fig 42. Determine the center of gravity in each piece, together with its area. When these particulars have been fixed, the center of gravity of the whole mass may be found in the ordinary way, by multiplying the area of each piece by the distance from *AC* to its center of gravity, and dividing the sum of these products by the total area of the section, thus:

Section 1. $2.2500 \times 0.5625 = 1.2656$
2. $1.1250 \times 1.6875 = 1.8984$
3. $1.2187 \times 2.4375 = 2.9707$
4. $3.8437 \times 2.8125 = 10.8105$
5. $1.5937 \times 3.1875 = 5.0800$
6. $1.9687 \times 4.6875 = 9.2285$
7. $3.0000 \times 7.0000 = 21.0000$

Complete area = 15 square inches; sum of moments = 52.2527. Then

$$\frac{52.2527}{15} = 3.48,$$

or about 3½ inches from *A* to the center of gravity and neutral axis of the section.



Figs. 38 to 41. Types of Girder Sections in Common Use

The next step is to find the moment of inertia of each half as divided by the neutral axis.

The moment of inertia of a section taken about its base is equivalent to 1/3 $b\,h^3$; therefore the moment of inertia of the section shown will be found as follows:

$1/3\,[\,(3.5^3 - 2.375^3) \times 2 + (2.375^3 - 1.25^3) \times 1 + (1.25^3 - 0.875^3) \times 3.25 + (0.875^3 - 0.5^3) \times 10.25 + (0.5^3 - 0.125^3) \times 4.625 + (1\tfrac{1}{8}^3 \times 1.125)] = \frac{80.7}{3} = 26.9$ = moment of inertia of the upper half.

The moment of inertia of the lower part can be found in a similar manner, as follows:

$1/3\,[(7.5^3 \times 0.375) + (2.5^3 \times 0.75)] = 56.6$ = moment of inertia of lower half.

Total moment of inertia of section = $26.9 + 56.6 = 83.5$.

This quantity, divided by the distance from the neutral axis to the upper or lower outer edge of the section, will give the compression and tension moduli, respectively, thus:

$$\frac{83.5}{3.5} = 23.8 = \text{compression modulus.}$$

$$\frac{83.5}{7.5} = 11.13 = \text{tension modulus.}$$

It is also necessary to know the maximum bending moment in the unsupported part of the top member, which, in the present case, occurs when one wheel of the crab is in the

center of the bay. It is difficult to say how much benefit is due to the fact that the unsupported parts of the top flange form a more or less continuous girder. The results due to taking the bending moment as being equal to $\frac{WL}{6}$ give satisfaction; the bending moment, in this case, is therefore equal to

$$\frac{5 \times 72}{6} = 60 \text{ inch-tons.}$$

The stress in the section from this load alone will be:

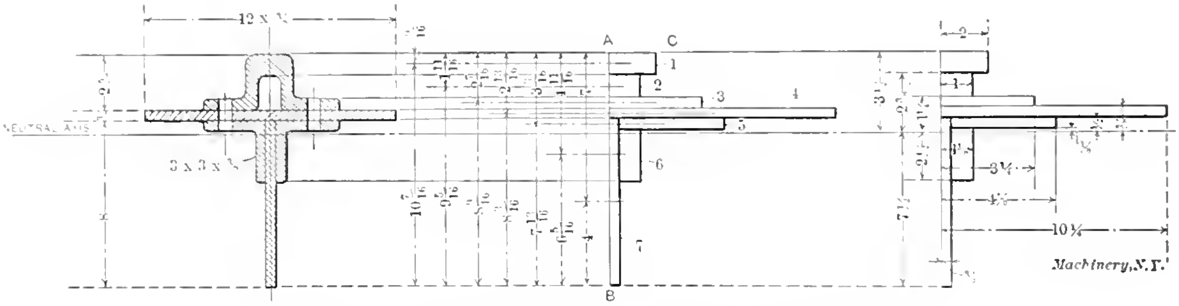
$$\frac{60}{23.8} = 2.5 \text{ tons per square inch, compression.}$$

$$\frac{60}{11.13} = 5.4 \text{ tons per square inch, tension.}$$

the values given in Table XII will be found useful. The safe loads given in this table are calculated by Gordon's formula. The factor of safety is five.

Generally speaking it is safe to consider that the struts have the ends fixed, in the plane of the rivets, but free in the opposite direction. Matters may be more nearly equalized between these two conditions if a small tie plate is used to tie the two sections forming one strut together. When, however, the work throughout is light, it is safer to take all struts as having free ends, and thereby avoid the possibility of flexure in different directions. A sufficient number of rivets should be allowed for at the joints to limit the stress to 5 tons per square inch in shear, and 8¾ tons per square inch of bearing.

Generally speaking, the last bay should be plated in, in order to stiffen the end joint and provide sufficient section to meet the shearing stresses.



Figs. 42 and 43. Lay-out for Calculating Section Modulus of Girder Section

The maximum compression in the members from the load is equal to about 2.2 tons per square inch, and to this quantity the compression found above must be added, making the total maximum compression = 2.2 + 2.5 = 4.7 tons per square inch.

The above method is approximate and only suitable for the comparatively small girders used in crane work, and is not directly applicable to large bridge girders.

The stresses from bending alone should be kept as low as possible, in order to minimize the possibilities of deflection, which detracts from the value of the member as a strut. The safe working stress of this member, taken as a strut, pure and simple, and fixed in the plane of the joints, is generally taken as equal to about 4½ tons per square inch for a section having a radius of gyration of from 1/30 to 1/40 of the unsupported length. In fixing the size of the struts, some consideration should be given to the practical economy effected by using as few sections as possible, so that, although in the case of heavy cranes it is advisable to select sections to suit the varying stresses, it is better to select, say, two sections equal to the maximum stresses and use these throughout for girders of moderate size.

Angle sections are generally used both for diagonal and vertical struts, and in order to avoid continual calculations,

TABLE XII. SAFE LOADS IN TONS FOR ANGLE IRONS WHEN USED AS STRUTS

It is seldom necessary to make any extra provision for shearing stresses at the various flange joints for small and medium sized girders, but for large girders these stresses should always be calculated and checked.

* * *

An interesting piece of apparatus employed by electricians is the "fish wire," used for threading insulated wire through pipes and other long narrow conduits. This fish wire is a finely tempered steel tape about 1/4 inch wide and 1/16 inch thick having slots in the ends for attachment to the wire that is to be pulled through. The fish wire is introduced into the pipe and pushed in as far as it will go by direct pushing. When it meets obstruction because of bends or the friction of the wire against the sides of the pipe, the workman then propels the wire along by pushing it in until the wire bends up, and then "snapping" it. A wave motion is transmitted along the wire or tape with the result that the far end jumps ahead a short distance. The operation is repeated indefinitely, and in this way long distances are threaded by the slender wire. It is even possible to guide the wire through a number of right angle bends, provided the elbows are of easy curvature. The secret of the process lies in taking advantage of the fact that wave motion can be produced by crumpling up the wire and snapping in that position.

EXPERIMENTS ON TWIST DRILLS—2

The following continuation of the article in the May number, gives the results of experiments conducted to obtain more accurate data for larger drills and heavier feeds. These experiments, briefly stated, are as follows:

(*e*) A series of experiments to determine the twisting moment or torque and end-thrust on twist drills of varying diameter when operating on soft cast iron with different rates of feed. No lubricant used. Termed ordinary trials.

(*f*) A set of experiments similar to the above when operating on Whitworth's medium hard (fluid-pressed) steel. No lubricant used. Termed ordinary trials.

(*g*) A set of trials on soft cast iron to determine the variation of torque and thrust with different cutting speeds. No lubricant used. Termed speed trials.

(*h*) Trials to determine the variation of thrust and torque on soft cast iron and medium hard steel with different diameter of drills and rate of feeds. An initial hole equal to the width of the chisel point was drilled in the specimen operated upon. No lubricant used. Termed minus-chisel-point trials.

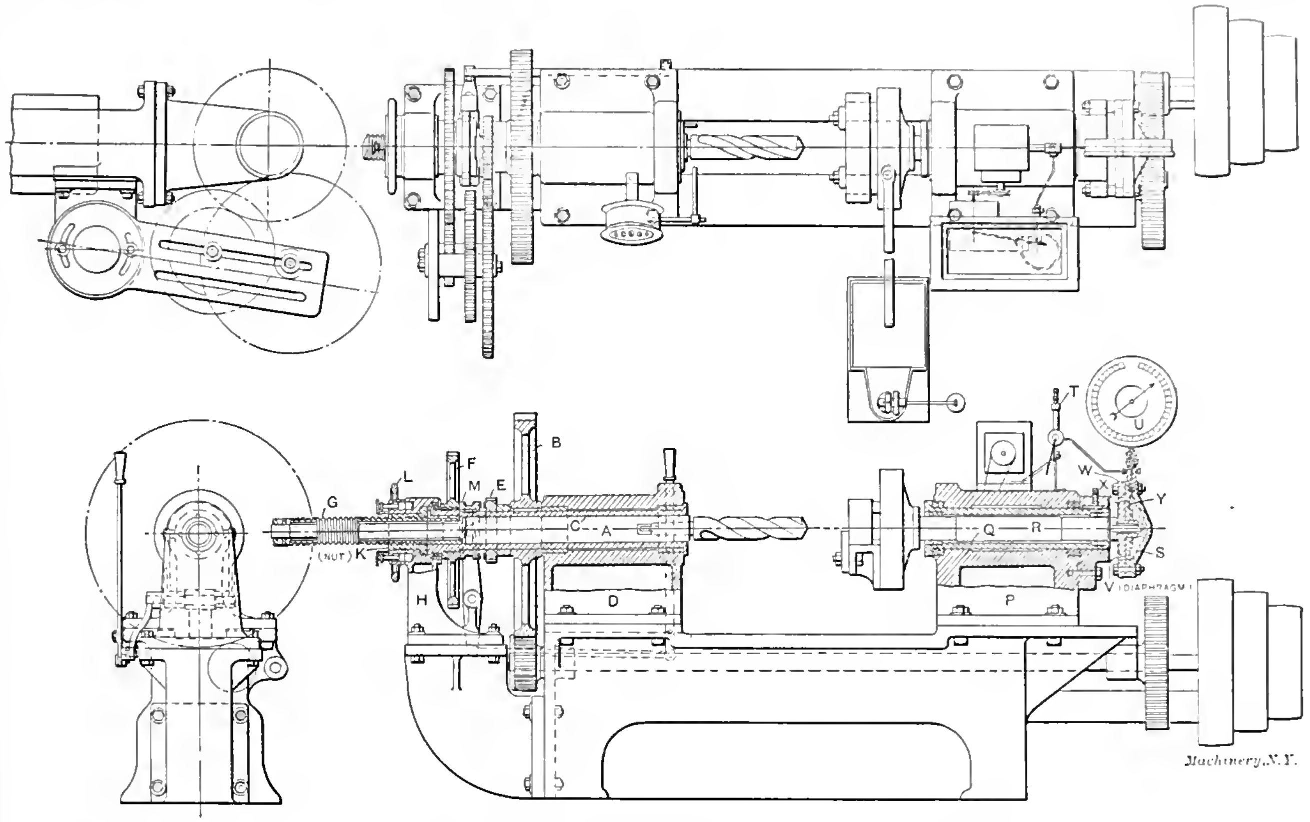

Fig. 2. Section and Elevation of Apparatus used in Second Set of Experiments

(*i*) A set of experiments to determine the variation of thrust and torque when operating on soft, medium and hard cast iron. No lubricant used. Termed hardness trials.

(*j*) A set of experiments similar to the above when operating on Whitworth soft, medium and hard (fluid-pressed) steel. No lubricant used. Termed hardness trials.

(*k*) A set of trials similar to (*j*) but with a lubricant of oil and water. Termed lubricated trials.

(*l*) A set of trials to find the effect produced by varying the point angle when operating on soft cast iron. No lubricant used. Termed point angle trials.

(*m*) A set similar to (*l*) when operating on soft (fluid-pressed) steel and lubricated with a mixture of water and oil. Termed point angle trials.

Description of Second Apparatus

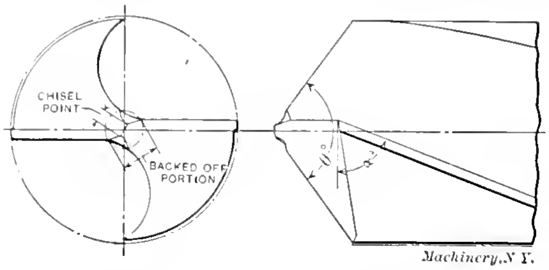
The experiments (*e*) to (*m*) were carried out on a horizontal milling machine which had been reconstructed and modified. The arrangement is shown in detail in Fig. 2, and by the half-tone in Fig. 4. The power was obtained from a motor which drove a countershaft whereon was mounted a three-stepped cone pulley similar to that on the machine. Two pairs of wheels were introduced between the cone and the driving spindle, but one pair could be suppressed to allow of an increased speed to the spindle. The arrangement permitted of a total speed variation to the drill of from 5 to 150 revolutions per minute. A counter fixed to the front of the machine and actuated from the spindle indicated the revolutions. The drill was held in the rotating spindle *A*, and could be advanced at varying rates, from 0.0025 to 0.050 inch per revolution, by suitable change wheels driven from the spindle sleeve and a square threaded cylinder on the end of the spindle. The work was supported on an angle plate bolted to the face-plate on the spindle in the tail stock. This latter spindle, being free to slide, transmits the thrust on the drill to the diaphragm dynamometer fixed to the end of the spindle. The twisting force is taken by an arm bolted to the face-plate and having a knife edge on its further extremity which rests on a scale pan.

The driving gear *B* is keyed to the cast iron sleeve *C* which rotates within the bearings of the headstock *D*. A long key fitted at the end of the sleeve *C*, nearest to the work, drives the spindle *A*, while permitting it to slide longitudinally. The employment of a sleeve as a driver in this manner reduces the twist that would otherwise come on the spindle if it were driven from the gear *B* direct. It also divides the wear due to rotation and sliding. As the wear due to the former is greatest, adjustment for the same is provided. It is clear that if the spindle is allowed any freedom it will wobble, thereby enlarging the hole and in all likelihood breaking the drill. The feed to the drill is secured through the pinion *E*, mounted freely on the sleeve *C*, which engages the train of gears on the quadrant, bolted to the bed, and the gear *F* keyed to the threaded cylinder *G*. The gear *F* is held in bracket *H* by an annular plate, while immediately ahead of it is a nut *K* which embraces the screw *G* and is held to the bracket by pins through the hand-wheel *L*. The cylinder *G* rotates independently of the spindle and is prevented from moving longitudinally thereon by a shoulder at one end and lock-nuts at the other. Friction washers are introduced between these members to take the wear. Thus, on the engagement of the clutch *M* (which is keyed to *C*) with the pinion *E*, a definite horizontal movement is given to the spindle per revolution of the same. The hand-wheel *L* is keyed to *K* and furnishes a quick withdrawing motion to the drill, on the locking pins being withdrawn.

The torque on the drill is obtained by multiplying the load on the scale pan (after the initial load due to the weight of the arm and unbalanced weight on the face-plate has been

subtracted) by the length of the arm measured from the center of the hole to the knife edge.

Balls have been fitted in pockets of the cast iron sleeve *Q* to allow the spindle *R* to slide longitudinally with the minimum of frictional resistance. The hydraulic support to take the end thrust of the drill consists of a phosphor bronze casing *S*, fitted with a filling plug *T* and a standard pressure gage *U*. The diaphragm *V* is of cold drawn brass 0.010 inch thick. It is held to the casing by bolts and a steel ring *W*. The thrust pad *X* is provided with a cup-shaped recess to receive the spherical end of the spindle *R*. The pad is made fast to *V* by the nut *Y* within the casing. The end-thrust on the drill deflects the diaphragm at that part which is free (about 1/8 inch) between *S* and *X*, thereby producing a pressure in the fluid which is shown on the gage. The fluid in this case is water. A small filling plug is fitted in the end of the gage tube to allow any air to escape in order that the diaphragm deflection may be as small as possible. When the fluid is air-free, the diaphragm will only yield by the amount necessary to supply the increased volume of the gage tube due to the added pressure. The spring of the tube is sufficient to bring the diaphragm back to its original position when the load is removed.



Machinery,N.Y.

Fig. 3. Form of Point of Drill used in Experiments

The shape of the point of a 3-inch drill used in the experiments is shown in Fig. 3. The width of the chisel point (or thinned down web) is approximately 0.096 *d*, and the width of the backed-off portion 0.168 *d*. The average cutting angle at right angles to the lip at the periphery is 68 deg. 48 min.

Results of Second Set of Experiments

Experiments (*e*) showed that the torque does not increase as fast as the feed for any given diameter of drill. The formula below closely agrees with the results obtained for all sizes of drills and all feeds:

$$T = 785\, d^{1.82}\, t^{0.72 - 0.0065d} \qquad (20)$$

The coefficient and exponents of the right-hand term in the formula above may be modified, and the error in the simplified formula

$$T = 740\, d^{1.8}\, t^{0.7} \qquad (21)$$

is inappreciable. A safe approximation without fractional exponents may be given in the form

$$T = 10\, d^2 + (14d^2 + 3)\, 100\, t \qquad (22)$$

As the drill entered the specimen, the torque gradually increased, and the torque at starting at no time exceeded the value obtained when drilling the full diameter hole. The torque increases almost in proportion to the square of the diameter of the drill, for any given feed.

The cutting pressure *f*, in tons per square inch, is found from the formula

$$f = \frac{35.4}{d^{0.2}\, t^{0.3}} \qquad (27)$$

It is clear from the above equation that the cutting pressure per square inch decreases with an increased diameter and also with increased feed. The cutting pressure, which is exerted along the radial cutting edges and resists rotation, should not be confused with the end thrust which is exerted in the direction of the axis of the drill.

Experiments for Determining the End Thrust

The following formulas, of which the latter is an approximation of the former, express the results obtained in the experiments for the determining of the end thrust when drilling soft cast iron:

$$P = (d - 0.4)\, 325 + (24\, d + 65)\, 1{,}000\, t, \qquad (28)$$

$$P = 240\, d + (24\, d + 65)\, 1{,}000\, t, \qquad (28a)$$

For ordinary feeds the following approximation is fairly correct:

$$P = 200\, d + 10{,}000\, t. \qquad (28b)$$

The end thrust can also be expressed by an equation of the form:

$$P = 35{,}500\, d^{0.7}\, t^{0.75} \qquad (30)$$

At no time did the force required for starting the drill exceed that when the drill was cutting a full diameter hole, and the first sets of experiments were thus confirmed. In this, the results of the experiments differ from those given by Prof. Breckenridge; the results also differ from those obtained by Messrs. Bird and Fairfield, who found that the thrust increased much faster than the feed. The results obtained by Messrs. Bird and Fairfield may possibly be accounted for by the high-speed at which they ran the drill, which produced a bluntness affecting the thrust more than the torque. In the trials at the Manchester School of Technology the speed was kept at 10 revolutions per minute in order that the blunting would not affect the results.

Experiments on Medium Hard Steel

The experiments (*f*) on medium hard steel showed much regularity. The torque was found to increase in a slower proportion than the feed, and it was also found that the torque did not increase as the square of the diameters of the drills, but in a smaller ratio, so that as far as the torque is concerned, the most economical way to remove metal is to use a coarse feed and a large diameter drill. A fairly simple, although approximate expression for the torque when drilling medium hard steel is:

$$T = 28\, d^2\, (1 + 100\, t). \qquad (32)$$

Another approximation may be expressed by the formula:

$$T = 1{,}640\, d^{1.8}\, t^{0.7}$$

which is fairly correct for all feeds in common use.

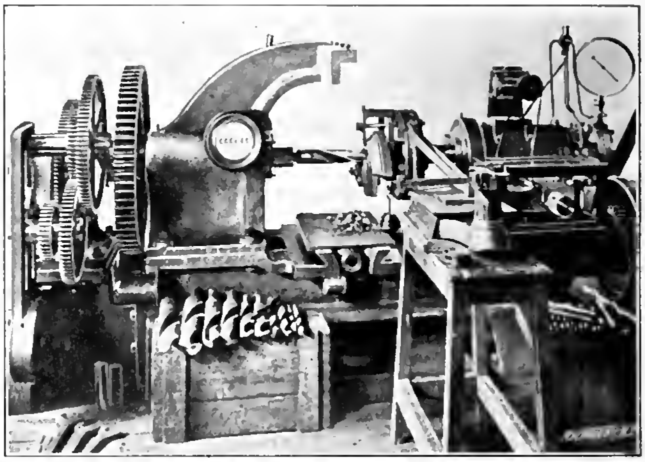


Fig. 4. Apparatus used in the Manchester Drill Experiments

For the end thrust the two following formulas are given, which are fairly simple in their form, but which, however, are only approximations which are correct for the range of feeds ordinarily used in practice. The latter formula, however, closely agrees with the rather complicated exact equation which was obtained from the experiments. While no experiments were undertaken at this time with blunt drills, it was noticed during the trials that the thrust may increase as much as 20 per cent by the dulling of the chisel point alone. This, of course, indicates that for ordinary shop practice it is useless to insist on anything but the approximate formulas.

$$P = 750\, d\, (1 + 150\, t), \qquad (35)$$

$$P = 35{,}500\, d^{0.7}\, t^{0.6}$$

Variations of Cutting Stress with Cutting Speed

In experiments (*g*), the speed, instead of remaining constant at 10 revolutions per minute was varied from 7.5 to 126 revolutions, with the object of determining the variation of thrust and torque due to speed. There did not seem to be any marked difference due to the speed, and in this particular, these experiments, therefore, confirm those made by Messrs. Bird and Fairfield.

The experiments show that metal is most economically removed by increasing the feed or diameter of drill rather than

the speed, since the power in the latter case is directly proportional to the speed. The friction horse-power of the machine is practically proportional to the speed, so that if the speed is doubled the power is also doubled. When, on the other hand, the feed is doubled, the frictional horse-power remains about the same. By increasing the number of lips to three or more, the torque and the thrust are increased for any given feed as the feed actually taken by each lip is $\frac{1}{n}$ of the whole feed, where n is the number of lips.

Tables I and II have been calculated from the above results for the speed and feed recommended by drill makers for ordinary shop use. There is no general agreement among the makers of high-speed twist-drills as to what the cutting speed should be for ordinary shop practice. Some decrease the speed with the increase of diameter of drill, some recommend the reverse, but most makers advise a constant periphery speed throughout. The mean of these values is about 60 feet per minute with a feed per revolution of $\frac{d^{\frac{1}{3}}}{100}$ for machine steel. For cast iron it is usual to decrease the above speed 20 per cent and increase the feed by a similar amount. Using these figures and the experimental force values previously given, an estimate of the net horse-power required for drilling can be made. With the object of presenting these results in concise form and to show at a glance the influences of speed, feed and diameter, the values so deduced have been tabulated in Tables I and II.

TABLE I. REVOLUTIONS PER MINUTE, FEED PER REVOLUTION, CUBIC INCHES REMOVED PER MINUTE, AND HORSE-POWER WHEN DRILLING CAST-IRON WITH HIGH-SPEED STEEL DRILLS

The cubic inches of metal removed per minute (V) is found approximately from the equation:

$$V=\frac{\pi}{4}\,d^2\,t\,N,$$

where $N=$ revolutions per minute.

The cutting horse-power is obtained by multiplying the torque for each feed and diameter of drill by $\frac{2\,\pi\,N}{33{,}000}$.

$$\text{Cutting horse-power}=\frac{2\,\pi\,N\,T}{33{,}000}.$$

The horse-power required for feeding is obtained by multiplying the end thrust for each feed and diameter of drill by $\frac{t\,N}{33{,}000}$.

$$\text{Feed horse-power}=\frac{P\,t\,N}{33{,}000}$$

Minus-chisel-point Experiments on Soft Cast-iron and Medium Steel

These experiments were undertaken with the object of determining the difference in the thrust and torque due to the chisel point of the drill. Many efforts were made at the outset to drill a hole with a chisel shaped and ground similar to that on the drill itself. Frequent breakages, particularly when operating on steel, led to the abandonment of this procedure in favor of that where a hole was initially made in the specimen, having a diameter equal to the width of the chisel point of the drill to be employed. The tests were then made with different feeds and diameters of drills at a speed of 10 revolutions per minute as in the ordinary trials previously discussed.

It was found that the torque in these experiments was practically the same as the torque obtained in the regular experiments. Of course, the torque in the minus-chisel-point trials should be smaller, but the difference is so insignificant as to be lost sight of in the approximate formulas adopted. Considerable difference, however, is found in regard to the end thrust when a piece is removed in the specimen equal to the diameter of the chisel point. Thus, for cast iron the end thrust

$$P=12{,}600\,d^{0.7}\,t^{0.6} \qquad (39)$$

Comparing this equation with those just obtained in the ordinary trials (e), it will be seen that twenty-five per cent of the end force for feeds commonly required, is due to the chisel point.

The end thrust for medium steel in the minus-chisel-point trials was

$$P=27{,}000\,d^{0.73}\,t^{0.6} \qquad (40)$$

which is about twenty-one per cent less than the end thrust in the regular trials.

Results of Experiments Undertaken on Different Kinds of Metal

The experiments on the variation of torque and thrust when drilling different grades of cast iron showed that the torque and thrust increased very rapidly with the percentage of carbon.

The experiments on the variation of torque and thrust when drilling steel of different kinds without and with lubricant, showed that there is little difference between the torque and thrust for soft and medium steels when not lubricated. This, no doubt, is due to the high percentage of manganese in the soft steel. Roughly speaking, the torque and thrust are practically proportional to the combined carbon and manganese contents for any given feed. In the lubrication tests, it was found that the percentage of decrease in the torque

due to lubrication was almost the same in soft and hard steel, and that this decrease is most conspicuous in the finer feeds. The average torque for each feed in these trials varies from 72 per cent with the 0.0025 inch feed to 92 per cent with the 0.0285 inch feed of that obtained when operating dry.

The thrust for soft, medium and hard steel is 26 per cent, 37 per cent and 12 per cent, respectively, less than that obtained when operating dry.

Variation of Torque and Thrust with Angle of Drill Point

The experiments for determining the torque and thrust due to different point angles were carried out with three drills having 90, 120 and 150 degrees included point angle, respectively. These experiments indicate that the torque decreases as the included angle becomes larger, but the end thrust increases. It will thus be noted that while the 90-degree included angle drill has a smaller end thrust, the torque is larger, and the 150-degree included angle drill has a larger end thrust but a smaller torque. Two distinct opposite effects enter in the determining of the correct angle, and the experiments were insufficient to assign a value to each of these effects; but it may be assumed that the commonly accepted angle of 118 degrees included angle is the most advantageous to use, as here both the torque and the end thrust have average value.

Conclusions of First Set of Experiments

(*a*) The horse-power for a given diameter of drill and feed is proportional to the revolutions or the cutting speed.

(*b*) The horse-power $\dfrac{2\pi N T}{33{,}000}$ is proportional to the torque, and for a given drill and speed does not increase as fast as the feed.

(*c*) Since the torque is practically proportional to the square of the diameter of the drill, the horse-power, for a given feed and cutting speed, is directly proportional to the diameter of the drill.

(*d*) The horse-power per cubic inch of metal removed is inversely proportional to the feed and independent of the drill and cutting speed.

(*e*) The work required to drill a given hole, when one drill only is used, is greater than that required to drill the same hole in two operations with drills of different diameters. The greater the difference in the drill diameters, the greater the saving in work, speed and feed remaining the same throughout. This is due to the fact that the mean cutting angle of the single drill is greater than the average angle in use for the two drills and that the stress is proportional to the angle.

(*f*) With twist-drills having the usual proportions, the cutting angle is not sufficiently keen to drag the drill into the work when enlarging a hole in cast iron or steel.

Conclusions of Second Set of Experiments

(*g*) The horse-power when operating on soft cast iron or medium steel varies as $t^{0.7}$ for a given drill and speed; ($t =$ feed per revolution).

(*h*) The horse-power for a given feed and speed does not increase as fast as the diameter but varies as $d^{0.8}$; ($d =$ diameter of drill).

(*i*) The torque and horse-power when drilling medium steel is about 2.1 times that required to drill soft cast iron with the same drill speed and feed.

(*j*) The horse-power per cubic inch of metal removed is inversely proportional to $d^{0.2}\,t^{0.3}$ and independent of the revolutions.

If d remains constant, and feeds of 0.0025 inch, 0.010 inch and 0.040 inch be taken, the corresponding horse-powers will be in the order of 1, 0.66 and 0.435. If t remains constant and values of $d = 1\frac{1}{2}$ inch, 2 inch and 4 inches be taken, then the horse-power for each successive drill will be in the order of 1, 0.76 and 0.66.

(*k*) The power required to enlarge a hole may be estimated from the pressures given by equation $f = \dfrac{0.44}{t^{0.33}} \times$ cutting angle in degrees, for cast iron, and 2.1 times that value for medium steel.

(*l*) In a two-lipped drill the actual depth of cut taken by each lip is $\dfrac{t}{2}$; in a three-lipped drill, $\dfrac{t}{3}$; and so on. If the number of lips is increased, and t kept the same the pressure produced is equivalent to that for a proportionately decreased feed. If the lips are unequally ground, so that one lip does all the work, the cutting pressure is the same as that obtained by doubling the feed. By gashing the lips of the drill in such a manner that the cut taken by one lip is the metal left by the other, the pressure is the same as that given for twice the feed.

The finer the feed the greater the cutting pressure, and consequently the greater the power required per cubic inch of metal removed.

(*m*) The end-thrust when operating on cast iron or steel does not increase in *proportion* to the feed for a given diameter of drill or in proportion to the diameter for a given feed.

(*n*) While the chisel point scarcely affects the torque, it is accountable for about 20 per cent of the end-thrust.

(*o*) The lubricated trials on steel when compared with the dry tests show a diminution in the torque and horse-power, varying from 28 per cent with the 0.0025 inch feed to 8 per cent with the 0.0285 inch feed. This may be due to the lubricant washing away the small metal chips which tend to jam between the walls of the hole and the drill, and to the preserved cutting edge. The end-thrust is reduced by about 25 per cent for all feeds.

(*p*) The drill most commonly adopted in practice has an included angle at the point of 120 degrees. [United States, 118 degrees.—EDITOR.] If this angle is increased the torque diminishes, but the end-thrust increases, while if this angle is decreased, the reverse is the result. So far as economy in power is concerned the torque is the factor to consider, as the feeding horse-power is only about 1 per cent of the whole in small drills and very much less for the larger sizes. From this point of view the drill with the larger point angle is to be preferred. The accompanying increased end-thrust, however, strains the machine parts in proportion. When the point of the drill breaks through the metal at the bottom of the hole, a considerable portion of the end load is removed. The strain due to that load is released, thereby causing the drill to advance more than its rated feed and possibly break the drill. The drill with the greater included angle will be most likely to give trouble in this direction, both on account of the increased strain and torque.

(*q*) By decreasing the spiral of the drill a keener cutting angle with a decreased end-thrust and torque can be obtained without altering the point angle above the accepted standard. This, however, would in turn affect the durability of the drill.

(*r*) With a small included point angle there is little metal to support the cutting edge at the chisel point, and trouble due to blunting of this part is to be expected.

(*s*) In estimating the time required to drill a hole of given depth the length of the drill point must be taken into account. The length of the point for different included point angles is:

for 90 degrees $= 0.5\,d$.
for 120 degrees $= 0.29\,d$.
for 150 degrees $= 0.134\,d$.

* * *

A correspondent, in a recent letter commenting on the reluctance of some good mechanics to subscribe to a journal devoted to their business, mentions a case illustrating the ignorance of a round-house foreman who prided himself on being well-informed. This man came to the writer one day much excited over the wonderful exhibit of a new apparatus which with a tiny flame enabled the operator to either weld or cut steel with rapidity. With it, the foreman said, he would be able to cut a piece of high-speed steel in two, and weld it together again if it were requird, and so on at length. The writer, after some questioning, discovered that the apparatus was the oxy-acetylene torch used for autogenous welding and cutting, the work of which has been described several times in MACHINERY. Had the foreman been a reader of technical journals, he would not have displayed his ignorance of an apparatus that has practically demonstrated its value and which already is being used to a considerable extent for repair work, etc.

MACHINES AND TOOLS FOR AUTOMOBILE MANUFACTURE[*]

C. B. OWEN[†]

C. B. Owen[‡]

Upon first thought the design and construction of tools and jigs for automobile manufacture may not appear to present any problems radically different from those involved in the manufacture of any other power producing and transmitting machinery; but after a thorough consideration of the conditions under which a motor car necessarily operates, the importance of a standardized, interchangeable, simple and strong construction is realized. As one of the requirements of a car is maximum power with minimum weight, the use of nickel and other steel alloys is required, which, in turn, necessitates the use of high-speed steel in the machine tools. As an automobile engine is necessarily a high-speed engine, the provisions for adjustment of wearing parts and the cheap replacement of them when worn out, are of primary importance.

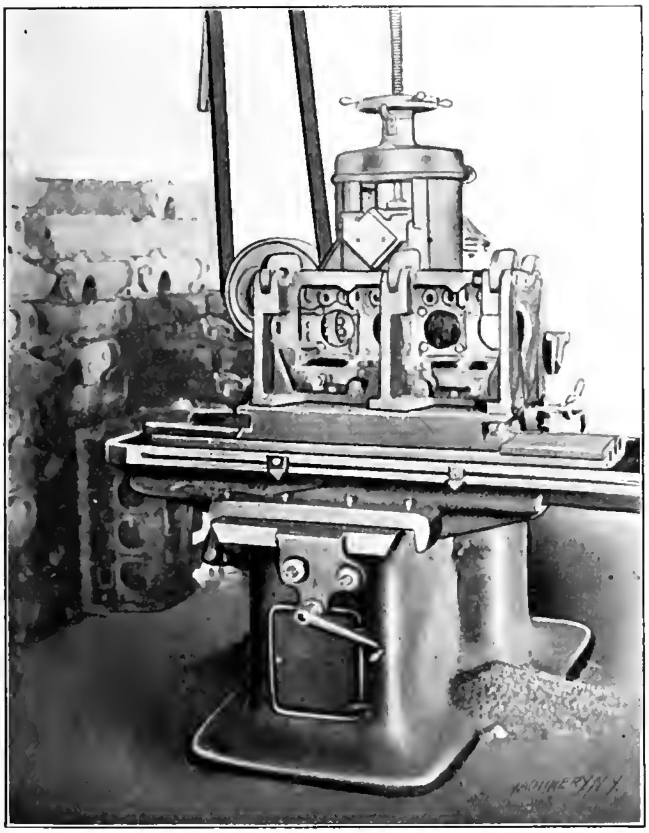

Fig. 1. Milling Engine Frames

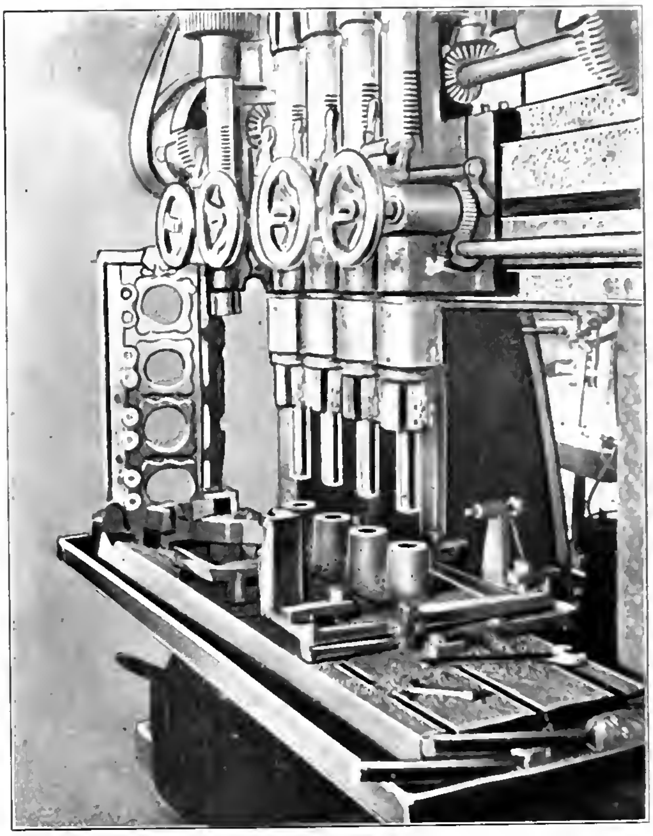

Fig. 2. Machine for Boring Frames

As the great majority of automobile owners are not mechanically inclined and wish the greatest amount of service with the least possible attention to their cars, the necessity of simple and reliable construction is apparent; and, as the motor car is forced by road conditions to do its hardest work on the poorest roads (which are usually farthest from the best repair facilities), under which conditions breakages are most likely to occur the advantages of interchangeable construction, the parts of which are so designed that they can *not* be incorrectly assembled, are apparent especially when road repairs must be made by men not thoroughly familiar with the construction of all cars. These are facts that the motor car designer must have seriously in mind, and which must reflect themselves to some extent in the tool design.

It is the purpose of this article to show how these ideas are carried out in practice, in the factory of the Cadillac Motor Car Company, Detroit, Michigan, and while space permits showing only a few of the several thousand special tools jigs and fixtures, it is thought that those shown will illustrate the care taken to secure absolute interchangeability and perfect alignment of parts. As the construction of the motor includes some very interesting tools, these together with some testing jigs are shown and described.

Engine Frames

As the engine frame is in two parts, divided horizontally at the shaft center, accurate milling and drilling is required. Heavy Brown & Sharpe, Cincinnati, and Leland & Faulconer machines fitted with heavy jigs and large inserted tooth cutters are used on this work. Fig. 1 illustrates the L. & F. machine milling the top face of the engine frame where the cylinders bolt on. This machine is very satisfactory for manufacturing, as the low table permits rapid handling of work, and its heavy construction, large bearing surfaces and all geared feeds and speeds provide for heavy and rapid cutting. The teeth of the cutter are seen through the openings in the work.

Fig. 2 shows the method of boring the seats for the cylinders in the engine frame. This operation follows that shown in Fig. 1. The cutter heads have a floating drive and are centered by the ground pilots entering inserted bushings in the jig bosses. The whole jig slides forward and back against a stop to facilitate inserting and removing the work.

Fig. 3 shows the lower half of the crank-case (shown in Fig. 7 of the article on "Organization and Equipment of an Automobile Factory in Machinery for March, 1909) clamped in the jig for drilling 24 holes for studs and cap-screws. The 24 spindle Baush machine drills these holes in about two minutes, including inserting and removing the work. A similar style of jig is provided for the upper half of the crank-case, which has 18 holes to be drilled in the lower face.

---

Organization and Equipment of an Automobile Factory, March, 1909; Automobile Engine Building in a Steam Engine Plant, April, 1907.

[†] Address: 857 Lincoln Ave., Detroit, Mich.

[‡] C. B. Owen was born in Coral, Mich., 1875, and served an apprenticeship with R. J. Tower Iron Works, Greenville, Mich., afterwards working for George D. Walcott & Son, Grand Rapids; Leland & Faulconer Mfg. Co., Detroit, in the engineering shops of the University of Michigan and the Cadillac Motor Car Co., Detroit, Mich., where he is at present employed. With these concerns he has held the position of machinist, tool-maker, foreman, road repair man, demonstrator, inspector, and the position of instructor of machine shop practice in the shops of the University of Michigan.

Fig. 5 shows the jig provided for boring the cam-shaft bearing seats in the upper half of the crank-case. These seats are indicated by the letter A, and are a very close fit for the five bronze bearings which carry the cam-shaft. The work locates over the two large bosses in the center of the jig, and rests on hardened and ground plugs inserted in the base. The swing clamps shown bear directly over the plugs. The boring tool, which is driven by a face-plate fixture, is seen projecting through one of the guides. The B. & S. plug gage seen on the lathe carriage, allows only 0.002-inch variation in the size of the holes. A similar type of jig (not shown) is used for boring the main bearing seats in the lower half of the crank-case, and an adjustable hand reamer with a very long pilot is used for finishing them. The variation in size allowed on the bearing bushings is only 0.0015 inch and only 0.001 inch on the shaft bearings.

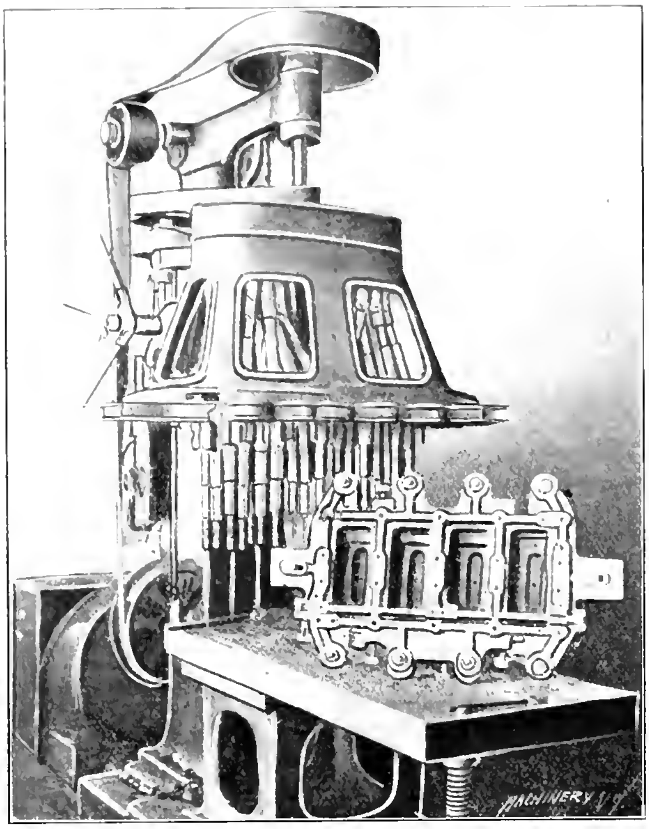

Fig. 3. Twenty-four-spindle Machine for Drilling the Frames

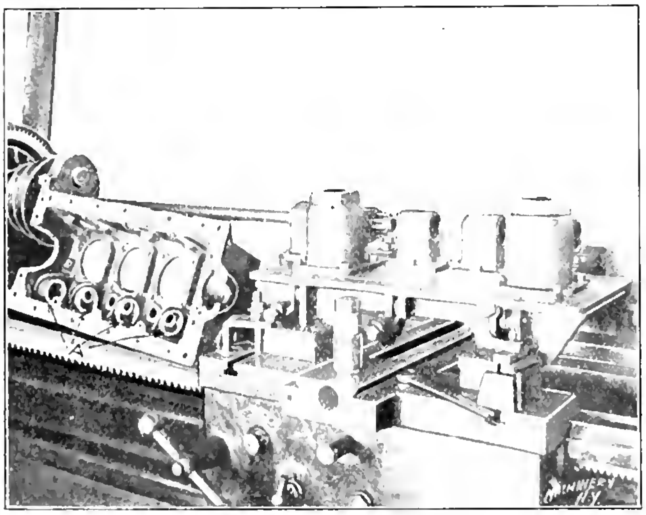

Fig. 5. Fixture for Boring Cam-shaft Bearings in Engine Frame

Cam-shafts

Fig. 6 shows both the cam-shaft drilling and reaming jigs on the same machine table, for convenience. The drill jig (seen in front) is of steel with hardened bushings with an adjustable stop-screw in the end. This jig gives the correct position of the holes for the eight cams and the drive gears. As the holes are to be reamed in pairs and each pair is 90 degrees from others, the reaming jig is designed with a view to extreme accuracy. In operation the first hole reamed is the one by which the drive gear (Fig. 3, March issue) is pinned on. The taper reamer is guided by the bushing in the clamping fixture at the right, and the collars are so adjusted as to ream the hole to the required size. The shaft is then slipped through the square, hardened-and-ground steel block seen at the left in the illustration, and a master pin is inserted. The block is then slipped along in the frame of the jig and clamped by the screws seen on top of the fixture as the various holes come under the reamer. The projecting block seen at the extreme right end of the jig, forms a rest for the cam-shaft as it is passed along. As the taper holes in the cam-shaft, cams and cam-gears, must bear the correct relation to each other, a set of master pins is provided for testing the depth of the reaming. These are hardened and ground tool-steel pins having two fine lines 0.020 inch apart around them at the point where they project through the hole in either the shaft, the cam or the gear. As a variation of 0.001 inch in the diameter of a standard taper pin hole permits the pin to enter 0.040 inch deeper into the hole, the accuracy of this work can be realized when it is known that no hand reaming is required in assembling the cam-shaft. The

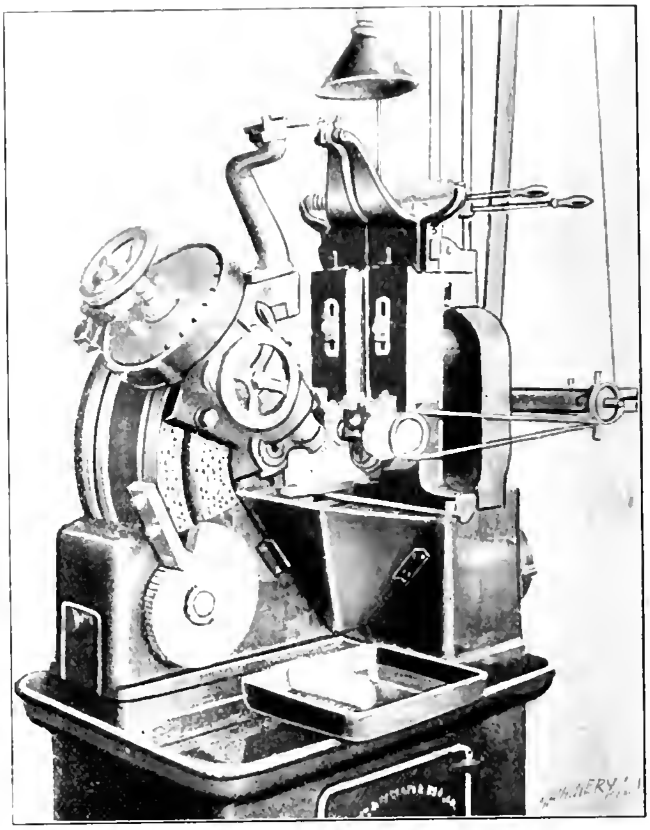

Fig. 4. Bevel-gear Milling Machine of the Templet Type

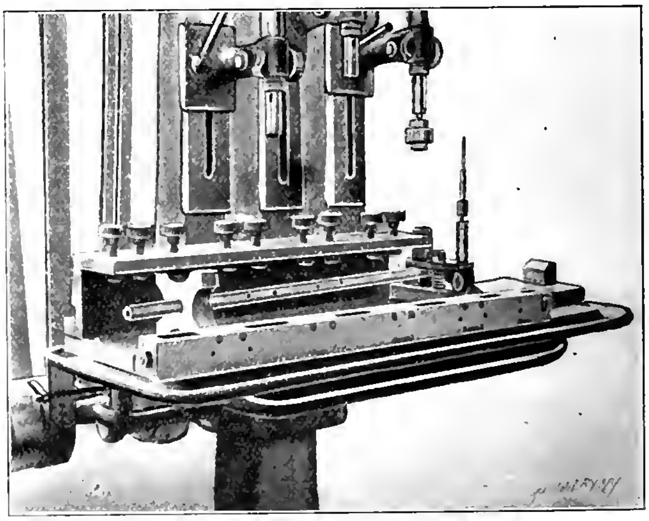

Fig. 6. Fixtures for Drilling and Reaming Cam-shafts

cams are drilled and reamed in similar jigs, which, in all cases, locate the cams by the eccentric portions. The inlet cams are alike and interchangeable, as are also the exhaust cams. The cams are of selected steel, properly hardened and finished by grinding the working surfaces in the correct relation to the pin holes.

Cylinders

Fig. 7 illustrates the method of boring the cylinders in a double spindle Beaman & Smith machine, with a turn-table fixture whereby two cylinders may be changed while two others are being bored. As the cylinder castings are very uniform in size, the boring leaves the walls very uniform in thickness. After being bored and reamed the cylinders pass to the testing bench where water pressure of 700 to 800 pounds per square inch is applied to test them for leakage. Those passing the test are taken to the screw machine department and put on an expanding arbor in a large Potter & Johnston machine for facing and tapping the top and turning the portion of the cylinder which enters into the crank-case of the motor. The machine and tools for these operations are seen in Fig. 8. The turret tools in the foreground are those used in roughing off and boring the upper end of the cylinder for the cylinder head nipple. The heavy overhanging turret tool finishes the flange on the cylinder for the copper water jacket. The rear cross slide carries the tools for roughing this flange and also the flanges through which the studs pass for fastening the cylinders to the engine frame, while the forward cross-slide tools finish the stud flanges and a portion of the cylinder where it enters the bored seat in the engine frame.

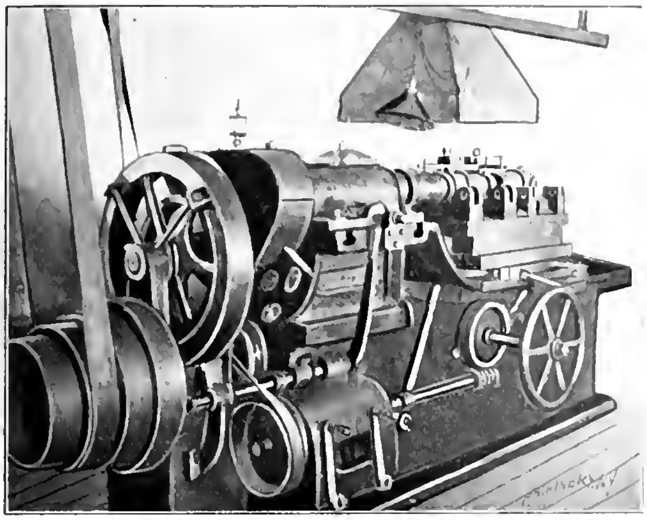

Fig. 7. Boring Cylinders

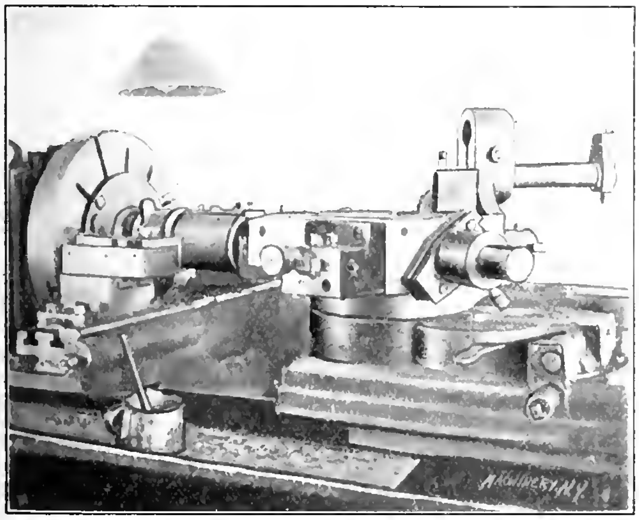

Fig. 8. Turning Cylinders

The cylinders are finished by grinding in Brown & Sharpe and Heald machines. A heavy angle-plate fixture, bored and faced to a very close fit on the cylinder diameter, is fitted to the table of the machine as shown in Fig. 9. The cylinder is clamped to this fixture exactly as it is held later in the assembled motor. Cooling water is supplied to the outside of the cylinder, and the air tube seen at the extreme right conveys the particles of metal and emery to a suction fan at the rear of the machine. The "Go" plug gage seen on the machine table, is 4 inches in diameter and the "Not Go" gage is 4.002 inches in diameter.

Pistons and Rings

The second operation of roughing off the pistons in a Gridley automatic turret lathe is shown in Fig. 10. The first operation is not shown, as it consists only in chucking and roughing off the outer diameter of the head end for about an inch to permit the steadying roll passing over the end. The upper roll has but slight travel, as it forms a part of the end facing tool. The heavy turning tool is carried in the rear tool-holder, which also carries another roller; this roller supports the piston against the side thrust on it, caused in cutting the ring grooves. The view shows the very heavy character of the tools, and the provisions for adjustment. The piston is held by an internal draw-in fixture, thus permitting the turning tool to travel its entire length. (An illustration and description of a similar fixture will be found in the article "Automobile Engine Building in a Steam Engine Plant" which was published in the April, 1907, issue of MACHINERY.) The finish is by grinding in heavy Brown & Sharpe and Norton machines, as illustrated in Fig. 11. The greatest variation in size permitted is 0.002 inch. A finishing cut is taken from the open end of the piston in a special reaming fixture just before grinding, which prevents any possible distortion of the piston due to changes in the metal after the open end has been machined. The piston pin hole is bored in box jigs and 0.001 inch is left for hand reaming previous to assembling the piston and connecting-rod. A final light finishing cut is taken from the piston ring grooves after the piston is ground.

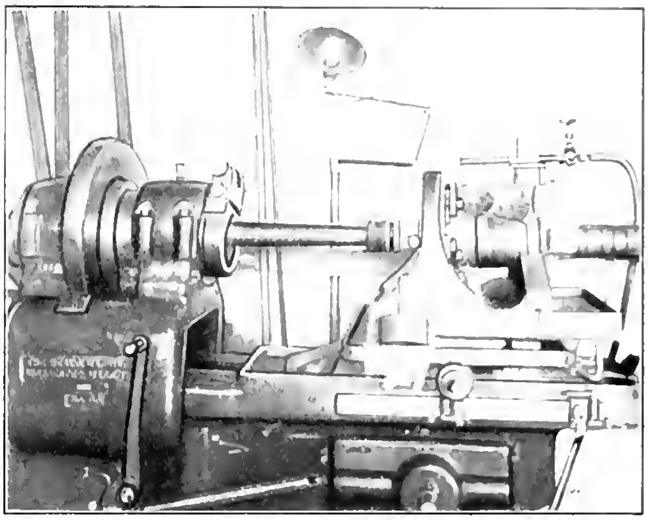

Fig. 9. Grinding Cylinders

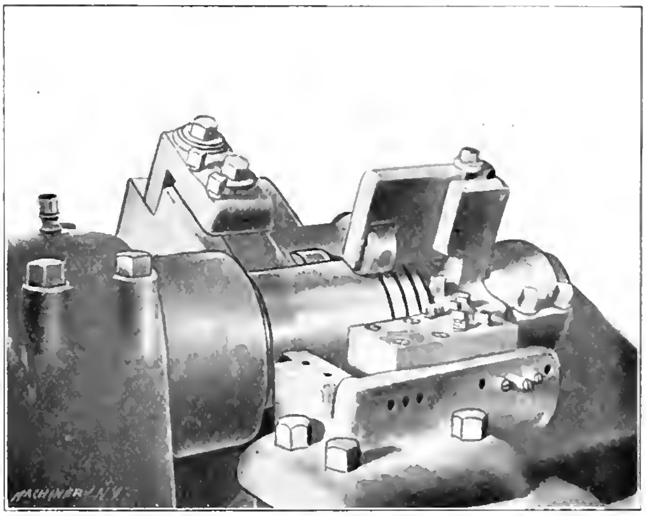

Fig. 10. Turning Pistons

The piston rings are of a special close-grained iron mixture, and are turned and bored on Gridley machines, and finished

by grinding. The ring joint is the standard 45-degree angle joint which has always given good results in practice.

Connecting Rods

The connecting-rods are drop forgings of H-section, having a pressed-in bronze bushing bearing for the piston-pin, and a hinged cap carrying babbitt-lined bronze half-bushing bearings for the crank-pins. While the machining of the rods requires a set of very complete and accurate jigs and tools, limited space prevents their illustration. Two of the fixtures for testing the alignment of the assembled rods, however are shown in Figs. 13 and 14. Fig. 13 shows the method of locating the piston-pin bushing central with the crank-pin bearing, which is held in the hinged end of the rod by large brass dowels. A plug is placed between the half bearings, and the adjusting screw tightened down sufficiently to hold them tightly in place. The piston-pin bushing having been pressed in approximately central and hand reamed, is then slipped on the ground arbor which is pressed into the casting and positively held by a large hexagon nut. The knurled nut *A* is then screwed on the outer end of the arbor, thus holding the piston-pin bushing against a ground shoulder on the fixed arbor. The micrometer screw is then brought up until it touches the edge of the crank-pin bearing, a reading taken, and the screw backed away. The nut *A* is then loosened, the connecting-rod slipped off, turned over and replaced on the arbor and another reading of the micrometer screw is taken. The difference in the two readings thus indicates the amount the two bearings are out of line with each other. For overcoming this variation, the two knurled nuts *B* and *C* are provided. Nut *B* is internally threaded to fit a threaded portion of nut *A*, and in use screws up against the face of the connecting-rod forging for pressing it farther on the bronze bushing. Nut *C* which is internally threaded to fit a portion of the fixed arbor, operates to move the rod forging in the opposite direction. When the rod is thus centralized, a dowel of brass tubing is put in, which prevents disalignment and also conveys oil to the piston-pin bearing.

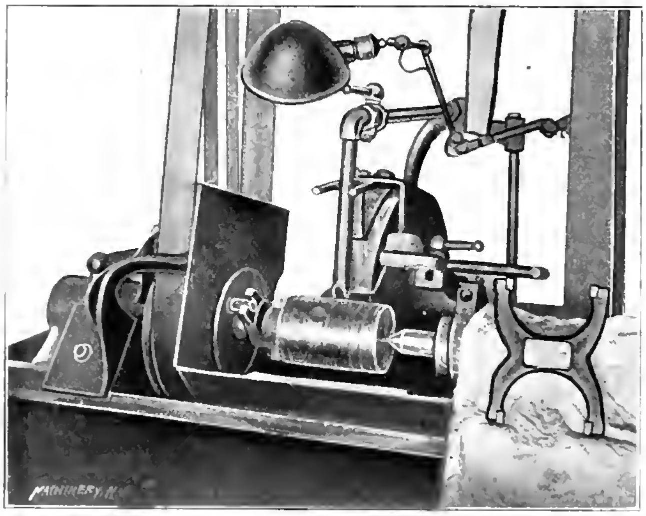

Fig. 11. Grinding Pistons

For testing the parallelism (both vertical and horizontal) of the rod bearings, the fixture shown in Fig. 14 is provided. In operation, two ground arbors which are tight-fits in the rod bearings, are inserted, and the rod laid in the fixture as shown. A pair of flat springs *A*, press the smaller arbor against the inserted hardened and ground plugs opposite them. A similar pair of plugs are seen in the other end of the fixture; between these and the arbor is inserted the taper strip seen in the foreground. The taper is such that the cross lines which are about 1/4 inch apart each give a reading to 0.001 inch. The two flat strips attached to the lower end of the fixture are so placed for convenience in reading any variation in the position of the taper strip. As all four horizontal surfaces on which the ends of both arbors lie are ground to the same plane, any wind in the connecting-rod is seen by the failure of all four points to touch at the same time.

Bevel-gear Templet Milling Machine

A pair of bevel gears are used to drive the short, vertical, commutator shaft from the cam-shaft of the motor, and as the relative positions of the commutator to the cam-shaft and main shaft of the motor must be accurately maintained, the necessity of correctly cut and carefully mounted gears is apparent. The arrangement of these gears is shown in Fig. 3 of the article referred to in the March issue. For producing these bevel gears a specially designed machine is employed, which is shown in Fig. 4. The machine is one of the templet type, which templet or form (seen on the arm at the top of the machine) is primarly developed by rolling contact with a rack. This produces a magnified tooth form which is mathematically correct, and even if it contained any errors these would be reduced in the actual work in the same proportion which the gear tooth bears to the form.

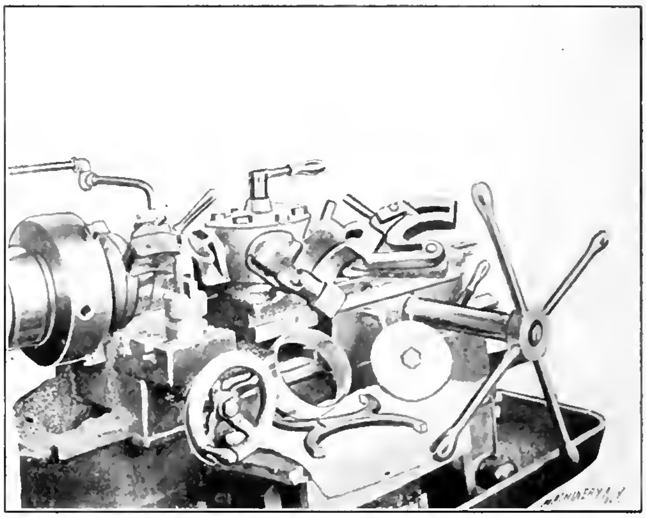

Fig. 12. Turning a Spherical Ring

The machine consists of two principal parts: the work spindle and its driving and indexing mechanism, and the cutters with their driving mechanism. The cutters are driven by round belts, at a high speed, and are mounted on geared spindles which are carried in two vertical slides, which, in operation, have a reciprocating motion on lines divergent from the cone center of the gear to be cut. The cutting edges of the cutters are thus always traveling along lines which become the clearance lines of the gear tooth. The gear blank is roughed out on a special gashing machine as the templet milling machine is not intended for roughing.

The work spindle is carried in the head, which has a working range of 75 degrees between the horizontal and vertical planes. This head is locked to the movable graduated quadrant, which is pivoted at a point coincident with the center of the gear. The work spindle has an end movement of several inches, for convenience in changing the gear blank, and has a draw-in arbor attached to the hand-wheel seen above the index plate, for locking the gear blank in position. The index plate is seen at the top of the work spindle. The index trip is set at the desired position on the rear slot of the stationary quadrant. In operation the large cam under the work spindle raises the pivoted quadrant to which the work spindle is locked, and gradually feeds the work forward between the two cutters, which are gradually forced to change their position by the action of the large tooth form entering between the two rolls on the cutter slide arms. The indexing is, of course, automatic, and occurs at the position of the cam shown in the engraving. This cam has, as shown, an edge consisting of a series of small steps, rather than a gradual curve, and is so geared to the cutter spindle mechanism that the work is fed into the cutters at the ends of the stroke of the cutter slides, rather than during a cut. The index mechanism shows careful thought in its design, in that the index pin enters the slots in the index plate in such a manner as to have no sliding contact on the master edge of the slot. An automatic trip stops the machine when the gear is finished. This machine is one of a series which was built by this company (then the Leland & Faulconer Manufacturing

Company) in 1898-1899, for producing either soft or hardened and ground bevel gears, the machine being designed to produce finished soft gears, or semi-finished gears for hardening.

Commutator Testing

Fig. 15 shows a fixture employed for testing the accuracy of the spacing of the contact points of the commutator. This fixture consists of a central portion carrying the commutator shaft, and of an outer graduated steel disk movable on the central part of the fixture. In operation, a commutator is slipped on over the stationary shaft and the bearings adjusted. The commutator brush is then placed on the shaft and locked in place, leaving the commutator body free to be revolved. A battery and coil which are a part of the fixture, indicate the electrical contact by the buzzing of the coil. The pointer is then put in place and clamped, and the commutator turned until a contact is indicated. The large outer disk (about 18 inches in diameter) is then turned around under the pointer until one of the 90 degree graduations are directly under the pointer. The commutator and pointer are then turned to bring the other contacts to the brush, and their variation read on the large disk, which is graduated in degrees at four equi-distant points around its edge. The requirement is that the commutator contacts be spaced 90 degrees apart, and the variation allowed is only one-half a degree, as the relation of the firing to the piston and valve movements must be very exact.

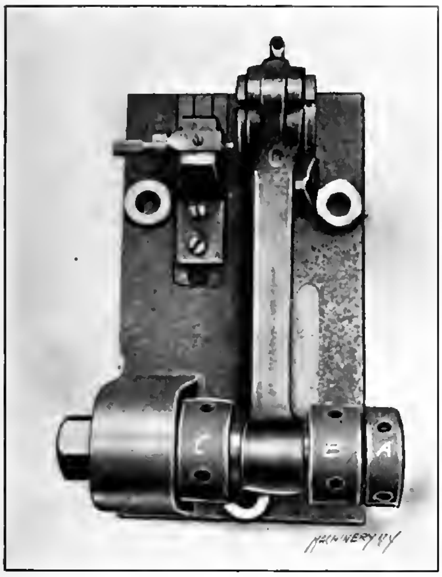

Fig. 13. Fixture for Testing the Relative Lateral Positions of Connecting-rod Bearings

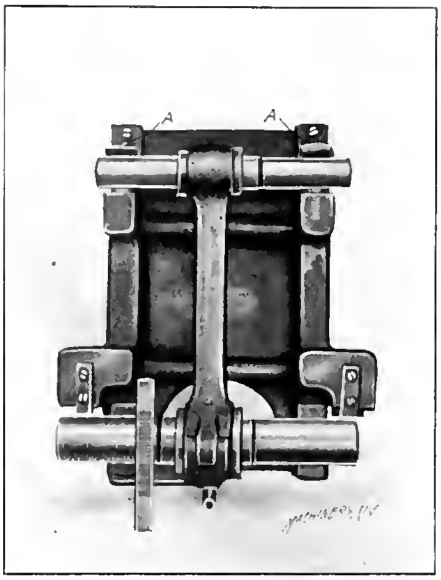

Fig. 14. Fixture for Testing the Parallelism of Connecting-rod Bearings

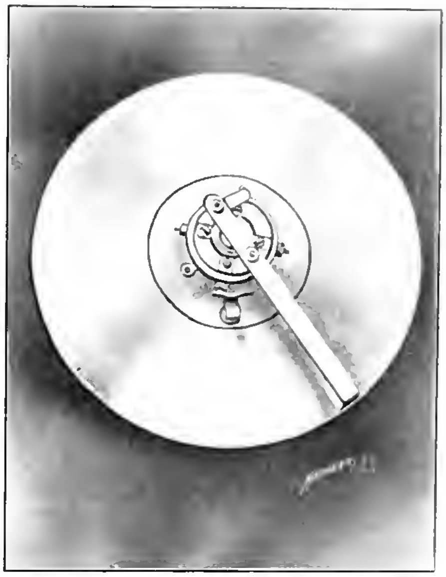

Fig. 15. Fixture for Testing the Accuracy of Commutator Contact Points

Fig. 12 illustrates a nice piece of screw machine work in the brass shop. The ring seen leaning against the machine is of bronze. The diameters of these rings range from 6.497 inches to 6.500 inches and the bore from 5.878 inches to 5.880 inches. The outside is spherical in shape, and the ring forms a part of the rear universal joint housing that the rear axle driving shaft casing pivots and also slides in to compensate for the rear spring action. Slight variations in size and a fine finish are necessary to make this joint oil tight. A casting is seen in the machine, and a roughing cut is being taken from the outside. It has already been rough bored, enough metal being left for a fine finishing cut to be taken after the outside is finished. The castings have heavy flanges for inside chucking, so that little trouble is experienced by their springing after being parted. The illustration clearly shows the construction of the spherical turning tools, and two of the gages used.

* * *

German engineers were comparatively slow in adopting the steam turbine for ship propulsion until its merits had been sufficiently proved; but at the present time the realization of the importance of steam turbines in connection with both merchant and war vessels is clearly evidenced by the fact that nearly all German ship-building yards are now building steam turbines.

A COLLECTION OF MACHINE SHOP RULES

ETHAN VIALL*

A booklet has recently been issued by the H. Mueller Mfg. Co., Decatur, Ill., for the employes of the shop, containing a number of directions for the use of tools. As these rules will doubtless be of general interest the essential points are given below.

Rule 1. A file must not be used as a hammer, chisel or pry.

Rule 2. Do not use a monkey wrench as a hammer.

Rule 3. A wrench used on the head of a bolt or screw, or on a nut, should fit closely, otherwise it will gradually round the corners.

Rule 4. Never use a large wrench on a small bolt, screw or tap, without considering the amount of strain that the bolt, screw or tap will stand.

Rule 5. When chucks are placed on the lathe spindle, be sure that the threads on the spindle and in the chucks are cleaned and oiled. Then screw the chuck on by hand within one-quarter turn of the shoulder, and finally give it a quick turn by hand against the shoulder. This will tighten it sufficiently to keep it in place, without causing difficulty when taken off. The chuck should be oiled at least once every twenty-four hours, though a more frequent oiling will do no harm.

Rule 6. All working parts of tools should be kept well oiled. The shanks of the tools should also be oiled slightly and wiped, before inserting into the holders, to keep them from rusting. The holes in the turrets which are not in use should be plugged up with wooden plugs, so that the chips cannot enter and get into the working parts.

Rule 7. Never accept a taper shank drill from the toolkeeper if it has a broken or distorted tang. It may cause damage to the socket.

Rule 8. Gages of all kinds must be handled with care. Never force a piece of work into or onto a gage. Do not slip a ring gage over a set-screw on the machine and allow it to remain while the machine is operating. The constant jarring of the machine will cause the gage to work on the set-screw, and gradually spoil it. Threaded plug gages should be screwed into a cap when not in use, in order to protect the threads.

Rule 9. Tools should not be forced into the holes in the turret, because it is then very difficult to remove them; the hole in the turret may be enlarged, which would damage it for use with regular tools. The tool shank should fit easily, so that it can be inserted by hand.

Rule 10. If a tool cannot be removed from the turret, try some of the following rules for removing it. For centers: If after loosening the set-screw, the center cannot be removed by hand, tap it lightly with a lead hammer; do not tap it too hard; if the center is flattened on one side, use a monkey

---

* Associate Editor of MACHINERY.

wrench to give it a turn; centers in hollow spindles should be driven out with a rod, from the rear. For tool holders: These can generally be loosened by applying a monkey wrench to give them a turn. For tap holders: The last piece of every job should not be taken out of the chuck until the tap holder has been extracted from the turret. If it is too tight to be moved by hand, the tap in the holder should be screwed into the work; then run the carriage back, and pull the tap holder out of the turret; this method can also be applied for adjusting the tap holder to the work. For die heads: These can be removed by running the die on the last piece of work, and moving the carriage back in the same way as for tap holders; if a self-opening die, hold the lever of the die-head, so that the chasers cannot open up. For chasers: A bar of lead or a piece of wood should be used to tap the chasers lightly, if they cannot be extracted from the die by hand.

Rule 11. A wrench, hammer or a piece of brass or steel should never be used for adjusting the tools in the turret, even a fraction of an inch. The tools should be tapped lightly with a lead hammer.

Rule 12. No hard material of any kind must be laid on the ways or bed of a lathe. The unused portion of the lathe bed should be covered by a smooth board.

Rule 13. When putting a tool into a turret or holder, turn the flat side of the shank so that the set-screw will rest on it. If the set-screw is tightened at the round part of the shank, it will set up a burr. The set-screw should never rest on the extreme end of the shank, as it is likely to tip the tool out of true.

Rule 14. Handle the shifter of the counter-shaft with care. If the machine is running at full speed, rest the shifter at the neutral position for a few seconds before reversing. Make the reverse as gradual as possible. Slipping and stretching of the belts, working out of the clutch, breaking of clutch fingers, loose counter-shafts, and the heating of bearings, are some of the bad effects of sudden reversal at high speed.

It will be seen that the foregoing rules were primarily intended for the men in the turret lathe department. Several of the rules may seem unduly elaborate, but often turret lathes are operated by comparatively inexperienced help.

* * *

THE LIVE PRESS

C. TUELLS

Business was booming at the old novelty shop, and lots of orders were in, some of which were marked "special rush" in large red letters, so it was only natural that the press department should be taxed to its full capacity for turning out punchings. The floor was littered with scrap-brass and the fly-wheels of the presses were spinning merrily around to the tune the dies played as they snapped through the stock.

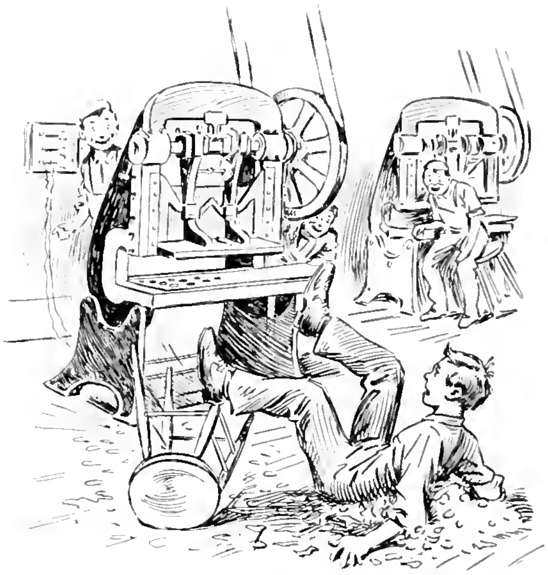
During the rush an unlucky press-hand had cut a scallop out of the end of one of his fingers in spite of the warnings of Jim (the "master-mechanic" of the press-room), to keep his fingers clear of the dies. Press-hands were not hard to get, so the next morning a new boy appeared on the scene to take his place. The foreman had brought him around and told Jim to start him at work, so he was soon initiated into the mysteries of running a punch-press, and though the piece-work price was only thirty cents a thousand, the counter on his press was soon clicking around as fast as any of those on the other presses.

The boys working on the nearby presses were jealously watching him and speculating as to how much he would make and how long he would last—just as the old hands in any shop always keep tab on a new man to see how he gets along and what mistakes he makes.

The new boy was a hustler; in fact the other press-hands decided he was "killing the job"—so fast did he work—and, full of envy, they began to put their heads together to devise a way to "do" him. After much scheming they hit upon an idea, and while he had gone to the stock rack for more brass they detached the wires from an electric switch and connected them to the back of the new boy's press in such a way that a foot on the treadle and a hand on the press-bed completed the circuit.

Back came the press-hand with his arms full of sheet-brass, all stripped and ready to be punched. He sat down on his stool, started a strip of stock under the die, and put his foot on the treadle—but no, he didn't press it—the treadle pressed him. He jumped back about two feet, looked at his hands, at the stock, and at the press; they looked all right, so with an expression on his face that was partly pained and partly puzzled he pluckily sat down and tried it again, with the same result—only more of it.

"Shocking" was a new and decidedly disagreeable experience to him, and he didn't understand it, so he went off looking for Jim, the cure-all for press troubles. The rest of the boys were convulsed with laughter, but before Jim got there they had replaced the wires, and, naturally, he found the press all right, and though the new press-hand looked on with fear and trembling, Jim tripped the press a few times and told him to get to work again.



"Over he went, stool and all, into a pile of scrap-brass"

As soon as Jim had left, back went the wires while the press-hand's back was turned, and by the time he was ready to start, the press was ready too, and the minute his foot touched the treadle, over he went, stool and all, backward into a pile of scrap-brass, letting out a yell that would have done credit to Sitting Bull. The other boys could hold in no longer, and amid their shouts of derisive laughter he got up, gave one last look at that press, and bolted for the door, grabbing his hat as he ran—the worst frightened boy that shop had ever seen, and if the expression on his face counted for anything he should be going yet.

Next morning a large placard appeared in the office window. It read: "BOY WANTED."

* * *

A great deal has been written from time to time decrying the mechanic who does his work so that it is merely "good enough." However, there is something to be said in favor of the man who does his work merely "good enough," provided it is always as good as required. It is not in harmony with modern manufacturing conditions to finish work to a thousandth of an inch, when a limit of a thirty-second inch is amply accurate, and it is no special virtue in the man to carefully work within close limits to the dimensions on the drawing without using his judgment as to which dimensions should be as accurate as possible and which would be "good enough" if they were within one-sixteenth inch. In fact, the man who is able to judge for himself, in every case, exactly when his work is "good enough" for each specific purpose, is really the best mechanic. In years gone by, exceptional skill only was supposed to be the final qualifications of the master of mechanics, but to-day skill alone is not enough. It is skill combined with sound judgment and good common sense that is required in any successful mechanic, and the man who is able to decide for himself in every case exactly when his work is "good enough" for the purpose intended, is really the best man to have around a manufacturing plant.

POWER HAMMERS AND FORGING APPLIANCES*

JAMES CRAN†

Power hammers, previous to the advent of steam, were of the helve and trip types, usually operated directly by the shaft of a water wheel, and principally used in the manufacture of wrought iron and steel. They were crude and cumbersome, but they were equal to the needs of a past generation of iron and steel workers, who were more noted for the thoroughness with which they did their work than the speed with which it was accomplished.

The steam hammer was invented by James Naysmith about 1842. Naysmith's hammer was direct acting, and was a decided improvement over the helve and trip types; but it was defective in several ways. The valves were operated by hand, and it was often difficult to raise the ram immediately after a blow was struck. This had a tendency to chill the metal being worked. The steam hammer remained in this condition until Robert Wilson applied a valve motion which enabled the blows to be regulated both in speed and force, thus bringing the hammer at all times under perfect control of the operator.

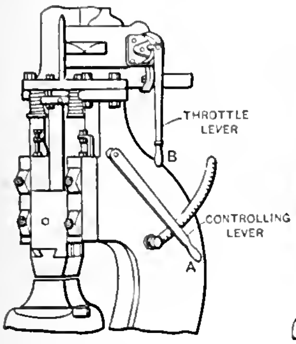


Fig. 1. Single Frame Steam Hammer, showing Common Arrangement of Levers

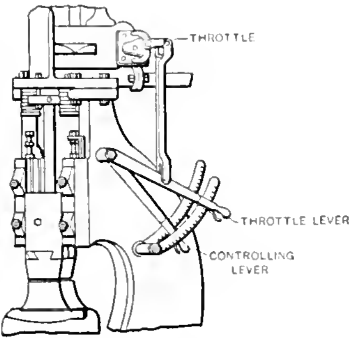


Machinery,N.Y.

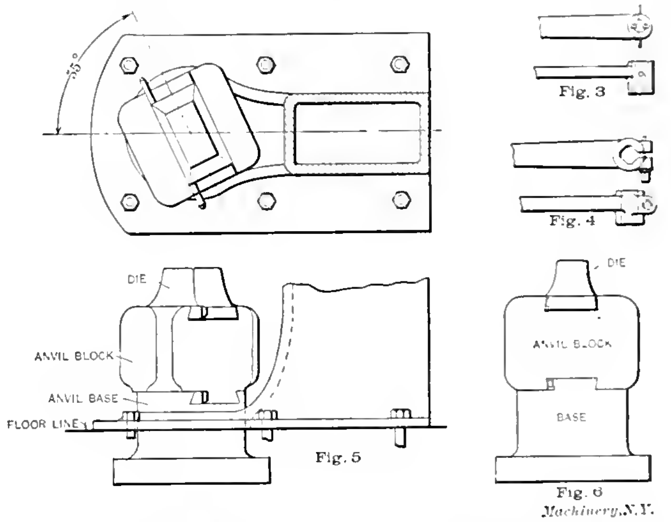
Fig. 2. Improved Arrangement of Throttle Lever

The steam hammer has been the most potent factor in the development of the iron and steel industry. When considering the important part it has played in the development of machinery, and the effect it has had upon progress and civilization, it is natural to suppose that no pains would have been spared in perfecting this useful tool. This has, however, not been the case, and the steam hammer of to-day is but slightly superior to that made by Naysmith and Wilson. The improvements made since it was originally invented have mostly been on the valves, the guides for the ram and the general construction of frames. Minor details, in the majority of cases, have been left to take care of themselves.

Take, for example, the arrangement of the hand levers on most of the single-frame hammers in general use. It will be found that the greater part of them are made as shown in Fig. 1. To manipulate levers arranged as shown, the operator is placed not only in a cramped, awkward position, but so that he can only with difficulty see the work being done. The controlling lever *A* being held in the right hand, makes it necessary for the operator to use his left hand for the throttle lever *B*. When working under a full head of steam, his left arm comes directly in front of his face, obscuring his view of the work. He must remain in this position until the operation on the work is completed; should he release his hold upon the throttle lever, the jar of the hammer would immediately bring that lever to the perpendicular position and shut off the steam. The operator's view of the work being obscured is also often responsible for his mistaking the signs which must necessarily be used while work is being done at a steam hammer on account of the noise. On some makes of hammers this defect has been overcome by placing both levers on the same stud, and operating the throttle by means of a connecting rod connecting the lever with a short lever directly attached to the stem of the throttle valve, as shown in Fig. 2. This permits the operator, at all times and under all conditions, to get an unobstructed view of the work.

The methods of attaching the levers may also be improved. The usual method for attaching them is shown in Fig. 3. The lever hubs are fitted or at least placed on round stems and kept from turning by keys. A taper pin is driven through the hub on the lever and the stem, to keep it in place. It is, generally, but a very short time before levers attached in this manner work loose, no matter how well they may be fitted. Lost motion is an annoyance on any kind of machinery, but is actually dangerous on a steam hammer. If the levers were made with a binder across the end of the boss, as shown in Fig. 4, and fitted to square stems, there would be little danger of lost motion, or of the levers working loose; and their removal when repairs are necessary would be an easy matter compared with removing pins and keys.

There is also room for improvement on the common method of fitting and attaching the anvil-block to the base. Almost invariably the male part of the dovetail is a projection of the anvil-block and fits into a recess in that part of the base which projects through and a little above the flange which forms the base of the frame, as shown in Fig. 5. Should the key which is necessary to hold anvil-block and base firmly together be driven in too tight, the chances are that the side of the recess will be broken away. When this happens, there is no possible means of effecting repairs and the base must be replaced by a new one, which can only be done by disconnecting all pipes to and from the hammer and raising the whole frame to allow the old base to be removed and a new one placed in position. Apart from the work and expense, the hammer is out of commission from one to two weeks. If the dovetailing were reversed, making the male portion part of the base, as shown in Fig. 6, it would be almost impossible either to break or damage the base accidentally, as the driving of a key however tight would only tend to compress it. Should the anvil block happen to be broken, the replacing of that would be but a trivial matter compared with replacing the base.



Machinery,N.Y.

Fig. 3. Common Method of Attaching Throttle and Controlling Levers Fig. 4. Improved Method of Attaching Levers Fig. 5. Anvil and Dies of Steam Hammer set at an angle with the Frame; also shows Usual, but Objectionable, Method of Dovetailing Fig. 6. Improved Style of Anvil Block and Base

Upon nearly every other class of machinery weaknesses and defects of the kind mentioned have either been overcome or guarded against by placing the pieces most liable to break in positions where removing or replacing them can be done at the least expense. The probable reason for the details of steam hammers not receiving the attention that is usually given to machinery used in other branches of metal working may be that designers as a rule never have any practical forge shop experience apart from that taught in the industrial departments of schools and colleges, which at the best is only elementary and does not, usually, bring them in contact with forging appliances other than those used by hand around the anvil. Much valuable information relative to steam hammers and other forging appliances could be gathered from the blacksmith, who has every opportunity of not-

---

* For further information on this and kindred subjects, see MACHINERY, May, 1909: Anvils and Forges, and the articles there referred to. See also MACHINERY'S Reference Series No. 44: Machine Blacksmithing, and No. 45: Drop Forgings.

† Address: 916 West 3rd St., Plainfield, N. J.

ing their efficiency and their weak points as well; but suggestions from him, no matter what his experience may be, are seldom considered, rarely adopted, and often have a similar effect upon the manufacturer and designer that a red rag has upon a bull.

Nearly all kinds of machinery used in the different branches of metal working, outside of the forge shops, are constructed so that they can be adjusted or set to work to any angle. Tool equipments for any particular class of work are made and supplied, and all the data and instructions that will insure that the machine will give satisfaction in turning out work to its full capacity are given. When a special tool or a fixture for some particular piece of work is required, it is designed and constructed in strict accordance with mechanical principles. Steam and power hammers, however, are supplied with no tool equipment whatever, more than a plain-faced pair of dies which are of comparatively little use in the making of forgings without an equipment of tools to be used in connection with them. Such tools the builders of hammers do not supply, nor do they generally give any information that could be turned to good account in making them. It is usually "up to the blacksmith" who has to use such hammers and appliances to design and construct such tools and fixtures as facilitate the making of forgings and make the machines paying investments.

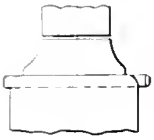


Fig 7. Common Form of Dies

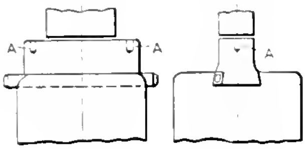


Machinery,N.Y.

Fig 8. Improved Form of Dies for General Use

Steam hammers are built in a variety of styles to suit the different classes of forging. The smaller sizes are of the single frame type, while those intended for the heavier work have an arched or double frame. For medium weight and light forging, the single frame hammer with the anvil and dies set at an angle of from 55 to 60 degrees from the frame, as shown in Fig. 5, will be found to be the most suitable, as work of any length can be forged either across or lengthways of the dies without its coming in contact with the frame.

Nearly all dies supplied with steam hammers are tapered from the shank to the face, as shown in Fig. 7, and are only suitable for plain straight forging, as it is impossible to work close up to a shoulder on a forging, on account of the taper, or to break down work except by using special tools, as the faces of both dies are the same length. If the dies were made as shown in Fig. 8, where the lower die is considerably longer than the upper one, with the sides of both perfectly straight, several advantages are gained over the more common shapes. The square sides allow of working close up to shoulders, and the extra length of the lower die permits of breaking down work without the use of special tools. Work is also much more easily straightened, and there is more space upon which to place formers or special tools. The hole at each end of the lower die, as shown at *A*, adds considerably to the utility, as these holes can be used for stakes to keep formers from moving while they are being used. Work of irregular shape can also be butted against the stakes while the hammer is used to finish some portion that otherwise would have to be done by hand. Forks could also be used to keep spring swages from being moved with the work when it is forced or drawn through them.

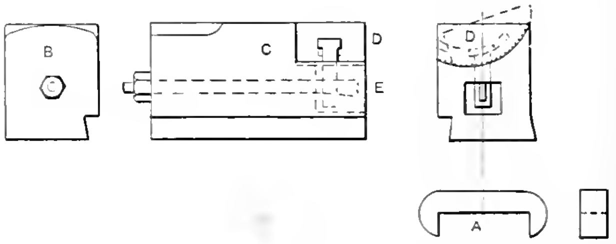
To make a steam hammer as useful and handy a machine in the forge shop as a lathe with a taper attachment is in the machine shop, a lower die as shown in Fig. 9, can be used to draw and finish tapers to any angle. The rougher part of the work is done on the rounded end *B*, and the finishing on the adjustable end *D*. The level portion *C* in the center can be used for flat work. The adjustable section *D* of the die is about one-third of the entire length, circular in shape, and corrugated on the lower side which is provided with a T-slot. A T-headed bolt fits into the slot, and the adjustable section is held firmly in place at any angle by a wedge-headed bolt *E*, which is passed through a slot in the T-bolt and is tightened by a nut on the end which projects through the other end of the die. When the end of the adjustable section is raised above the level of the face of the die, as shown by dotted lines, a piece shaped as shown at *A* can be placed on the center of the die to prevent the upper die coming in contact with it.

To set dies of this kind accurately to any desired angle, the adjustable gage shown in Fig. 10 should be used. The gage is jointed at all the corners, and locked at any angle by means of a thumb-screw. It can be adjusted by means of a protractor and is used by placing it between the upper die and the adjustable section in the lower one while the bolt that keeps it in position is loose.

The arrangement of piping to and from hammers is also worthy of consideration. Generally both the supply and exhaust pipes are placed overhead, where they offer an obstruction to the free use of jib cranes, which are essential in the handling of heavy work. Besides, any steam that is condensed in the supply pipe, is supplied to the hammer in the form of water, especially when the hammer is installed any distance from the point at which the steam is generated. When water is supplied to a hammer in any considerable quantity, it generally finds an outlet other than the drip cocks and is one of the greatest annoyances to the workman. If it gets on the dies it is spread in a fine spray in all directions when a blow is struck.

The trouble with leaking water can be overcome to a great extent by placing both supply and exhaust pipes under the level of the floor and providing the supply pipe with a trap which would take care of the greater part of the water caused by condensation. The fact that the steam is supplied from below instead of from above would tend to prevent water reaching the cylinder of the hammer in quantities sufficient to cause trouble. The absence of overhead pipes would allow of the free use of cranes or any other conveying devices.

Among forging appliances the steam hammer is paramount; it can be used for any kind of forge work from the lightest to the heaviest; but for some of the lighter grades of forging some of the lighter types of power hammers may be used with equal, and perhaps better, results than could be obtained with the average steam hammer, because they are lighter and capable of striking blows much more rapidly. When the term power hammer is used without qualification it applies to the types of hammers that are operated by a belt from a countershaft almost directly over them. The belt is just long enough to clear the lower side of the pulley attached to the hammer; it runs constantly and is rendered operative by a tightening pulley or idler controlled by the foot of the operator. Hammers of this type are generally referred to by forgemen as trip hammers. The term is misleading, and is only a survival of the name applied to one of the earliest types of power hammer now almost obsolete. Power hammers are built in a variety of different styles, each of which is designed with reference to its adaptability to certain kinds of work that may be done by them somewhat more economically than by the other types.



Machinery,N.Y.

Fig. 9. Adjustable Lower Die for Drawing and Finishing Tapers

The types of power hammer best adapted for general forge work are those with the ram running in guides. This arrangement insures their striking a square blow upon any size of material within their capacity. They require less adjusting than most of the other types, and their utility is such that they can be advantageously used for any operation in the making of light forgings with the exception of upsetting.

The helve hammer is extensively used for the making of any kind of light forging that can be done in open dies such

as round work, edged tools, cutlery and springs. On this type of hammer the head is mounted on the end of a wooden beam which is cushioned both on the upward and downward stroke either by blocks of rubber or springs, making the blows, which can be delivered with great rapidity, very elastic. These hammers, however, are poorly adapted for general forge work because the head is raised and returned upon a radius which makes adjustment for each size of material necessary. If not properly adjusted, the side of the work nearest to the fulcrum will be drawn thinner than the side away from it. Generally the arrangement of dies in helve hammers as they are supplied by the manufacturer are as shown in Fig. 11, the rounded ends being toward the fulcrum. This is all that is necessary when the hammer is to be used exclusively for the drawing of stock to smaller dimensions, but for general forging they should be reversed as it is often necessary to spread stock to greater width, which can only be done to advantage when the rounded ends of the dies are accessible. The dies could be used equally well for all the purposes for which helve hammers are generally used if placed cross ways in the head and anvil.

When floor space is an item of importance, the upright power hammer, of which there are various styles, is more compactly built, equally as efficient, and can be installed and manipulated in less space than most of the other types.

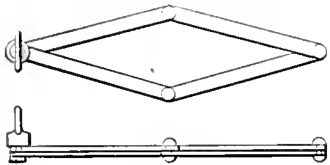


Fig. 10

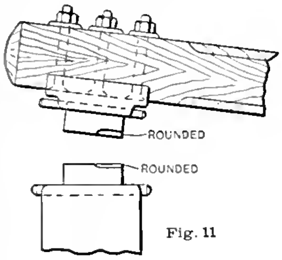

Fig. 11

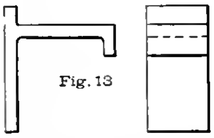

Fig. 13

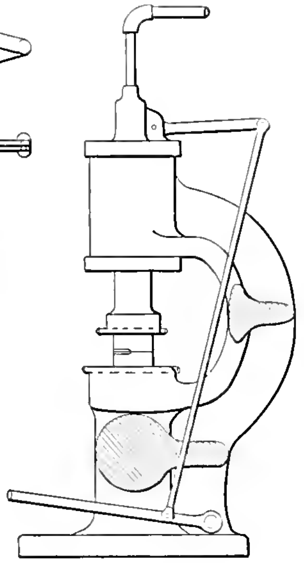

Fig. 12

Machinery, N.Y.

Fig. 10. Gage for Setting Adjustable Die to any angle. Fig. 11. Common, but Objectionable, Way of Placing Dies in Helve Hammer. Fig. 12. General Appearance of Pneumatic Hammer for Light Forging. Fig. 13. Piece that can be forged to Advantage in the Forging Machine

Lately marked attention has been given to the development of pneumatic or compressed air hammers, which without doubt is a step towards progress. Pneumatic tools have proved their efficiency and utility in other branches of manufacturing, and there is no apparent reason why they cannot be advantageously used in forge shops, providing they are designed and constructed for that class of work. Compressed air is quite often used for the operation of ordinary steam hammers and has proved to be a very efficient substitute; but when it is possible to operate a hammer by steam direct, it can be done as effectually, and at less cost, than would be the case indirectly through an air compressor.

With the modern pneumatic hammer it is an entirely different case, as it is built self-contained with air compressor attached, and can be operated either by belt power or an attached motor, the advantage of which needs little explanation. No piping to speak of is required, power is used only while the hammer is being operated, and its utility for work within its capacity combines most of the advantages of steam and belt driven hammers.

There is another type of pneumatic hammer that so far has not received much thought or attention, but which has proved itself to be a valuable addition to the equipment of forge shops where it has been tried. The working parts are constructed upon the same principle as the hand pneumatic hammer used for chipping, and is simply larger and mounted upon a frame in the shape of a G clamp supported by a column and base as shown in Fig. 12. Hammers of this type are so compact that they can be installed and operated in about half the space required for any other type of hammer of the same capacity. They can be used for the very lightest of forge work and the exhaust from the cylinder can be utilized to keep the dies free from scale, which is important when smooth, clean forging is essential.

For making duplicate forgings in large quantities, there is no forging appliance that is so extensively used as drop hammers. As the term implies, the heads of drop hammers are raised to sufficient height for the required blow, released and allowed to fall on the work being forged, after the principle of pile drivers. There are various methods of raising the heads of this class of hammers. The most common for forge work is by friction. A hardwood board is attached to the hammer head and passed between two rolls which rotate in opposite directions on the top of upright guides. These rolls are rendered operative by a mechanism controlled by the foot of the operator. When the head has been raised to sufficient height, a projection on the head engages a dog which releases the board from the rolls and allows the head to drop upon the work. Blows may be struck automatically or their force can be regulated at the will of the operator. Drop hammers are designated by their falling weight and are built in all sizes up to 3,000 pounds, which is the limit at which a friction drop can be successfully operated.

Duplicate forgings larger and heavier than can be economically made by drop hammers are either made by steam drops, which are practically steam hammers designed for the making of forgings in dies. Hydraulic presses may also be used.

The only disadvantage in using hammers of the kind mentioned is that the dies used in connection with them must necessarily be made with from 3 to 5 degrees of draw in the impressions to allow of easy removal of the forgings after each blow is struck; otherwise scale would accumulate in the impressions and be worked into the surface of the pieces being made. Hot material left for any length of time in dies has also a tendency to soften them. It is therefore obvious that forgings of a shape other than round or oval cannot be made perfectly parallel on all sides except by more than one forging operation.

In the making of duplicate forgings such as are used on cars, wagons, agricultural implements, etc., where smooth surfaces are not so essential as shape, strength, and level bearings, there is no forging appliance that can be used to greater advantage than the modern forging machine. Take, for example, a forging of the shape shown in Fig. 13; it is plain, and looks as if it should not be difficult to make. This however, is just the kind of work for which the drop forging process falls short. By being roughly bent to shape it can, however, be forged complete at one stroke of a forging machine.

The bulldozer is also worthy of attention although it can not be used to advantage for work other than bending. In the modern forge shop it is indispensable for that work alone, as there is no bending job, however complicated, that can not be done by it with properly constructed fixtures.

If an equal amount of thought, ingenuity and skill were devoted to the improvement of forging appliances and methods of working hot iron and steel, that has been given to the manufacture and finishing processes in the machine shop, it would be just as easy for the blacksmith to make light forgings within 1/16 inch, medium weight within 1/8 inch, and heavy pieces from 3/16 inch to 1/4 inch of finished size, as it is to turn out the shapeless pieces that must be hogged to shape by high-speed tools in the machine shop, where the part of the material that has been refined by hammering is removed, leaving the soft core for the finished product, at a cost out of all comparison with a good clean forging.

* * *

The making of flying machines is rapidly becoming a commercial proposition. The French company which has bought the French patent rights for the Wright brothers' aeroplane has, according to *Industritidningen Norden*, so far contracted for the building of more than 25 flying machines.

COIN AND MEDAL DIES

CHESTER L. LUCAS*

Chester L. Lucas†

The making of dies for coins, medals, trade checks, etc., is a branch of the die-making trade apart from the general run of work. The conditions to be met are peculiar to themselves, and even in making dies for jewelry work more latitude is given, both in measurement and design, than is allowed in the best of medal work.

The steel used in this class of work is necessarily of the very best, as steel that would give satisfaction when made into dies for other work is often inadequate to stand the enormous pressure to which coining dies are subjected while in use. Different die-makers prefer different makes of steel for this class of work, and the best steel obtainable is none too good for coin and medal dies. Personally, the writer prefers Jessops' steel for these dies, on account of its uniformity and the fact that dies made from this steel can be hardened to a greater depth than is possible with other steels. Another point in favor of Jessops' steel is that it will not crack as easily if overheated during the hardening process; in other words, it will stand more abuse.

In making a set of coining dies for use either in the regular type of coining press or in the drop press, the first part to be considered is the ring shown in cross section in Figs. 1 and 2. The object of this ring is to confine the metal blank while being embossed between the top and bottom dies. The tendency is for the metal to squeeze out sideways from between the two dies when the blow is struck; but as this ring, which is a close fit around the dies, confines the metal to the space between the dies, it is obvious that if sufficient pressure is applied, the metal must fill every impression in the dies, as it can go nowhere else. In making the ring to be used in a coining press, which is the modern machine for producing coins, the outside diameter is turned to fit the steel ring holder of the press, usually from three to four inches, according to the size of the press. For independent use in the drop press, the stronger this ring is made the better. A good rule is to have its diameter at least four times the diameter of the coin, and its thickness equal to the coin's diameter; thus, a coin one and one-half inch in diameter will require (when used in a drop press) a ring six inches in diameter and one and one-half inch thick. The hole in this ring gages the size of the coin, and should be ground and lapped to a mirror finish after the ring has been hardened and drawn to a dark straw color.

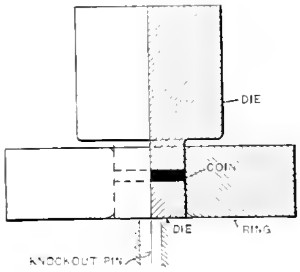

Fig. 1. Coining Dies and Ring for Coining Press

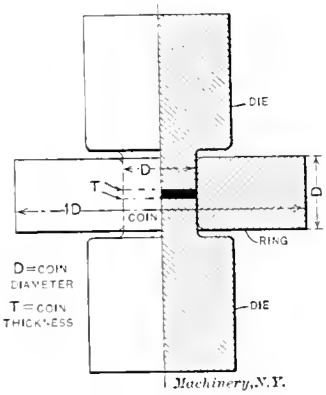
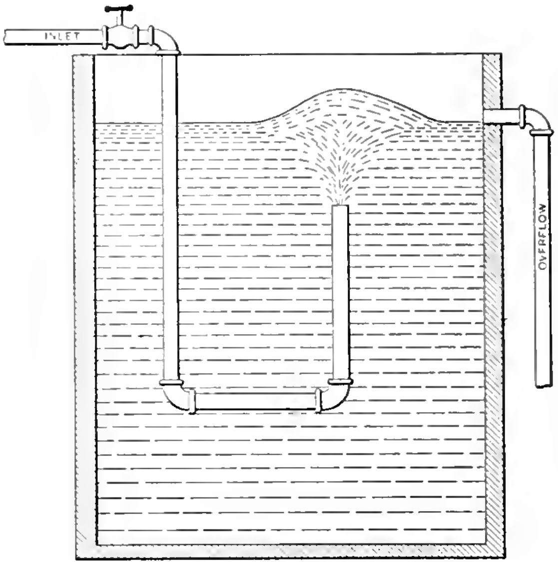


Machinery,N.Y.

Fig. 2. Coining Dies and Ring for Use in Drop Press

The next step is the turning of the die blanks. Fig. 1 shows a pair of dies and a ring for coining press use. In turning this pair of dies it is best and quickest to make the two dies in one piece and then, with the cutting-off tool, cut off that part to be used for the lower die, which as the illustration shows is simply a small piece of steel the same diameter as the coin and about half as thick as the coin's diameter. Every coining press is fitted with a knockout which automatically raises this lower die at the end of each stroke of the press, thus ejecting the coin and leaving the dies free to receive another blank.

Fig. 2 shows a pair of dies and ring for use independently in the drop press. The drop press is not an economical machine for making coins or medals, but is many times used in shops where there is no coining press or where the coin is too large to be struck in the coining press with which the shop is equipped. The process of striking up coins with the drop press is slow, because after each coin is struck, the ring must be taken from the lower die (on which it rests during the striking) and the coin driven out with block and mallet. While this method seems crude, the work is equal in quality to coining-press work, and it often helps a small shop to "get by" on jobs which it otherwise could not do.



Machinery,N.Y.

Fig. 3. Hardening Tank for Coining Dies

When finishing the faces of the die blanks, all borders, plain or knurled, and rings or circular panels should be turned before removing the blank from the lathe. The finished dies should be a sliding fit in the ring. The blank dies are now ready to be lettered and engraved with any required designs. After laying out the lettering on a piece of lead or cardboard to make sure of the way it is going to appear on the die, it is stamped into the steel die blanks with die-letters. Die-letters differ from ordinary stamping letters in that they are made reverse; and great care is exercised in the making to have each one as nearly perfect as can be made regarding size and shape. It is obvious that with good die-letters and careful stamping, taking pains to have the letters properly spaced and of even depth, the results will be satisfactory.

After all lettering has been stamped into the die and the roughness caused by stamping removed, the dies are ready for the engraving of any design that it is necessary to reproduce on the finished medal. When the design is very deep, most of the steel may be removed by hammer and chisel and only the finishing done with rifflers, gravers, etc. It is, however, best to avoid deep designs whenever possible, for they are very hard to strike up. If it is absolutely necessary to employ such designs, they should be placed on a sunken panel, as was the figure on the religious medal next to the "Eric Pape" medal in the center of the half-tone illustration, Fig. 4. At this stage of the die-making, the dies may be placed in the press and a lead impression taken to make sure that they are perfect in every detail before hardening.

In hardening these dies, or any dies which must withstand heavy pressure, the essential point is to cool the face of the die as rapidly as possible after the proper heat has been attained. For this purpose it is advisable to have a strong

* Address: Saugus Station, Lynn, Mass.

† Chester L. Lucas was born in Middleboro, Mass., 1881, and received a high school education. He served a three-year apprenticeship with Schwerdtle & Siebert, Bridgeport, Conn., and has since worked for John Robbins Mfg. Co., Boston, Mass., and General Electric Co., Lynn, Mass., as tool-maker and working foreman. His specialty is die and tool work and die-sinking. Mr. Lucas has had some experience in teaching classes of boys in industrial work.

jet of cold water run into the hardening tank in the manner illustrated in Fig. 3. If properly arranged, the water should come up like a geyser, and into this bubbling mound of water the red-hot die should be plunged, face down. After the first few minutes the face of the die will be glass-hard and the back end may be cooled more slowly so as to lessen the danger of cracking. In the case of the small lower die for coining press use, however, it is necessary to harden it all over; otherwise it would spread out when used and stick in the ring. As soon after hardening as possible, the temper should be drawn to a light straw color.

The matter of hardening coining dies is an important factor of the work, for the heavy pressure which they receive would quickly "dish" any die not hard enough, or crack any die that has been overheated or left too hard. To give an idea of the great amount of pressure exerted in embossing United States currency, the following table, which appeared in MACHINERY, October, 1905, is given. The comparative coining properties of gold, silver, and nickel will be noticed by observing that the gold half eagle, silver quarter, and nickel five-cent piece require the same pressure of 60 tons, though the sizes and weights differ greatly:

Double eagle, gold	155 tons
Eagle, gold	110 tons
Half eagle, gold	60 tons
Quarter eagle, gold	35 tons
Standard dollar, silver	160 tons
Half dollar, silver	98 tons
Quarter dollar, silver	60 tons
Dime, silver	35 tons
Five cents, nickel	60 tons
One cent, copper	40 tons

Much of the pleasing effect of a good coin or medal is due to the polished or matt surface, as the case may be, which is given to it by the dies. The contrast between a polished background and a matt or frosted panel is very effective. The glossy finish is given to the dies by means of stoning and polishing with crocus in the lathe. The frosted or matt finish is given by first polishing and then applying nitric acid for a few minutes.

Some designs, especially human heads or figures, are more easily engraved on a hub, which is afterwards hardened and struck into a piece of steel a little larger in diameter than the die to be made. When this impression has been struck deeply enough the piece of steel is held in the lathe chuck, and after centering up the impression, the die is turned in the usual way. An example of the results of this process is the Lincoln medal shown in Fig. 4. The keystone on the Masonic medal with its sunken letters was done in the same way, for the sunken letters were, of course, raised in the die and could not have been produced in any other manner. The hubbing process is also used when duplicate dies are to be made, as it is not only quicker, but each successive die is an absolute fac-simile of the original, and for this reason this process is extensively used in the government mints for making dies for currency.

Fig. 4. A Collection of Coins and Medals struck in the Coining Press and Drop Press

The sheet metal stock from which blanks for coins are cut must be kept free from scratches and other defacing marks, and after cutting, the blanks should be annealed and dipped. The coins and medals in Fig. 4 were made of copper, brass and aluminum, and all were embossed in coining presses with the exception of the central medal, which was struck in a very heavy drop press.

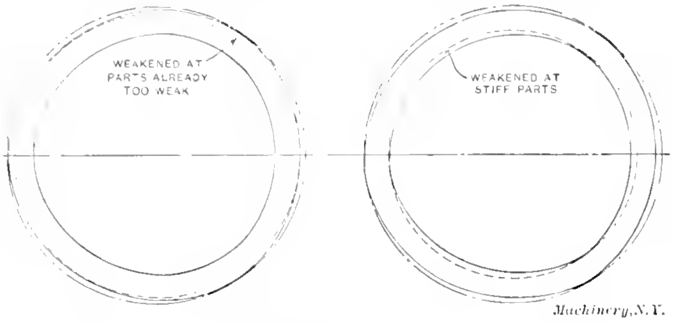
Manufacturers in the United States and Europe appear to have a just cause for grievance in regard to the Argentine law of trade-marks. According to this law, anyone who first registers a trade-mark in the Argentine Republic becomes the lawful owner of the same, in spite of the fact that the foreign importer may be the sole owner of the mark in all other countries, and that his goods may be known everywhere by that particular trade-mark. In some cases it has been necessary for the foreign importer to purchase the right of his own mark from unscrupulous individuals who have secured the registration for the purpose of extortion.

THE MANUFACTURE OF PISTON RINGS*

JAMES McINTOSH†

While a great many other details of gas engines for automobiles have been standardized, there are hardly any standard dimensions or methods for making piston rings. Some makers prefer wide rings and some narrow, some favor an eccentric ring and others a concentric, some prefer the stepped joint and some the diagonal slot, etc. Cast iron, however, may be considered as the standard material for piston rings, but there are many kinds of cast iron. A suitable grade of cast iron for piston rings should be as hard as is consistent with the machining of the rings, in order to give the maximum wear, and the ring metal must have sufficient spring. To get uniform results, great care should be taken from the start. A good metal pattern should be used and a minimum amount of stock allowed for finishing. The castings should be machine molded, as they will then be more uniform. When too much stock must be removed, the best part of the casting is removed, and the resulting ring will have a short life.



Figs. 1 and 2. Illustration of Result of Grinding Piston Rings on the Outside and on the Inside

When machining, the ring blank can be rigidly held in a chuck by a flange cast on one end, which is somewhat larger in diameter than the blank proper. This flange need not be more than one-half inch thick; the edge should be tapered so that the chuck jaws will tend to draw the blank against the chuck. The ring may be further stiffened by the addition of an inside flange somewhat wider than the outside, so that considerable pressure can be applied without distorting the blank. To prevent the blank from turning in the chuck, a stop may be cast on the edge of the flange which bears against the chuck jaw. If the rings are to be made in quantities, a very suitable tool for the machining is the Gridley automatic turret lathe. This machine can be arranged to turn, bore, and cut off the rings whether they be concentric or eccentric. The lead and timing of the cutting off tools may be such that the cutting off of the rings begins before the blank is completely turned and bored. Blanks five to seven inches long may be used successfully by this method.

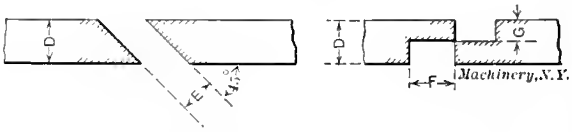
To avoid trouble due to the fact that the rings lack the proper amount of spring, it is well to test the material after the first operation has been performed. A simple test is to have a taper block with a stop on it, and then cut a few of the rings from each cast and spring them over the block, so that the amount of spring will be slightly in excess of that required when the ring is mounted on the piston. The opening at the joint in the ring before and after the test is noted to see that it is not in excess of the limits allowed for different kinds and sizes of piston rings. If the rings stand this test, it is safe to assume that all the rings in the same lot will be satisfactory when finished; but there is no reason why all the rings should not be tested in a similar manner when completed.

The second operation is the finishing of the sides of the rings to a standard width. This can be best done by the use of a magnetic chuck. The Heald ring grinder will be satisfactory for this work; it is regularly fitted with a magnetic chuck and has a micrometer feed to gage the width of the rings. The next operation is the cutting of the slot at the joint of the rings. This can be done on a hand miller with a suitable fixture. There is some difference of opinion as regards the proper form of joints; some prefer the stepped joint, while others favor the diagonal slot. The stepped joint is more expensive to make and more difficult to fit and it is more easily broken than the diagonal joint. If the joint is open, say one-sixteenth inch, when made according to either system, the area for leakage is approximately the same; in one case the gas may have a straight flow, and in the other it must pass around under the ring to get by the joint. The writer personally prefers the diagonal joint.

The next operation is the finishing of the outside of the ring. Great care should be exercised in order to obtain good results with the larger sizes. These are usually closed with a suitable band, clamped between two surfaces, one at a time, and a light cut taken off the outside; but this method is rather slow in automobile building. The usual method in this manufacture is to have a suitable arbor and sleeve, the arbor being built up with a spindle having a fixed collar at one end, and an adjustable one at the other end. The latter should be fitted with a key or pin to keep the collar from turning while tightening the nut, otherwise the rings will be distorted. The collars should be made so that the diameter of the inner edge equals the diameter the ring is to be ground to, and the outer edge the diameter of the sleeve, so that the rings may be readily centered on the arbor, care being taken to see that the large diameter of the collar is far enough from the inside so that the grinding wheel can pass over the rings without touching the large diameter. The collars should be hardened and ground, so that the edge will keep its shape and hold the ring better.

A suitable sleeve is best made of cast iron. The sleeve may be light, but should have a band cast on each end to keep it in shape, and should be provided with a lug with clamp screws at each end. The sleeve is more easily removed when it is split and then clamped by the lug screws. The hole in the sleeve is bored to fit the large diameter of the collars on the arbor.

PISTON RING DIMENSIONS



A = amount piston ring is larger than the cylinder
B = thickness of piston ring at heavy side
C = thickness of piston ring at light side
D = width of piston ring
E = width of cutter for 45 deg. diagonal opening in ring joint
F = width of cutter for stepped opening in ring joint
G = depth of joint step

Cylinder Diameters.				A	B	C	D	E	F	G
8	$7\frac{3}{4}$	$7\frac{1}{2}$	$7\frac{1}{4}$	$\frac{7}{32}$	$\frac{1}{4}$	$\frac{9}{64}$	$\frac{9}{16}$	$\frac{15}{32}$	$\frac{11}{16}$	$\frac{9}{32}$
7	$6\frac{3}{4}$	$6\frac{1}{2}$	$6\frac{1}{4}$	$\frac{3}{16}$	$\frac{7}{32}$	$\frac{1}{8}$	$\frac{1}{2}$	$\frac{13}{32}$	$\frac{19}{32}$	$\frac{1}{4}$
6	$5\frac{3}{4}$	$5\frac{1}{2}$	$5\frac{1}{4}$	$\frac{5}{32}$	$\frac{3}{16}$	$\frac{7}{64}$	$\frac{3}{8}$	$\frac{11}{32}$	$\frac{1}{2}$	$\frac{3}{16}$
5	$4\frac{3}{4}$	$4\frac{1}{2}$	$4\frac{1}{4}$	$\frac{1}{8}$	$\frac{5}{32}$	$\frac{3}{32}$	$\frac{5}{16}$	$\frac{9}{32}$	$\frac{13}{32}$	$\frac{5}{32}$
4	$3\frac{3}{4}$	$3\frac{1}{2}$	$3\frac{1}{4}$	$\frac{3}{32}$	$\frac{1}{8}$	$\frac{5}{64}$	$\frac{7}{32}$	$\frac{7}{32}$	$\frac{5}{16}$	$\frac{7}{64}$

There is one question of marked importance when using this method. Assume that the rings are too large in diameter. Then, when slotted, the circumference of the ring when closed is greater than that of the sleeve inside, causing the joint to crowd. Again, if the ring be too short, or open at the joint, the ring will touch on three or more points, and the irregularities which the grinding is supposed to correct will be increased, and the ring may be worse than before grinding. The writer would recommend that if a joint is desired with least amount of end clearance, the ring be ground a certain fixed amount open and that allowance for that amount is made on the diameter when grinding.

To correct irregularities on the outside diameter of the piston ring, by either turning or grinding on the outside is incorrect. Assume, for example, that a ring shows high spots when put in a cylinder. The high spots are due to excessive bending at those points, and the low spots to stiffness, which prevents the ring from conforming to the bore, or, in other

---

* For previous articles on piston ring manufacture, see Finishing Fly Wheels, Hoist Drums and Piston Rings on the Libby Turret Lathe, July, 1908; Making Piston Rings, May, 1908, and Finishing Pistons and Piston Rings on the Gisholt Turret Lathe, March, 1908.

† Address: 3525 East 72d St., S.E., Cleveland, Ohio.

words, the stiff parts do not touch the bore. We cannot, therefore, correct the high spots, which are weak, by removing more stock from these points by grinding on the outside, but if we reverse the method and grind on the inside, then the irregularities on the outside will be corrected. The high spots on the outside cause the part opposite on the inside to be further from the center of the arbor or sleeve, and the low spots on the outside will be nearer the center, and when grinding on the inside, these will be the first points to be touched by the wheel. When grinding, these stiff portions will become weaker and tend to bend more, and by leaving the weak spots alone the stresses in the ring will be equalized and there will be a uniform bending all around. This is illustrated in Figs. 1 and 2. Fig. 1 shows the effect of grinding a piston ring, when out of true, on the outside. Dash-dotted line shows true bore of cylinder; full line, piston ring out of round; and dotted line piston ring ground on the outside. Note how the weak parts of the ring have been made still thinner by grinding. Fig. 2 shows the effect of grinding a piston ring, when out of true, on the inside. Note how grinding weakens the ring at the stiff points, thereby equalizing the stresses and making the ring spring out at these points and bear evenly all around, as mentioned.

The accompanying table gives piston ring dimensions based on the writer's experience, and conforming to good average practice. The dimensions are so arranged that the same general sizes will suit four different ring diameters so that the tools and gages required are reduced to five sets to take care of twenty cylinder diameters. The width *D* of the piston ring may, of course, be increased with a corresponding increase in wearing surface, but the dimensions given give satisfactory results. The inside of the ring should always be machined, because if the casting surface is not machined, irregularities in the casting will prove a source of trouble. The practice of annealing cast iron ring blanks does not seem desirable to the writer, as internal stresses due to cooling in a mold are rather remote with a ring blank of uniform thickness.

UNIQUE CALCULATING DEVICE

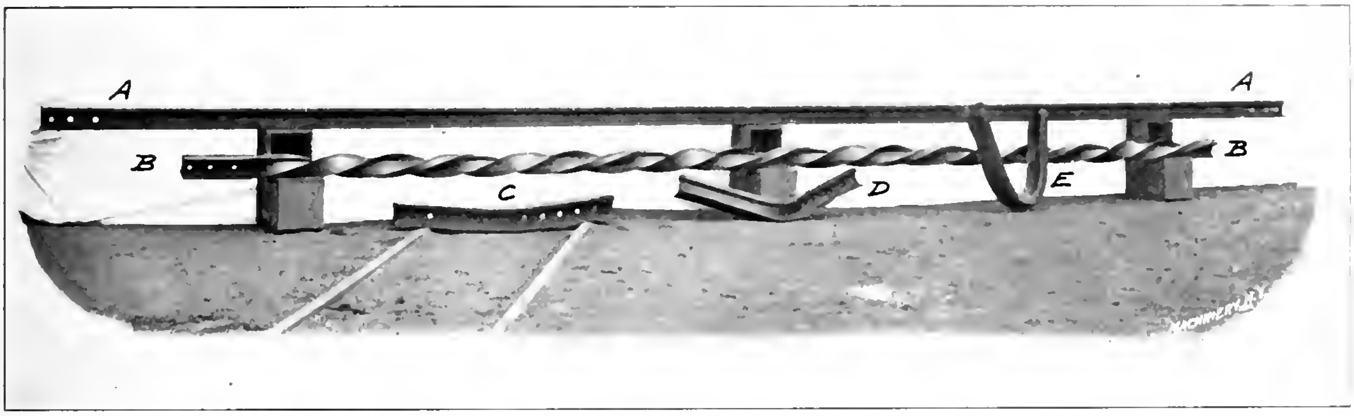
An interesting calculating table with some rather novel and unique features (*Graphische Rechentafel*) has been brought out by the Rechen-Apparate-Fabrik Fr. Schneider, Munich, Germany. The device consists of two tables with logarithmic scales printed on celluloid. The upper table or scale is made of thoroughly transparent material, so that the figures and graduations on the scale below can be read as clearly with the upper table in place as with it removed. The arrangement permits of much closer readings than are possible on the ordinary slide rule, due to the fact that the total length of the logarithmic scale on the lower table in the device is 110 inches. The method of graduating also differs to some extent from that of the ordinary slide rule, and it is possible by means of the device to multiply three factors at one setting as well as to carry out two divisions at once. This feature of being able to multiply three numbers at once is unique, and the only drawback of the instrument is that it is somewhat difficult to work the upper scale on the lower, there being no other guiding means than that of the hand of the operator. Were it possible to provide the instrument with quickly operated slides in two directions, the device would be a most convenient and accurate slide rule.

* * *

REMARKABLE PHYSICAL CHARACTERISTICS OF ROLLED MANGANESE STEEL RAILS

The Pennsylvania Steel Co. showed, at the recent convention of American Engineering and Maintenance of Way Association at Chicago, Ill., a remarkable exhibit of rolled steel rails, which had been bent and twisted to a degree almost unbelievable, considering the excellent condition of the pieces, after the tests. These rails differ from the manganese rails heretofore used, in that they are rolled instead of being cast. The rolled product is given a trade name of "Manard." The company succeeded in producing rolled manganese steel after several years of experiments, as the difficulties of rolling so peculiar a material on a commercial scale were hard to overcome. This steel has much the same red-hardness characteristic at the proper rolling temperature as high-speed steel. Ordinary rail mills are not applicable for the work, special designs of rolls and special rolling methods being necessary to achieve successful results; and the machinery is of extraordinary power and strength.

The rolled rails are much superior to the cast rails, and what this means may be inferred when it is known that the experience of the Boston Elevated Railway Co. shows that the ordinary cast manganese steel rails used by that company had a life fifty times that of the ordinary Bessemer rails on curves and in other difficult situations. The rolled rails show a uniform structure throughout when fractured, whereas the cast rails have a spongy head and coarse grain. Test bars forged from the head give a tensile strength of 150,000 pounds to 159,000 pounds per square inch, with 50 to 60 per cent elongation in 8 inches.



Rolled Manganese Steel Rails subjected to Twisting and Bending Tests

In the illustration showing rolled Manard manganese rails, *A* is a 100-pound 33-foot rail of the 1909 Pennsylvania Railroad standard section; *B* is an 85-pound rail American Society of Civil Engineers standard section twisted cold until six twists remained as a permanent set in 26-foot length; *C* is an American Society of Civil Engineers standard section with ten 1 1/16-inch holes in the web, bent on the drop testing machine. The total work done represents a dynamic force of about 45,000 foot-pounds, and the rail showed no signs of failure after the bending. *D* is a 100-pound A. S. of C. E. standard section bent on a drop testing machine, the work done representing a dynamic force equal to 150,000 foot-pounds. *E* is a 90-pound A. S. of C. E. standard section bent on a drop testing machine and later bent into a U shape under the hammer. All of this bending, of course, was done cold.

The manganese rolled rails cannot be machined with ordinary appliances, but are readily bent to any desired curve with ordinary trackmen's curving tools. They are not magnetic, and the electrical resistance is about 3.4 times that of the ordinary Bessemer steel rails of the same section. The increased resistance, however, does not interfere with track signals in which the track forms part of the circuit.

THREE-FLUTED DRILLS

R S F

Three-fluted reaming drills have been manufactured for a long time by the tool makers of this country. Their common name is "three-fluted drill," and they are so termed in the various catalogues advertising them. The catalogues also note, generally in small type, that these drills will not drill the initial hole. Therefore extensive users have annexed the word "reaming," calling them "three-fluted reaming drills," which impresses upon the workman at once the purpose of the tool. The use of the tool to which the writer desires to draw particular attention is in structural steel work. Therefore, in order to more fully appreciate the class of material on which the tool is used, the reader should be acquainted with some of its irregularities. For instance, the so-called structural steel, such as shapes, plates, bars, etc., in most specifications call for 55,000 to 60,000 pounds tensile strength per square inch with 25 per cent elongation, and it is not only an occasional, but an everyday occurrence, for bars to test as low as 40,000, and as high as 90,000 pounds per square inch tensile strength, with elongations of only 15 per cent and as much as 40 per cent. In fact, in plain words, some material is as soft as iron and some as hard as tool steel.

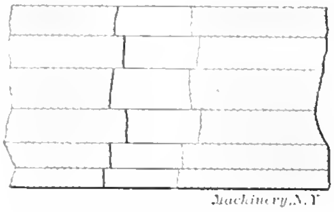


Fig. 1. Several Thicknesses of Structural Steel with Punched Holes, which the Reamer Drill "lines up"

The specifications also state that all material 5/8 inch thick and above shall be sub-punched 3/16 inch smaller in diameter than the finished hole and reamed to size. Material under 5/8 inch thick is punched full size, and when assembled, this work is easily reamed by the ordinary taper bridge reamer, as there is no material to remove, it merely being necessary to "straighten up the hole" produced by irregular punching.

On the other hand, the sub-punched work (as it is termed in structural shops) is built-up girders, chords, etc., and their thickness varies according to the number of plates, angles, etc., used, being generally from 2½ to 6½ or 7 inches thick, very few being much heavier. When assembled, the punched holes rarely "line up," but usually present an appearance similar to that in Fig. 1. A glance will show that the drill has difficulty in cutting its way through, though very few cases occur where the holes are not "trued up" or nearly so. The average number of reamed inches for high-speed drills for a year's run on this class of work with unskilled labor is 7,500 per drill, breakage being the cause of 75 per cent of the loss on account of the difficulties mentioned.

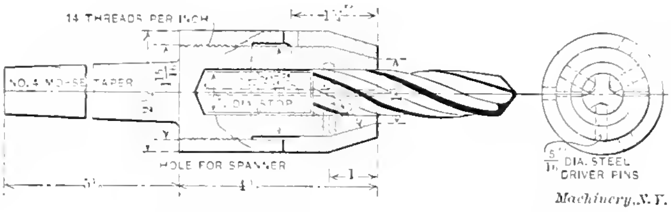

Fig. 2. Chuck for Holding Drills with Broken-off Shanks

The reader should not draw the conclusion at this point that faulty workmanship causes all bad punching; in some cases it does, but a large part is attributed to stretch in material. It is necessary to use the same templet on various thicknesses of material, and as each thickness has a corresponding amount of stretch, the drill must straighten up all inaccuracies.

The three-fluted reaming drills, when made of carbon steel, are practically useless in these days of "speed," the average life of a drill being less than 1,000 reamed inches. A chuck, as shown in Fig. 2, is well adapted for using drills after their shanks are broken off, in cases where the thickness of material will allow the use of a short drill.

The foregoing will give the reader a good idea why the high speed three-fluted reaming drill has been adopted, and the following costs of manufacture, compared with the best price for which they can be bought, will explain why some users make their own drills.

COST OF 15-16-INCH THREE-FLUTED REAMING DRILL

	Morse Taper Shank, Over-all Length, 12 inches		Graham Shank, Over-all Length, 10 inches
Turning	$0.18		$0.09
Fluting	0.063		0.063
Milling Tang	0.008	Groove Milling	0.012
Grinding	0.043		0.043
Total shop cost	$0.294		$0.208
Proportion of gen. shop expenses	0.277		0.182
	0.571		0.390
Hardening	0.065		0.065
Material	1.764		1.50
Total cost	$2.40		$1.955

Two inches less material is required for the Graham shank than the Morse taper shank, when both drills have standard length of flute.

The best price known to the writer, previous to the late business depression, for a 15/16 inch drill was $3.90 net. This has been reduced to about $3.15 within the past few months, still leaving a large saving for the user. The above costs are not caused by any special machinery whatever, with the exception of a device fitted to the table of a No. 4 Cincinnati universal milling machine for fluting and backing off.

The accompanying half-tone illustrations illustrate twelve milling cutters on one arbor, six fluting and six backing off. They are placed in pairs, with a separating bushing between, thereby milling six drills at one time. The cutters are all made of high-speed steel and are kept cool by numerous streams of oil supplied by a 1-inch Gould's rotary pump. It requires two 1-inch flexible steel hose to carry the used oil back to the pump. A feed of 0.016 inch per revolution is used. The shape of the cutters for milling a 7½-inch lead, with the table set at 27 degrees, and a half section of the finished 15/16 inch drill is shown in Fig. 3. As all are formed cutters, there are no variations in the flutes caused by the re-grinding. The depth of the backed-off part will be noticed. It is so milled that after hardening, the grinding is a simple operation, the drills being only ground to their exact size with a taper of 0.010 inch in six inches, the size decreasing toward the shank.

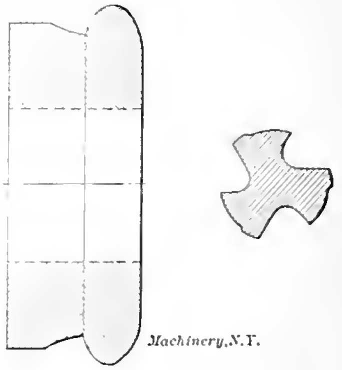

Fig. 3. Fluting Cutter and Section of 15-16-inch Reamer-drill

Ordinary methods of hardening have proved superior to all the fancy ones; the fluted part is heated to a bright yellow and permitted to cool in the open air, laid horizontally upon two suspended ½-inch thick square rods, thereby allowing the air to come in contact with all sides. Some makers claim success by cooling in air blast, then drawing in oil, and various other methods; but after having used all the principal makes, the writer has found the above mentioned method superior to them all, especially when performed in the winter months.

Evidence to substantiate the above statement has been acquired from tests made on a large number of various kinds of drills of different brands of high-speed steel. A recent prolonged test proved that drills made of "Blue Chip" steel by the above method out-class all other brands and even excel drills made of the same steel by a certain manufacturer of high-speed steel and small tools.

These tests serve to bring out another phase of the subject, namely: that the best cutting high-speed steel, that is, one that will carry off the greatest amount of heat, does not make the best drills. For example, "Novo" steel will stand a higher speed than any brand known to the writer, but when it is subjected to shocks, such as a twist drill is likely to receive, it generally breaks, and the drill is ruined. Only recently 1 9/16 and 1 7/8 inch diameter drills given to the

writer were split the entire length and yet showed no trace whatever of flaw or crack in the steel.

The "Blue Chip" steel drills are much tougher, and successfully accomplish a very large percentage of the work just described. A 15/16 inch diameter three-flute reaming drill made of this steel has made a record with us of 28,000 reamed inches, only 1½ inch of the drill being used up. Frequently these drills have been twisted a half turn backward in the flutes without breaking. The steel, in its annealed state, is easily worked, a reduction of only about 15 per cent of the speed of machine tools being required below that used on good carbon steel. It straightens easily either in the bar or drill length.

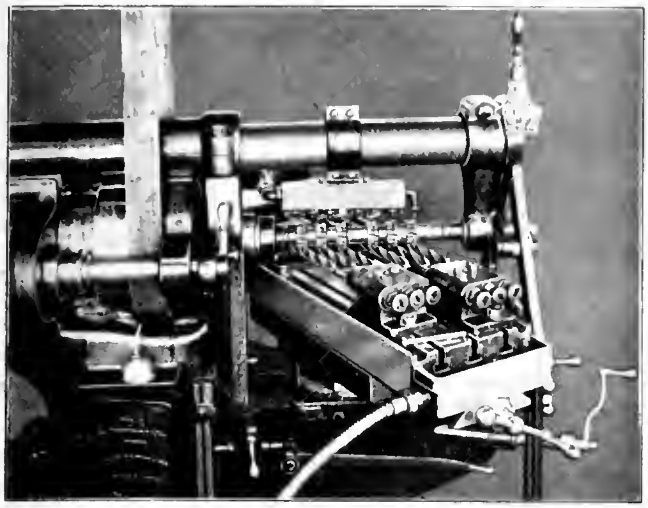

Fig. 4. Fluting and Relieving Six Drills simultaneously

A Warner & Swasey two-inch turret lathe is used for turning, and a maximum cutting speed cannot be obtained for one reason, viz.: the heat generated by the length of the bar against the back-rest is so great that the bar burns fast to the back-rest, despite the continuous flow of oil on that part, therefore the necessity for reducing speed. The roller back rest was brought out to overcome this difficulty, but it does not, for two reasons: First, the rake for the tool recommended by the makers turns a chip like a ribbon and this ribbon-like chip becomes tangled in the turret and among the other tools and thus is a great nuisance and time-consumer. Second, a tool ground to cut an ordinary curled chip works satisfactorily, except that the rollers pull the chips in between themselves and the work, resulting in numerous "digs" in the length of the cut. The Cincinnati No. 4 universal milling machine for fluting the drills works excellently, though taxed to its limit with twelve cutters working simultaneously. A Brown & Sharpe universal grinder, which has an automatic reversing feed, is used for grinding. This machine enables the operator to produce a large quantity of duplicate work at a low labor cost.

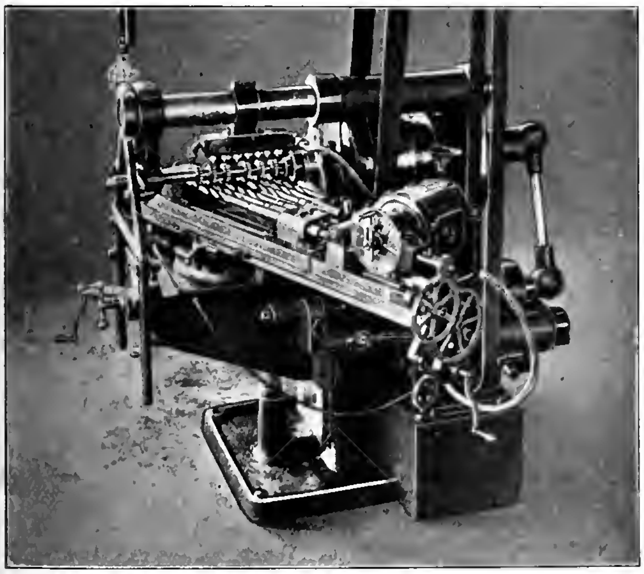

Fig. 5. Multiple Indexing Head used when Fluting and Relieving Drills

BEARING FOR HIGH-SPEED SHAFTS

In bearings for rapidly-rotating shafts such as are employed in steam turbines, high-speed engines, etc., the surface of the bearing structure is often not of sufficient extent to keep the bearing cool by the radiation therefrom of the heat generated by the friction of the bearing surfaces. In order to maintain the temperature of the bearing within safe and proper limits, cooling mediums are circulated over the radiating surfaces to absorb and remove the heat. A method of cooling such bearings by circulating the lubricant for the bearing surfaces through the body of the bearing was illustrated and described in a recent issue of the *Mechanical Engineer*. This bearing, which is the invention of the Vereinigte Dampfturbinen-Gesellschaft mit Beschränkter Haftung, of Friedrich Karl-Ufer 2—4, Berlin, results, it is claimed, in the effective control of the temperature and is attended with many other incidental advantages.

The shaft *A* rotates in a shell *B* which is supported by a seat *C* formed in the bearing frame *D*, and a cap *E* which is secured to the frame and holds the shell in place. The seat *C* is circular in cross-section, and the outer surface of the shell is of similar shape. The shell *B* is made in two parts by dividing it in a horizontal plane extending through the axis of the shaft, and it is provided with a number of external flanges *F* which support it on the seat *C* and assist in the radiation of of the heat imparted to the relatively thin body portion *G* of the shell by the friction between the shaft and its bearing surface. The outer edges of the circular flanges are in contact with the surface of the seat, thus forming a conduit between the flanges and the surface. By suitably arranging the flanges, this channel or conduit is made to follow a winding or tortuous path through or over the shell. The outline of this path may be that of a helix, or it may have a zig-zag shape or the form shown in the illustration, the object being merely to secure a circulation of the cooling medium over a sufficiently large radiating surface formed by the walls of the conduit so that the heat due to friction will be effectively removed. Lubricant is supplied to the conduit *J*, whence it flows back and forth over the radiating surfaces of the shell and is delivered by the passage *L* (Fig. 2) to the conduit *M* in the upper half of the shell. This conduit directs it back and forth over the radiating surface in the manner indicated, and delivers it to the passage *N* and to the bearing surfaces. Grooves, *O*, *P*, *Q*, assist in the distribution of the lubricant over the bearing surfaces, after which it escapes into chambers *R* and *S* and then flows downward into the chamber in the lower part of the frame. A conduit *U* drains it from the bearing and returns it to the source of supply for repeated use. Before the oil is delivered to the bearing surfaces, its temperature is raised by the heat which it removes from the bearing in the cooling operation. The lubricating effect of the oil is, it is claimed, increased by this pre-heating, warm oil being a better lubricant than cold oil, so that the friction of the bearing surface is decreased, resulting in a superior operation of the bearing and a reduction in the amount of heat removed by the oil. The result of the decrease in friction and amount of heat generated is that a given bearing may be made to carry a much heavier load without overheating.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,

49-55 LAFAYETTE STREET, CORNER OF LEONARD,
NEW YORK CITY.

Alexander Luchars, President and Treasurer.
Matthew J. O'Neill, Secretary.

Fred E. Rogers, Editor.
Ralph E. Flanders, Erik Oberg, Franklin D. Jones, Ethan Viall,
Associate Editors.

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit exclusive contributions from practical men on subjects pertaining to machine shop practice and machine design. All accepted matter is paid for at our regular space rates unless other terms are agreed on. All copy must reach us by the 5th of the month preceding publication.

JUNE, 1909

PAID CIRCULATION FOR MAY, 1909, 21,189 COPIES

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 650 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

A FACTOR IN GRINDING

To those familiar with cylindrical grinding, it is well known that increasing the work speed increases the wheel wear. In case a wheel is too hard for the work, it is a common expedient to increase the work speed until the wheel cuts satisfactorily. An emery wheel cannot grind freely unless it wears itself away so as to present constantly new cutting points to the work; consequently, increasing the work speed causes the hard wheel to cut more freely because it wears away more rapidly.

The reason for increased wheel wear because of higher work speed is not clear to many who have studied the question, and the first deduction is likely to be that increase of wheel wear because of greater work speed is simply due to more work being done per minute. While this is a reason, it is not the only one, because experience has shown that increasing the work speed will increase the wheel wear *for the same amount of material removed*. Why is this so?

We believe the answer involves a matter of grinding wheel mechanics that apparently has not been given much attention by grinding machine authorities. A particle of emery embedded in the bond of a wheel is held quite insecurely. This can be demonstrated by attacking the face of the wheel, while stationary, with a metal tool. It is an easy matter to scrape off particles of emery, and under this test the wheel appears to be a fragile thing when we consider what it is capable of accomplishing. The common method of testing wheels for grade is to dig into them with a pointed tool, and experts can quickly determine the relative hardness of wheels, or rather the strength of bond in this manner.

Now, what enables the emery to cut when held so insecurely? Largely because of its kinetic energy. The condition is similar to that which gives a rifle bullet its power. A Spitzer bullet weighing 150 grains is projected from a modern Springfield rifle with such velocity that it has a striking energy of 2,400 foot-pounds, 50 feet from the muzzle. It is almost inconceiveable that so small a piece of metal can develop such great striking energy, and the fact gives one a vivid conception of the effect of velocity. In less degree, the cutting power of an emery wheel point depends on its velocity.

The standard velocity for grinding machine wheels is about 6,000 feet per minute or, say, 100 feet per second. A particle of emery weighing one grain, embedded in the circumference of a wheel running at the standard speed, has a kinetic energy of $E = Wv^2 \div 2g = 154$ foot-grains, nearly. That is, a particle of emery, because of its velocity, has a kinetic energy equal to 154 times its weight, falling one foot. This kinetic energy enables the point to plow its way through the opposing metal without throwing heavy stress on the bond holding it in place.

The contact of the grinding wheel with the work cylinder is theoretically on a line parallel with the axes, but actually on a surface. A particle of emery is in contact with the work for a period that depends on its speed and the work speed. Suppose that the work were standing still. It is obvious that the grinding wheel will instantly lose its contact with the work, as it will grind an arc into the metal and no longer touch it, but by the constant rotation of the work, new metal is brought into contact with the wheel and removed. During the period of contact the cutting points of emery plow narrow grooves through the metal, the length of each furrow depending on the work speed. If the work speed is doubled, obviously the length of the furrow is doubled. The possibility of an emery point cutting its way through the opposing metal depends upon how much material is opposed to it. The emery points do not act as a mass, but individually and as such have the weakness of scattered fighting units, which, as every soldier knows, can be easily defeated "in detail." There is a near balance existing between the force required to remove the opposing metal, the kinetic energy of the emery points and the centrifugal force tending to throw the loose particles on the wheel face off on a tangent. When the work speed is increased, this balance is lost and a new condition set up which causes the particles of emery to be more rapidly disrupted and new and fresh grinding points will be brought into action resulting in freer cutting.

* * *

BLIND ACCEPTANCE OF AUTHORITIES

It is important for a young engineer to avoid the blind acceptance of authorities, so common in the college-bred youth. The young man fresh from college usually enters practical life with but a vague understanding of many conditions that are deciding factors in constructive engineering work, and he is likely to believe that the formulas and rules laid down by the writers of his text-books may be relied on to give satisfactory results in all cases. He does not doubt the authority of those who wrote the text-books or deduced the formulas, and when he finds that the practical engineer sometimes accepts solutions which appear to be contrary to the rules laid down by his "authorities," he immediately concludes that the men under whom he is working are wrong. Someone has said, with a great deal of truth, that the college-bred engineer is really the best engineer in the long run, if he only is given time to unlearn what he has been taught in college. Of course, this expression must not be taken literally, but there is no doubt that there are many conceptions in the young college engineer, due to his education, which must be modified and sometimes discarded before he can make a success in practical engineering. This is not a reflection on college training and education, but merely implies that it is impossible to take into consideration in the limited scope of a technical college education all the practical factors, limitations and requirements, which enter into almost every engineering problem. In general, the training of the engineering school includes principles only, and the young man who enters into practical occupations must learn that while the principles always hold true, it is seldom that any one principle can be applied, by itself alone, to the solution of a problem. There may be a dozen fundamental principles, each of which enters into the problem; and it is impracticable to lay down a rule exactly determining to what extent each has an application to the problem.

The greatest asset of the engineer is *judgment* and *common sense*, guided by a fundamental knowledge of first principles; and the successful engineer is the man who fully realizes the value of his own judgment, and therefore dares to disregard, to a certain extent, the dictum of authorities, and rely upon his own investigations and experience.

ENTERTAINMENT FEATURES OF THE A. S. M. E. CONVENTIONS

A delightful feature of the semi-annual conventions of the American Society of Mechanical Engineers is the various excursions to points of interest in and about the cities where the conventions are held. The parties going on these excursions are given special attention, and unusual courtesies often are extended in honor of the society. To the ladies and other guests of the members such excursions are particularly enjoyable because of their novelty, and we fear that the majority of the members are more interested in them than in the regular proceedings.

Notwithstanding the popularity of such diversions, we are inclined to question the advisability of featuring them to the extent that has been the case in the last few years. It seems that the prestige of the society will suffer if the entertainment side of the convention is magnified so that it eclipses the technical side. We believe that the society will gain in prestige if less attention is given to pleasure, and more to the real business for which the conventions are intended. Let the Spring conventions be held in places where ample hotel accommodations are provided, but where the outside attractions are minimized. Then the attention of the visiting members will be centered on the papers and discussions. The chief value of the conventions lies in the oral and written discussion of the papers, and in the making of acquaintances and the renewal of friendly relations. If the discussions fail, there is comparatively little profit in traveling hundreds of miles to hear papers read, as every member receives the monthly journal of the society containing them. Let us continue to have entertainments, by all means; but let them be subordinate to the real business of the society.

* * *

THE SHOP OPERATION SHEET ON GRINDING DRILLS

We call special attention to the shop operations in another part of this number, describing the hand grinding of flat and twist drills. We believe they are of such a practical character as to command the attention of every machinist, foreman and superintendent of machine work, particularly if they are concerned with the instruction of apprentices and others.

The drill is the most used metal cutting tool, and receives the most abuse. Common laborers often are put to work on drill presses and required to keep their drills sharpened. When proper instruction in grinding is not given, the results are deplorable; power is wasted, drills are broken and rapidly worn out, and holes produced larger than the desired sizes, all of which could be avoided by giving practical lessons in drill grinding at the start. It is comparatively easy to grind a flat or twist drill by hand to a fair approximation of the correct shape if the proper shape is known to begin with, but that is just what many otherwise good mechanics do not know. A study of the operation sheet by those who *do* know, undoubtedly will give them a better understanding of the matter and better fit them for instructing those in their charge in the matter of upkeep, that is sadly neglected in many shops. A drill grinder is a tool whose value is not properly appreciated, and until it is a common part of machine equipment, hand grinding will be a matter for every machine man to understand.

THE MECHANICAL ENGINEER IN PUBLIC RELATIONS

An amendment to the constitution of the American Society of Mechanical Engineers was offered at the Washington meeting, which provides for a committee on public relations. It is the belief of a number of the members prominent in the society's affairs that the influence of the mechanical engineer on civic matters should be made much greater than it now is. In these days of machinery and great mechanical engineering works, the advice of the mechanical engineer on matters of public importance is not sought by the heads of municipalities and civic authorities as much as it should be. It is the aim of those standing sponsors to this movement for public relations to bring about a realizing sense of the value of the advice of the mechanical engineer in projects affecting the general welfare of communities. The paper "The Engineer and the People," read by Mr. Morris Llewellyn Cooke at the December, 1908, meeting of the society, called the society's attention to the importance of closer relationship between mechanical engineers and the national and municipal governments, and doubtless the proposed amendment to the constitution was inspired by it.

The movement is one that we heartily endorse; and any other movement that will tend to place the mechanical engineer and his worthy assistant, the machinist, in a position commanding greater respect of those benefited by their work, will receive our commendation. We feel that the mechanical work that has been largely instrumental in placing this country among the foremost nations of the world, has not been properly appreciated by the majority of those who have benefited thereby. The age of the politician is passing away, and following it is the age in which the achievements of the business man and the mechanical engineer will receive national recognition. Let us bring into prominence the work of our engineers, and stimulate in the minds of the younger generation the desire to emulate the constructive work of these men, which means so much more for the world's welfare than does politics, diplomacy or war.

THE NEWER HIGH-SPEED STEELS

O. M. BECKER[*]

After the metal cutting industries had taken breath, so to speak, following the advent of air-hardening or high-speed steels, and begun to adjust themselves to the new situation, the use of self-hardening or mushet steels rapidly decreased until very little call for it existed and most manufacturers ceased making it altogether, putting out instead a more or less excellent quality of the high-speed kind. This, however, was not for some little time after the Taylor-White discoveries became public. The self-hardening steels had come into rather general use in difficult jobs, and in progressively managed shops were used to a considerable extent on all sorts of jobs; and so, while the new steels with their wonderful possibilities were justifying themselves and establishing their place, very properly there was a disposition to hold fast to that which had already proved itself, rather than to take up something but little known or tried. Recently there has again come to be some demand for steels which, while possessing the qualities of high-speed steel to a moderate degree, enough to adapt them to a class of work not requiring its high cutting powers and red-hardness, could be bought at a price considerably below that of high-grade air-hardening steel; and a number of manufacturers have brought forward steels to fill this gap. There doubtless are many kinds of work wherein a steel of less endurance than the best high-speed varieties would answer every requirement and yield results equally as good—jobs where extremely high speeds or heavy cuts are in the nature of the case impracticable, or as in certain woodworking operations, where a cutter of higher endurance than one of the best carbon steel would have an almost indefinite life anyway. In such cases, it would seem, the high cost of air-hardening steel imposes an unnecessary expense in tool equipment.

Most such "new" steels are nothing more nor less than mushet or self-hardening, though some seem to be manganese rather than tungsten steels. A typical example of such a "special," "intermediate," or "semi-high-speed" steel, of excellent sustaining power and not exceptionally hard to treat, has the composition:

Carbon	1.190 per cent.
Tungsten	7.560 per cent.
Chromium	3.340 per cent.
Manganese	0.460 per cent.
Phosphorus	0.024 per cent.
Sulphur	0.025 per cent.
Silicon	0.200 per cent.

Another, corresponding still more closely in its composition to mushet steel, gave this analysis:

---

[*] Address: Berwyn, Ill.

Carbon	0.94 per cent.
Tungsten	1.78 per cent.
Chromium	0.69 per cent.
Manganese	0.27 per cent.
Phosphorus	0.01 per cent.
Sulphur	0.01 per cent.
Silicon	0.11 per cent.

Both these steels, it will be observed, are rather lower in carbon than most mushet steels formerly were, and the first is rather higher in tungsten while the second is lower in chromium. A third, which scarcely falls within the mushet class, is thus composed:

Carbon	1.25 per cent.
Tungsten	2.25 per cent
Chromium	0.28 per cent.
Manganese	0.85 per cent.
Silicon	0.21 per cent.

The latter is advertised and sold specifically as a "finishing" steel; and it unquestionably gives excellent results in this particular kind of work. There are, besides, a number of other steels on the market, sold for tool use, whose tungsten content (or molybdenum equivalent) ranges anywhere below that essential to a high grade high-speed steel—say 17 per cent—and down to that indicated in the analyses above. Most of these are sold as high-speed steels, though usually at a lower price than is customary for those of highest grade, and to a greater or less extent are so, when the chromium content corresponds with the tungsten.

Still another steel very widely advertised as an "intermediate" steel, and certainly working exceedingly well in certain classes of work, including blanking and stamping as well as cutting wood and metals of moderate hardness, has this anomalous composition:

Carbon	1.03 per cent.
Tungsten	0.46 per cent.
Chromium	0.06 per cent.
Manganese	0.30 per cent.
Phosphorus	0.025 per cent.
Sulphur	0.009 per cent.
Silicon	0.008 per cent.

This is represented as a very dense steel requiring very slow and careful heating to a bright cherry red (800 to 850 degrees C. or about 1,500 to 1,550 degrees F.) for cutting tools, and somewhat lower for tools intended to withstand pressure or blows. It is water hardening, as might be supposed from its composition, and requires the temper to be drawn, as in the case of carbon steel tools. It is claimed to be at least 50 per cent tougher than carbon tool steel—though that is about what it seems really to be except for being high in manganese. Several other steels sold for about the same purposes also have about the same manganese, and some a good bit higher.

The most recent development in tool steels seems to be quite as startling as was the announcement of the Taylor-White process and the advent of high-speed steels. If the preliminary experiences with these remarkable steels can be maintained, as there seems to be no reason to doubt, another long step has been taken in tool steel development. For some time, perhaps as long as two years preceding this writing, it has been known to the informed that in certain steel works tools were in use very greatly superior to those made from steels regularly upon the market, tools capable of cutting at greatly superior speeds and maintaining themselves much longer in good cutting condition than is customary with ordinary high-speed tools. Experiments had been going on, apparently in a number of places at the same time, looking to the production of a superior steel which would free the makers from the limitations imposed by the Taylor-White patents, should the litigation relative to them terminate favorably to the holders of the patents. The results have been startling indeed.

It is possible, without any question, to cut at speeds double those possible with ordinary high-speed steels, and even much higher, the tools standing up to such astonishing speeds as five hundred feet per minute under good condition, it is reported. The greatest advantage, however, lies not so much in the increased cutting speeds as in the very greatly superior lasting quality. A tool of the new high-speed steel can be made to last as much longer than one of the best kind previously made, as that will outlast one of carbon steel. The most refractory metals can be cut with ease. Chilled iron, which could be cut with ordinary high-speed steel with difficulty, that is to say, at speeds near ten feet per minute and then only with very frequent grindings of the tool, can now be machined with comparative ease. Hard spots in skidded tires, to mention another example of the possibilities, which were likely to play havoc with the very best of tools, are cut through with little or no sign of their presence. Chilled rolls which the best tools previously available would scarcely touch, have been turned at 80 feet per minute. In hard material particularly do these newest steels show their powers to the best advantage. In softer metals, as in low carbon steels, there is a possible gain ranging from 25 to 60 per cent over ordinary high-speed tools, in regular work; though the makers seem to prefer to recommend in general that there be no distinctive increases in cutting speeds on this class of work.

The lasting qualities of these steels is astonishing, compared with ordinary high-speed steels even. Tools last from two to eight times as long before requiring re-grinding, depending upon conditions, the greatest advantage apparently being in the case of cutting very hard materials. The tool will cut without any diminution of its powers, apparently, while the nose is glowing at a bright red. Evidently the temperature points at which red-hardness or tempering begins is considerably higher than that of ordinary high-speed steels.

Following the first announcement of the new or superior high-speed steels, few details concerning them were obtainable, the makers preferring to keep their secret for the time being The steels are now sold upon the open market, and it can be stated that in details of working up into tools they do not differ in any essential particular from the ordinary high-speed steels. It is true they can be hardened in salt water; and it is reported that this has been done in the case of a particular tool a great many successive times without any cracks developing. Nevertheless even the makers admit that cracking is likely to take place, hardening in air or oil being the preferred and recommended method. For cutting exceedingly hard materials, like chilled iron, the water hardening is recommended, in spite of the possibility of cracking.

The new steels are easily forged, though the forging heat is best kept rather higher than is usual with the other high-speed steels, say at a yellow, or at the least at a bright red. The heat must on no account be lower than the latter, say not far from 950 degrees C. or 1,750 F. Annealing is done easily and simply, and it is declared that there is no possible danger from overheating in hardening.

The cost of the new steels is considerably higher than that of the ordinary high-speed kinds, so that its use in preference to the latter must be justified by exceptional conditions, such as especially difficult materials to cut, or the possibility of great economies. The latter arise, as already mentioned, less from increased speeds than from superior lasting qualities. The consumption of tool steel results from grinding the tools and the final rejection of the tool stock as too small for proper use. Evidently if a tool can run four to eight times as long without grinding (and give a superior finish at the same time) as the best previously available, this saving in steel and in time lost changing tools would go a long way toward justifying its use, even at double the cost.

* * *

If a delicate piece of machinery can not be adequately protected from rough handling by the operator, it is better to leave the parts exposed and let his own judgment dictate the usage to which the parts should be subjected. An example illustrating the idea is the method employed in packing high grade glassware, especially cut glass that is very costly A plan which has been followed with success is to pack it in barrels with excelsior, filling the barrel full and exposing a piece of the glass at the top. That exposed piece is the danger signal and a freight handler must have considerable hardihood who will treat that barrel disrespectfully. He knows that he cannot turn the barrel over on its side, and the exposed glass effectually prevents piling other freight on top.

NEW ENGLISH VERTICAL MILLING MACHINES

FRANK C. PERKINS*

The accompanying illustrations show the construction of four milling machines designed and constructed at the Manchester Works of Sir W. G. Armstrong Whitworth & Company. Fig. 1 shows a small, sensitive, vertical milling machine driven by an electric motor and designed chiefly for use on the breech mechanism of guns. The base plate, it will be seen, is arranged as a tank into which the lubricating oil runs and from which the oil is pumped through pipes to the milling tool. This machine is driven by a variable-speed motor and is suitable for high speed work. It will be noted that it consist of a box pattern frame with square slides to receive the knee. The machine is fitted with a steel spindle running in a tube having adjustment vertically by a hand-wheel, worm gear, and rack and pinion. The spindle is locked in any position by the lever seen just below and to the left of the hand-wheel, and it is arranged with conical bearings, the thrust being taken by ball bearings, while the upper end is supported in a bushing running in a bronze bearing. A variable-speed motor is used for driving, as mentioned; it is directly connected to the base of the upright and drives by belt over guide pulleys to the pulley on the top of the machine. The longitudinal traverse of the table is 10 inches, and the transverse movement 18 inches. The vertical adjustment of the table is 18 inches, and the vertical adjustment of the spindle, 2 inches.

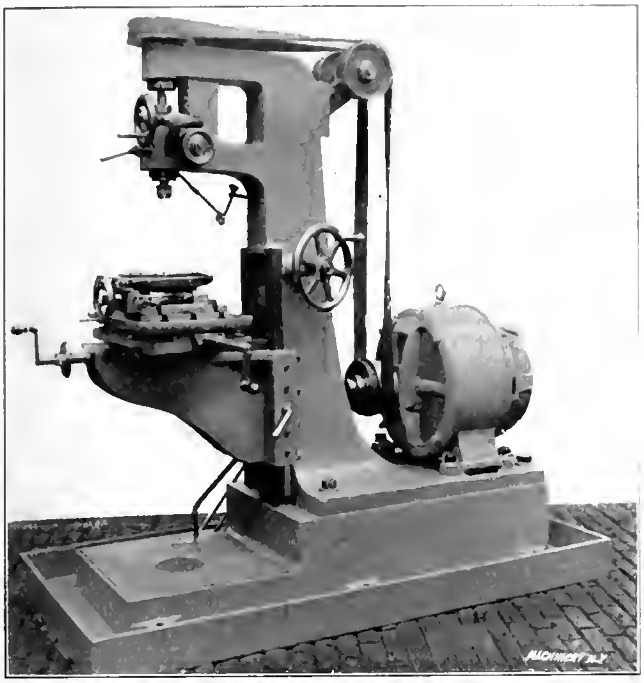

Fig. 1. Electrically-driven Sensitive, Vertical Milling Machine, built by Sir W. G. Armstrong-Whitworth & Co.

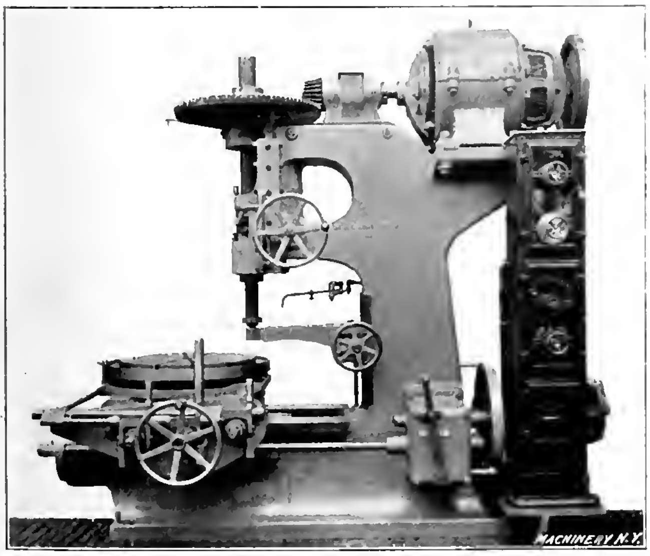

Fig. 2. Vertical Milling Machine with Two Motors—One for the Main Drive and the other for Operating the Feeds and Quick Traverse

The electrically driven vertical milling machine seen in Fig. 2 is operated by two electric motors. One of these is mounted on the top of the upright and is used for the main drive through bevel gears, while the other motor is fitted to the back of the upright at the base, for the feeds and quick traverse. The machine has longitudinal, transverse and circular feeds, all of which can be automatically tripped. The main motor on the top of the upright has a variable speed which gives the necessary spindle speeds. It may be stated that one of the features of this vertical milling machine is that the feeds can be thrown in or out of gear by means of clutches worked by levers, which are always in a convenient position, as they do not revolve with the feed-screws as do the handles of the machine shown in Fig. 3; consequently the feeds can be easily thrown in or out of gear. The electric controlling panel seen at the right in illustration Fig. 2 is of special interest. This panel contains a starting switch for the two motors, and a regulating switch for the main drive motor as well as a regulating switch for the feed motor,

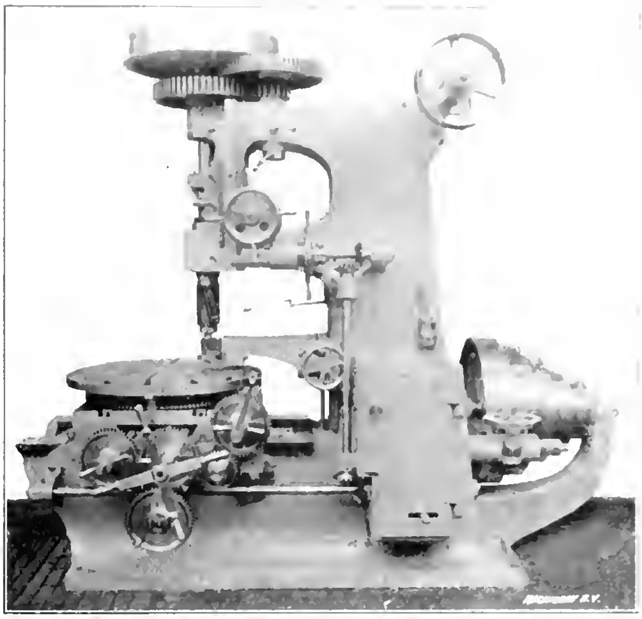

Fig. 3. Belt-driven Profiling and Vertical Milling Machine

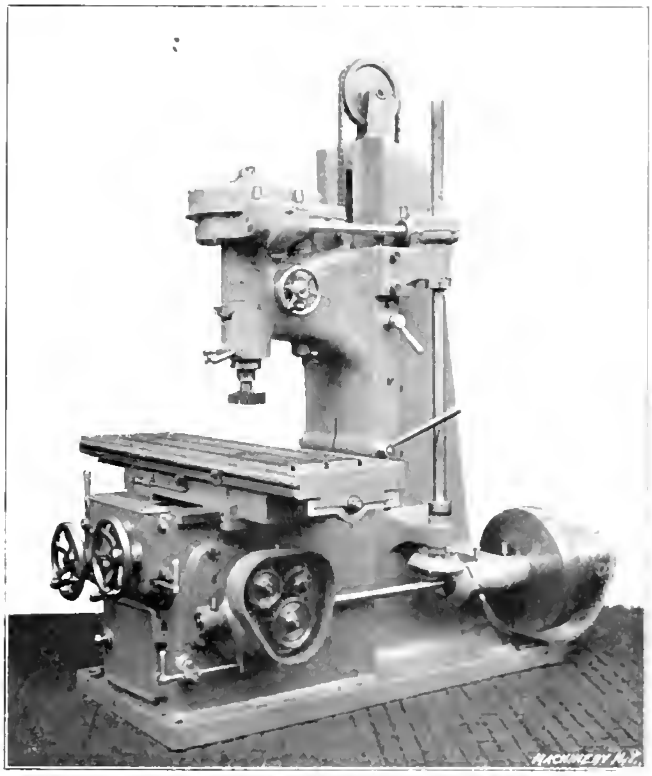

Fig. 4 Vertical Milling Machine designed for a Wide Range of Work

---

* Address: Erie Co. Bank Building, Buffalo, N. Y.

It is also provided with electric circuit breakers, which are so arranged that it is not possible for one motor to run while the other is stopped. On this machine there is a vertical hand feed to the spindle for adjustment. The machine was designed for locomotive work and has a capacity for removing 6 cubic inches of material per minute.

The profiling and vertical milling machine seen in Fig. 3 is belt-driven from a counter-shaft, and is fitted with a cone pulley at the back and an endless belt which passes over the top of idler pulleys on the column. All the feed gear is contained in a box seen attached to the side of the column, and the various speeds can be connected by means of the hand wheel, rack, and pinion shown to the rear of the feed-box. The lever seen just above the box reverses all feeds. A machine which is adapted to a great variety of work and which is also constructed at the Manchester works, may be seen in Fig. 4. This machine has a solid base. The milling head is fitted with an adjustment for position, while the feed of the spindle is controlled by means of a small hand-wheel on the head. It will be noted that all of the motions of this machine are controlled by handles from the front, which is a great convenience.

* * *

WASHINGTON MEETING OF THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS

The regular Spring meeting of the American Society of Mechanical Engineers was held at Washington, May 4 to 7 inclusive, the New Willard hotel being the headquarters. Between 280 and 290 members were registered, and a large number of guests were in attendance. The meeting opened with an address of welcome delivered by Hon. Henry D. F. MacFarland, president of the Board of District Commissioners, and responded to by Jesse M. Smith, president of the society, following which was a reception and dancing in the large auditorium of the hotel on the tenth floor.

On Wednesday afternoon the members and guests attended a special exhibition drill of the United States Army troops at Fort Myer, where the Baldwin dirigible balloon and the Wright aeroplane tests were made last Summer and Fall. The balloon was on view at a remote point and was visited by a few of the members. On Wednesday evening Mr. F. H. Newell, director of the United States Reclamation Service, delivered an illustrated lecture "Home Making in the Arid Regions" which was a very interesting exposition of the great work being done by the United States government in the desert regions of the west.

On Thursday afternoon the members and guests were received by President Taft in the East Room of the White House. On Thursday evening, Rear Admiral George W. Melville, retired, addressed the society on the subject "The Engineer in the Navy." He was followed by Walter M. MacFarland of Pittsburg, Pa., who spoke on Rear Admiral Melville's service to the engineering profession and the nation, following which was the presentation to the National Gallery of a life-size portrait of Admiral Melville by Ivanowski.

On Friday afternoon a boat trip was made to Mount Vernon, the plan being to return to Fort Myer to witness an ascension of the Baldwin dirigible balloon under direction of Lieutenant Lahm. On account of a thunder storm, the ascension was not attempted.

Amendments to the constitution were proposed to section C10 regarding the qualification of associate members of the society, and C45 defining the standing committees, it being proposed that a public relations committee be added. According to the constitution all amendments to the constitution must be proposed at the Spring meeting and acted upon at the Fall meeting.

The following papers were presented:

"A Unique Belt Conveyor," by Ellis C. Soper, Detroit, Mich.

"Automatic Feeders for Handling Material in Bulk," by C. Kemble Baldwin, Chicago, Ill.

"A New Transmission Dynamometer," by Prof. William H. Kenerson, Providence, R. I.

"Polishing Metals for Examination with the Microscope," by Albert Kingsbury, Pittsburg, Pa.

"Marine Producer Gas Power," by C. L. Straub, New York.

"Operation of a Small Producer Gas Power Plant," by C. W. Obert, New York.

"A Method of Improving the Efficiency of Gas Engines," Thomas E. Butterfield, Philadelphia.

"Offsetting Cylinders in Single-Acting Engines," by Professor T. M. Phetteplace, Providence, R. I.

"Small Steam Turbines," by George A. Orrok, New York.

"Tests on Compressed Air Pumping Systems of Oil Wells," by Edmund N. Ivens, New Orleans.

"Safety Valves": Discussion continued from the February meeting in New York.

"Specific Volume of Saturated Steam," by Professor C. H. Peabody, Boston.

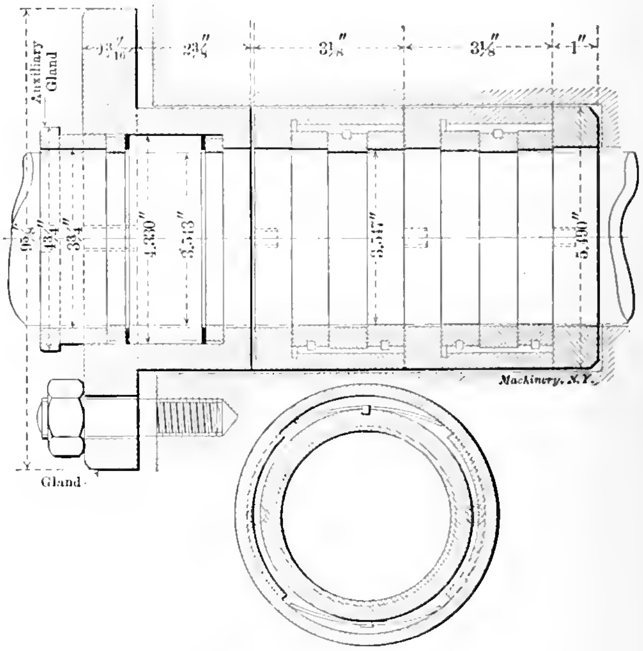
"Some Properties of Steam," by Professor R. C. H. Heck, New Brunswick, N. J.

"A New Departure in Flexible Staybolts," by H. B. Wille, Philadelphia.

* * *

FRENCH METALLIC PACKING CONSTRUCTION

The accompanying engraving shows a stuffing box made up of three rings whose bore is several tenths of a millimeter larger than the piston rod. The three rings are so arranged that two of them, one on each side, are pressed upward by means of springs, and the center one downward partly by its own weight and partly by a spring. By this arrangement, although the rings have play, the steam cannot escape. The rings do not suffer appreciable wear as the springs have a very slight tension. This stuffing box is the design of the Ateliers de Construction H. Bollinckx, Brussels, Belgium.



French Metallic Packing Construction

* * *

Some interesting figures relating to the number of telephones in use in some of the largest cities in the world are given in a recent issue of *Teknisk Tidskrift*. The figures give the number of inhabitants per each telephone and are as follows: Stockholm, 6.6; Chicago, 11.2; New York, 12.5; Berlin, 20.6; Paris, 42.4; London, 46.1. The figures for Stockholm, however, only take account of the number of subscribers of the private telephone company of the city. If the state telephones, owned and operated by the government, are also included, the figure would be about one telephone for every four inhabitants. The reason why telephones are so commonly used in Stockholm is due to the fact that in no city in the world of similar size have the charges for telephone service been brought down to so low a level, making it possible for almost everyone to have a telephone installed in their home. Less than $10 a year pays for a telephone permitting of liberal use without any additional charge, and $22 a year provides for unlimited service within a radius of forty miles.

A NEW TRANSMISSION DYNAMOMETER*

WM. H. KENERSON†

The author has received from time to time many requests for a simple transmission dynamometer, and has himself often felt the need of one which would be more generally applicable than those now in use. These continued requests, together with the requirements of a definite problem whose solution demanded a rigid transmission dynamometer in the form of a coupling, led to the design and construction of the instrument described below. The accompanying illustrations show the construction of the dynamometer and its method of application and use. In Fig. 2 and Fig. 4 the corresponding parts of the dynamometer are given the same letters.

The couplings *A* and *B*, each keyed to its respective shaft, are held together loosely by the stud bolts *C*. The holes in the flange *A* are larger than the studs *C*, so that these studs have no part in transmitting power from one shaft to the other. The power is transmitted from *A* to *B* through the agency of the latches *L*, four of which are arranged around the circumference of the flange *B*. These latches are mounted and are free to turn on the studs *E*. The two fingers of the latches engage the studs *F* on the flange *A*. On the ends of each latch are knife-edges parallel to the stud about which the latch turns. For either direction of rotation of the flange *A* the latches *L*, which are in effect double bell-crank levers, will exert a pressure on the disk *G*, tending to force it axially along the hub of the coupling *B*, and this pressure, it will be seen, is proportional to the torque.

Between the end-thrust ball, or roller, bearings *M M*, is held the stationary ring *S*, which is the weighing member. *O* is a thrust-collar screwed on the hub of *B*, and *P* is its check nut, which is ordinarily pinned to the hub when in position. The stationary member *S*, in the form of a ring surrounding the shaft, is prevented from rotating by fastening to some fixed object the attached arm shown in the view (Fig. 1) of the assembled instrument. In this ring is an annular cavity covered by a thin, flexible copper diaphragm *D*, against which the ball-race of one of the thrust-bearings presses. The edge of this ball-race is slightly chamfered to allow some motion to the diaphragm. The cavity is filled with a fluid, such as oil, and connected by means of a tube to a gage. The oil pressure measured by the gage is proportional to the pressure between the thrust-bearings, which in turn is proportional to the torque.

The instrument may be calibrated in the torsion-testing machine or by means of a sensitive friction brake. Fig. 5 is an actual calibration curve for a small instrument, obtained by hanging standard weights at proper distances from the shaft on a horizontal lever attached to the shaft, and reading the pressures indicated by the gage for the various torques shown in the diagram. For ordinary purposes, however, it is not necessary to calibrate the instrument by actual trial, since computations of the oil pressures for the various torques from the lengths of the lever arms and diaphragm area check very closely those thus obtained.

It will be seen that the weighing means is similar to that employed in the Emery testing machine, which is recognized as being extremely accurate. It will be possible to employ the Emery flexible steel knife-edges on the levers, if desired, but this has been found in practice an unnecessary refinement.

The construction makes the coupling as nearly rigid as materials will permit, the movement of the diaphragm being extremely small. The only flow of oil through the copper connecting-pipe is that sufficient to alter the shape of the Bourdon tube, if that be the form of gage employed. As soon as the normal position of the gage is reached this flow ceases, hence there can be no fluid friction. It is possible, therefore, to use as long and as small a tube as desired, without introducing error. Where the gage is placed at a distance above or below the coupling, correction should of course be made for the static head.

Other means than the gage shown may be employed to measure the fluid pressure. Where extreme accuracy is desired it will be well to employ the weighing device used with the Emery testing machine. The manograph has been used in this connection to measure variations in torque too rapid for indication by the ordinary gage. For example, the variations in torque in a single revolution of the shaft of a 3-cylinder gasoline engine have been recorded with its aid.

Where the rate of rotation of the shaft is variable and it is desired to indicate the horse-power direct, the combination of gage and tachometer shown in Fig. 6 is employed. The hydraulic gage is connected to the coupling described, its pointer therefore indicating torque. The pointer of the tachometer shows the number of revolutions per minute. Being a function of the revolutions per minute and the torque, the horse-power will be indicated by the intersection of the two pointers and suitable curves on the dial as shown. Arrangements for recording or integrating the work done may also be attached to the coupling.

A summary of some of the more important characteristics of the instrument follows:

a. The instrument is compact. The example shown in Fig. 2 and Fig. 3, which is designed to transmit 30 horse-power at

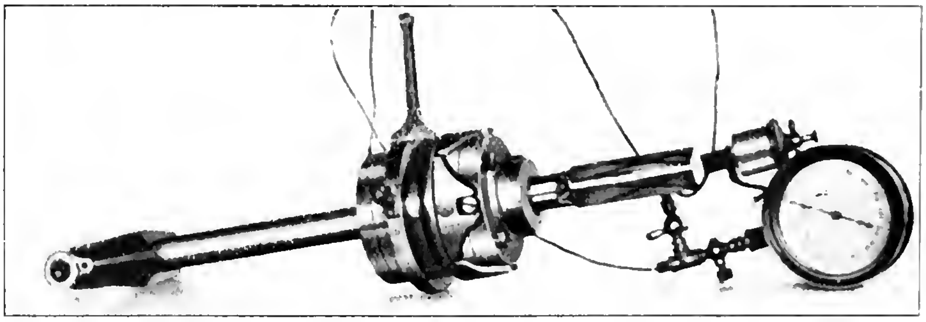

Fig. 3. Transmission Dynamometer in Automobile Propellor Shaft, 30 H.P. at 500 R. P. M., Weight 25 pounds

---

* Abstract of paper presented at the Washington meeting (May, 1909) of the American Society of Mechanical Engineers.

† Associate professor of mechanical engineering, Brown University, Providence, R. I.

500 R. P. M., is about 5⅜ inches diameter and weighs about 25 pounds.

b. It is as rigid as an ordinary flange coupling.

c. It may be made in the form of a coupling, and will then occupy about the same space as the usual flange coupling, or it may be made in the form of a quill on which a pulley is mounted. This form may be made in halves for application to a continuous shaft.

d. It will indicate for either direction of rotation of the shaft.

e. The torque may be read and recorded or the work integrated at a considerable distance from the coupling.

f. The readings do not require correction for different speeds of rotation. All parts containing oil are stationary, hence are unaffected by variation in speed. Other parts are likewise unaffected by centrifugal action.

g. It may be made very sensitive and accurate. The construction lends itself very easily to variation of range of application and to varying degrees of sensitiveness, since the oil pressure, and hence the sensitiveness of the instrument, depends upon the area of the diaphragm, the relative lengths of the arms of the latches *L*, and the diameter of flanges. Its accuracy is dependent mainly on the degree of accuracy of the means employed to measure the fluid pressure, of which a number of forms, other than the usual pressure-gage, are available.

h. The only power absorbed is the small amount due to the friction of the ball, or roller, bearings, and this can be determined from the pull of the retaining arm. It is unnecessary to make correction for this, however, since the amount is so small as to be negligible.

i. Since the only wearing parts are the ball, or roller, bearings, which may be lightly loaded, the instrument should not be deranged easily. Because of the very small volume of oil contained in the weighing chamber, ordinary temperature changes do not affect the calibration. All parts containing oil are stationary, hence all joints may be soldered and leakage entirely prevented.

* * *

A curious condition exists regarding the penetration of high power rifle bullets, the penetration actually being greater at 100 yards than at 50 feet from the muzzle. The official data on the penetration of the Springfield army rifle, model 1903, using the cartridge loaded with 48 to 50 grains of pyrocellulose and the 150-grain Spitzer bullet is 33.5 inches of white pine boards 1 inch thick placed 1 inch apart at 50 feet from the muzzle; 46.7 inches, at 100 yards, and 24.3 inches at 500 yards. The difference is even more marked with thoroughly seasoned oak, the penetration being 12.2 inches at 50 feet and 33.6 inches at 100 yards. This condition of greater penetration at long ranges and reduced velocity is what caused the failure of the so-called bullet-proof cloth invented in Europe several years ago. The cloth or padding did actually arrest high speed bullets fired at close range, but at 300 to 500 yards, it was readily penetrated.

RECLAIMING ARID REGIONS IN THE WEST

The illustrated lecture by F. H. Newell of the Government Reclamation Service, delivered the evening of May 5, at the Washington convention of the American Society of Mechanical Engineers, was one of the most interesting and instructive entertainments provided. The extent of the government's work in reclaiming the arid regions of the West is but dimly appreciated by the majority of people in the east. The work is of vast extent and is being pushed with vigor in Arizona, New Mexico, Colorado, California, Idaho, North Dakota, Washington, Oregon, and other states. The colored views thrown on the screen of the results already realized from this work, vividly impressed all with the wonderful work accomplished which will mean more for future generations than for the present. The fruit produced on irrigated ground surpasses that of any other part of the world, especially the products of the land in the Northwest where the long summer days and fertile soil are extremely favorable to the best development and coloring. The extent of the work from the engineer's point of view, staggers the imagination, even of engineers accustomed to think of big projects. Dams, ditches, sluices, and other hydraulic works have been constructed under conditions of greatest difficulty. In many places special roadways, miles in extent, and along the sides of cliffs and in other trying situations, were necessarily bulit before the work could be done. The highest dam in the world will be on the Soshone river, in Idaho, its height being 328 feet. In this case the vast body of water impounded will irrigate not only the land below the natural water level, but will also be used to irrigate land considerably above it; the power developed by the dam will be employed in part for pumping water to the higher levels. The development of electric transmission of power enables modern irrigation engineers to accomplish wonders that were impossible before. The power developed by the dams is in many cases large, and through long distance transmission the water from canals or ditches can be elevated at far distant points to levels considerably above the general level of the country and thus new areas are brought under the magic effect of water. A feature of the Western arid lands now under irrigation, not generally appreciated, is its great fertility. Not having been rain soaked for centuries, the mineral constituents of the soil have been retained and when watered, the luxuriant vegetation produced is marvelous.

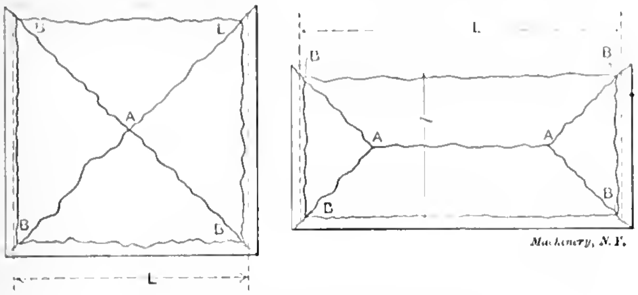
* * *

An airship of large dimensions is now being built at the Siemens-Schuckert Works in Berlin, Germany. The length of the airship is 426 feet, and the diameter of the supporting balloon is 42½ feet, the volume being about 460,000 cubic feet. The balloon space will be divided up into sections, so that if one part of the balloon is injured, it will still remain in the air. The airship is provided with four 125 H. P. motors, and it is expected that it will have a speed of at least 38 miles (60 kilometers) an hour.

FORMULAS FOR STRENGTH OF FLAT PLATES*

WILLIAM F. FISCHER†

The machine designer is often called upon to carry out designs consisting in part of flat surfaces, such as plates supported or fixed at the edges, with or without intermediate supports or ribs. Exact formulas for finding the bending moments of flat plates, and their resistance to the stresses created by pressures normal to their surface, have not, to the writer's knowledge, been determined. The formulas given by different authorities are founded on assumptions, and should be considered as probable approximations only; they should be used with caution, as the results obtained are not likely to be very accurate. In devising such formulas, all the assumptions should be made to err on the safe side.



Figs. 1 and 2. Probable Manner of Rupture of Flat Square and Rectangular Plates, held securely at the Edges

Square Plates

A square cast iron plate fixed or rigidly held at the edges and loaded with a uniformly distributed load, or a load concentrated at its center, would be likely to fail, as shown in Fig. 1. It would first fracture along the diagonal lines from *A* to *B*, and then fail at or near the fixed edges along lines *B B*. The plate, of course, might also shear off along the edges *B B*, depending upon the method of loading the span *L* between supports, and the thickness of the plate. If the plate were merely supported along all the four edges, it would be likely to fail by breaking along the diagonal lines *A B* only.

In the accompanying Supplement are given two tables of formulas for square flat plates. In Table I the plates are supported at all four edges and the load is uniformly distributed over the unsupported surface of the plate. Formulas given by different authorities are reproduced and the various values for total load, unit stress, etc., as obtained from the original formulas given by each authority, are given. A formula deduced by the author of the present article is also included.

In Table II in the Supplement are given formulas for square flat plates secured along all four edges with the load uniformly distributed over the unsupported surface. In the same table formulas are also given for square flat plates loaded at the center.

Rectangular Plates

In Fig. 2 is illustrated the probable manner of failure of a flat rectangular plate of cast iron loaded with a uniformly distributed load. The plate, if uniformly loaded and secured along all the four edges would probably fail by fracturing along the center line *A A* of the longer axis of the plate, and along the diagonal lines *A B*, and then fail at or near the edge of the support along the lines *B B*. If the plate were merely supported along all four edges, it would fail simply by fracturing along center line *A A* and the diagonal lines *A B*. As may be readily seen, the plate firmly secured at the edges offers a much greater resistance to the stress created by the load than does the plate merely supported at the edges.

In Table III in the accompanying Supplement, a number of formulas for flat rectangular plates supported at all four edges and loaded with a uniformly distributed load are given. Among these are also included formulas deduced by the writer. In Table IV are given formulas for flat rectangular plates firmly secured at all four edges and loaded with a uniformly distributed load. The fact that various authorities differ considerably, indicates the approximate nature of investigations along these lines. It is, however, important that formulas be deduced and used for designs of this character, because, while the formulas are only approximately correct, they indicate, in a general way, the dimensions required in flat plates, and the factor of safety assumed will always be taken large enough so that, practically, the difference between the various formulas is of small moment. It would be advisable, however, to use the formulas which give the greatest dimensions, indicating that they are on the safe side. Accompanying the present article will be found a table

RECTANGULAR FLAT PLATES SUPPORTED AT ALL FOUR EDGES AND LOADED WITH A CENTER LOAD W

Author and Reference	Formulas as Given by Author	Safe Load at Center of Plate $W =$	Unit Stress in Extreme Fiber of Material $f =$	Thickness of Plate in Inches $t =$
Grashof, Trautwines, C. E. Pocket Book, page 493	$f = \frac{3\,C\,W\,L\,l}{2\,t^2\,(L^2 + l^2)}$ $C = 2$	$0.34\,\frac{f\,t^2\,(L^2 + l^2)}{L\,l}$	$3.\,\frac{W\,L\,l}{t^2\,(L^2 + l^2)}$	$1.73\,\sqrt{\frac{W\,L\,l}{f\,(L^2 + l^2)}}$
Rankine, Civil Engineering, page 543	$M = \frac{3\,W\,L^4\,l}{8\,(L^4 + l^4)}$ where l is less than 1.19 l	$0.45\,\frac{f\,t^2\,(L^4 + l^4)}{L^3\,l}$	$2.25\,\frac{W\,L^3\,l}{t^2\,(L^4 + l^4)}$	$1.5\,\sqrt{\frac{W\,L^3\,l}{f\,(L^4 + l^4)}}$
Rankine, Civil Engineering, page 543	$M = \frac{W\,l}{4}$ being the same as for a plate supported at side edges only	$0.67\,\frac{f\,L\,t^2}{l}$	$1.5\,\frac{W\,l}{L\,t^2}$	$1.225\,\sqrt{\frac{W\,l}{f\,L}}$

RECTANGULAR FLAT PLATES, FIRMLY SECURED ALONG ALL FOUR EDGES AND LOADED WITH A CENTER LOAD W

Grashof, Trautwines C. E. Pocket Book, page 493	$f = \frac{2\,C\,W\,L\,l}{2\,t^2\,(L^2 + l^2)}$ $C = 1.75$	$0.38\,\frac{f\,t^2(L^2 + l^2)}{L\,l}$	$2.62\,\frac{W\,L\,l}{t^2\,(L^2 + l^2)}$	$1.6\,\sqrt{\frac{W\,L\,l}{f\,(L^2 + l^2)}}$

M = maximum bending moment, inch-pounds
L = long span between supports
l = short span between supports
W, f and t as given above.

Note: Rankine gives bending moment M only as given in second line.

Writer assumes resisting moment M_1 as $M_1 = \frac{f\,l\,t^2}{6}$

Then $M = M_1$ or $\frac{3\,W\,L^4\,l}{8\,(L^4 + l^4)} = \frac{f\,L\,l^2}{6}$; also $\frac{W\,l}{4} = \frac{f\,L\,t^2}{6}$

* With Data Sheet Supplement.
† Address: 220 W. 149th St., New York City.

for rectangular flat plates supported or secured at all the four edges and loaded in the center; in the tables where only one set of formulas is given, it indicates that the authorities quoted in the other tables do not give formulas for the case in question. As the formulas here collected usually are found only by diligent search in a number of different hand-books, and as these hand-books may not always be easily procurable, the author hopes that the collection will prove useful to many readers of MACHINERY who, at some time or other, may be called upon to lay out a design involving square or rectangular flat plates.

OIL TESTING MACHINE

An interesting machine for testing the durability of the lubricating qualities of oils has been designed by Mr. Paul Wendt, Kottbus, Germany. The machine, as shown in the accompanying engraving Fig. 1, reproduced from the *Zeitschrift des Vereines deutscher Ingenieure*, is mounted on a frame, and a slide *A* is moved forth and back by means of a crank motion. On top of the slide *A* is placed another slide *B* which rests freely on the lower slide, and is carried forth and back with it by friction only. When the contact surfaces of *A* and *B* are well lubricated, the inertia of the part *B* and the resistance offered by the mechanism will tend to make it move but little, but when the friction between the two surfaces becomes greater, the part *B* will have a tendency to follow the part *A* forth and back for the whole stroke. On the end of the rod passed through and secured to *B*, a ratchet pawl is mounted, which engages with the ratchet wheel *C*, provided with teeth of very fine pitch. When the motion of *B* becomes sufficient to turn the ratchet *C* one tooth space, the ratchet will stay in the position to which it had been moved by the engagement of the pawl *D*. On the same spindle on which the ratchet wheel is mounted is also mounted a cylinder around which is wound a sheet of paper, and under this cylinder is placed a scriber which is given a motion sideways, by a screw driven by bevel and spur gearing from the same crank-shaft which gives the motion to the slide *A*. On the end of the shaft, passing through the ratchet gear and recording cylinder, a lever is placed, on the end of which an adjustable weight *E* is attached. The lever hangs in a perpendicular position at the beginning of the test, but as the ratchet *C* is moved around, the lever and the weight will follow, moving to the right. By this means resistance to motion of the slide *B* and ratchet *C* is increased automatically, so that as the experiment proceeds, and the oil deteriorates, the frictional resistance between *A* and *B* becomes greater, and a greater force is required to move the ratchet *C* one tooth space.

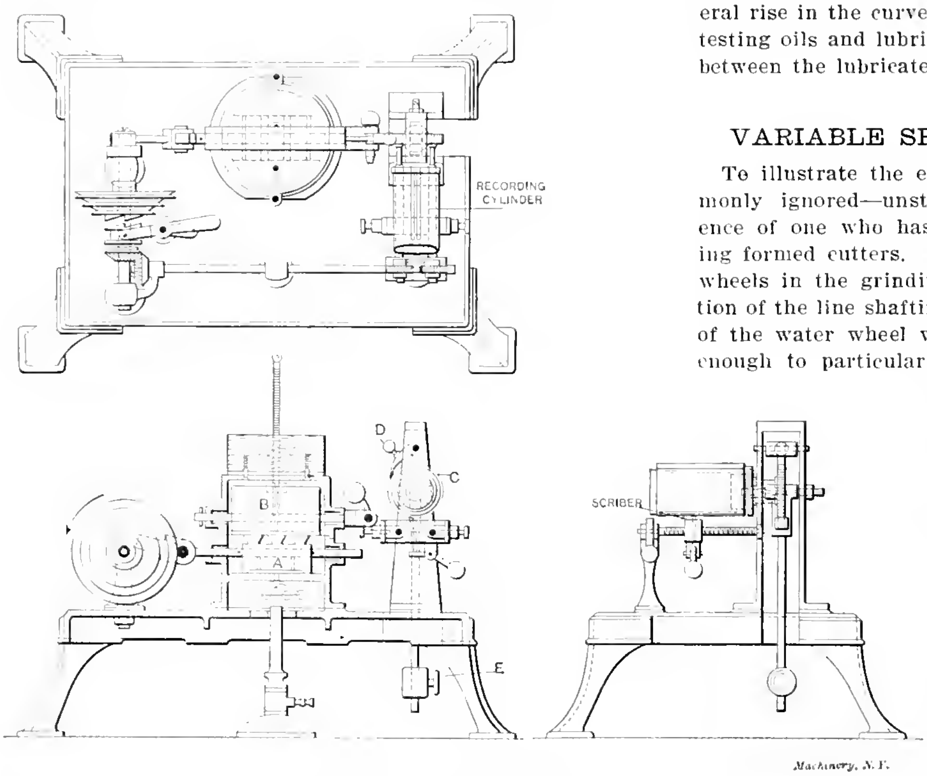

Fig. 1. Wendt Oil Testing Machine

The apparatus is of value for comparing the qualities of different oils. In the two examples shown in Fig. 2, the diagrams indicate that in one case the oil retained its lubricating qualities practically unimpaired for fifty-four minutes, but then, having become heated, it very quickly became impaired in quality. In the other case shown, another oil retained its lubricating quality only twenty-one minutes. By testing the oils by this machine, therefore, it was found that it would be likely that of the latter oil, more than twice the quantity would be required for equally good lubrication that would be required of the first kind of oil. The uneven character of the line recorded on the cylinder depends upon the fact that the slide constantly moves slightly forth and back and thereby gives a vibrating motion to the recording cylinder. But until the motions forth and back become large enough to move the ratchet one tooth space, there is no general rise in the curve produced. The machine is intended for testing oils and lubricants which are used in small quantities between the lubricated surfaces.

VARIABLE SPEED FACTOR IN GRINDING

To illustrate the effect of a factor in grinding quite commonly ignored—unsteadiness of speed—we cite the experience of one who has developed special apparatus for grinding formed cutters. When this work was first developed, the wheels in the grinding department were connected to a section of the line shafting driven by a water wheel. The motion of the water wheel was subject to some fluctuation, but not enough to particularly affect the grinding so far as casual inspection would show. There was trouble, however, from constant breakage of emery wheels, these having to be of very thin section to do the work required. A few years later, a steam turbine was substituted for the water wheel and at once a great reduction in the breakage of the wheels was noted. The steam turbine operated with more steadiness than the water wheel and to this fact alone is attributed the reduction in the breakage of the grinding wheels. It is not clear why the fluctuation of the water wheel should affect the grinding wheels in this manner. The amount of material removed in the grinding operation is small and the side-pressure on the wheels is low. The difference in operation due to the fluctuations of the water wheel should not account for the breakage, but the fact remains that the breakage has been greatly reduced with steadier motion. Who can give the best explanation?

* * *

According to *Page's Weekly* the results of the trials with the White Star liner *Laurentic*, which is equipped with a combined system of reciprocating and turbine engines, have been so satisfactory that it is probable that the same system will be used in the two giant steamers, *Olympic* and *Titanic*, which are now being constructed by Harland & Wolff in Belfast.

MAKING AN ENGRAVING BLOCK

ETHAN VIALL*

The old-time ball-vise or "sow-block," as it is known among die-sinkers, is scarcely recognizable in the beautifully finished engraving block of today, with all of its numerous adjustments and attachments; yet the rough old device with its rough-cast hemispherical-base and wooden pillow, was without a doubt the granddaddy of the present form. The engraving-block described in this article, was, as its name indicates, intended primarily for engravers' use only, but its usefulness to the tool- and die-maker will be at once recognized by those not already familiar with it, for while it will hold delicate articles without crushing them, it will also hold anything within the capacity of its jaws, as firmly as any vise made, and in any workable position. There is nothing weak or fragile about the tool even if it is a beautiful piece of workmanship.

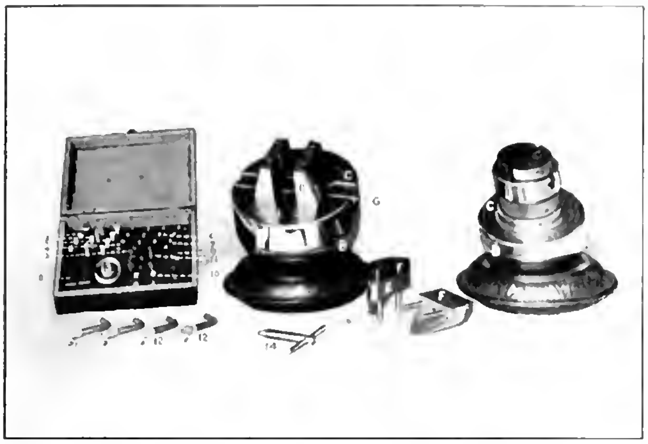

Fig. 1. Regular and Keylsss Engraving Blocks and Attachments

Fig. 2. Partly finished Castings for the Spherical Base

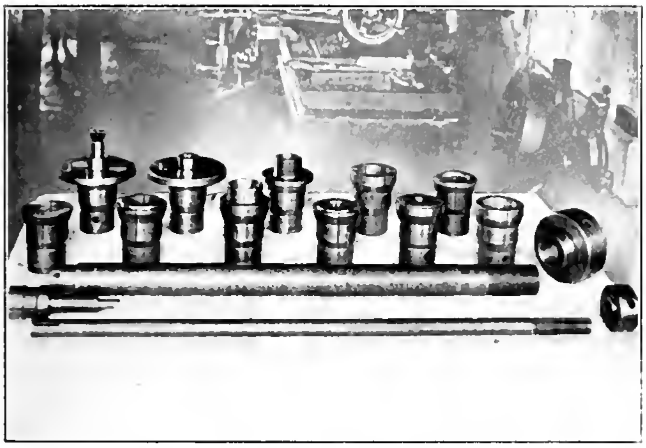

Fig. 3. Set of Split Chucks for Jones & Lamson Lathe

Fig. 4. Centering the Spherical Base

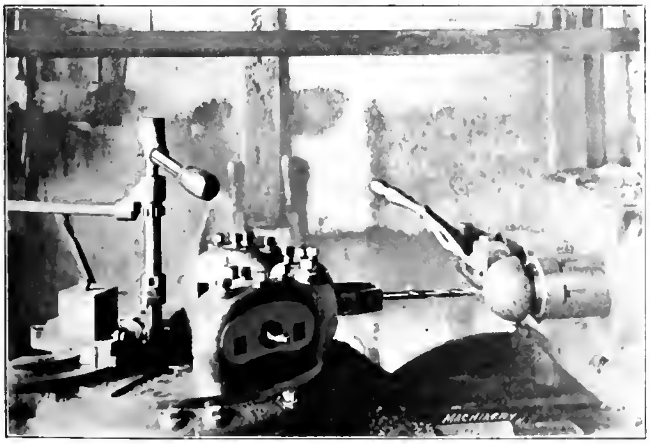

Fig. 5. Drilling the Hole in the Base

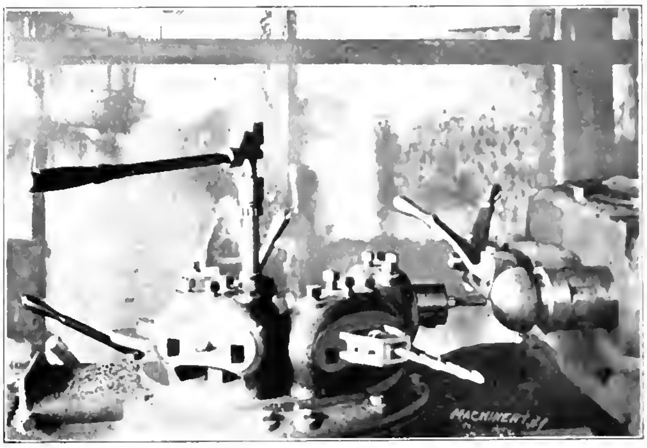

Fig. 6. Tapping the Hole in the Base

There are two things that must be kept in mind by anyone making goods for jewelers' or engravers' use; first, such articles must be well made, and, second, they must be well finished. The block here shown certainly fills these requirements in every way. This block was originally designed by L. W. Géry, an engraver of New Orleans, and it is manufactured by Adolph Muehlmatt of Cincinnati, Ohio. Mr. Muehlmatt is a practical engraver and toolmaker of more than local reputation, who has from time to time added improvements as the demands of the trade or his own originality suggested them, and it is through his courtesy that we are enabled to publish the following article.

Mr. Muehlmatt manufactures two styles of engraving blocks. The regular and the keyless form, both of which with their attachments are shown in Fig. 1. The jaws of the keyless block, which is shown at the right, are operated by a knurled ring in a manner similar to an ordinary scroll chuck. The regular block is, when shorn of its special attachments, simply a two-jawed universal chuck mounted on a turntable and "ball," the whole thing being set into a ring. This article will deal principally with the regular style, which is shown in detail in Fig. 7.

By examining Figs. 1 and 7 it will be seen that besides the two chuck-jaws *D*, there are two removable false jaws *E*, upon the top of which are placed two semi-circular pieces of

---

* Associate Editor of MACHINERY.

steel *F*, one of which is stationary and the other swiveled. These top pieces have holes drilled about three-quarters of the way through them for the insertion of the various attachments shown in the box and on the table at the left in Fig. 1. The numbers given to the parts correspond to those of similar parts which are shown in the line engraving, Fig. 8, except that 13 and 14 are omitted in the latter, as they are simply a key with a knurled head for light work, and a key with a cross handle for heavier duty. The way these attachments for the top pieces or third set of jaws, are used by the engraver for holding different shapes, is partially shown in Fig. 9. The method of holding a fancy pencil-case is shown at *A*; *B* shows the bowl of a spoon clamped to the block; *C* a spoon handle, and *D* a small locket or pendant. The large rubber-covered hooks shown at 12, Fig. 1, are intended to hold large metal plates, and they are usually used directly in the jaws *D*. The length of the two pins in the false-jaws *E* is such that the jaws will stand, as shown in the engraving. This is often a desirable feature when special attachments are used and the work is interrupted and must be removed for a few minutes on account of other and perhaps heavier work. The pillows *A* shown in the halftone are leather rings which are filled with sand. These rings are far more "clinging" and satisfactory than wood or metal ones.

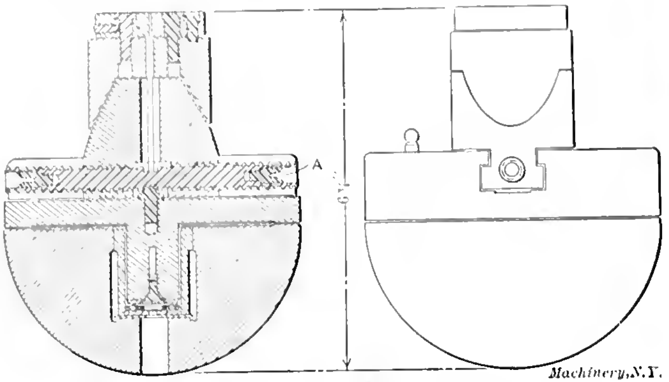

Fig. 7. Elevation and Section of the Engraving Block

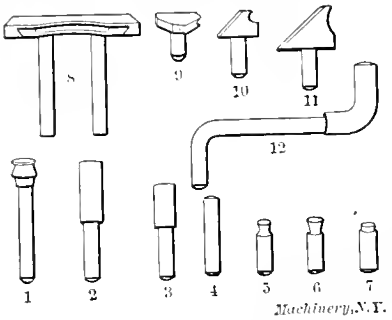

Fig. 8. Auxiliary Attachments for the Block

Making the Bases

The hemispherical, or "ball" bases *B*, are made of cast iron and are cored out to make them light and convenient to handle. In machining these bases they are first placed in an ordinary three-jawed chuck; the "flat" part is then turned and the hole bored as shown by the barrel of castings in Fig. 2. The bases are next held in a Jones & Lamson flat turret lathe, by means of the bored holes which fit over an expanding chuck.

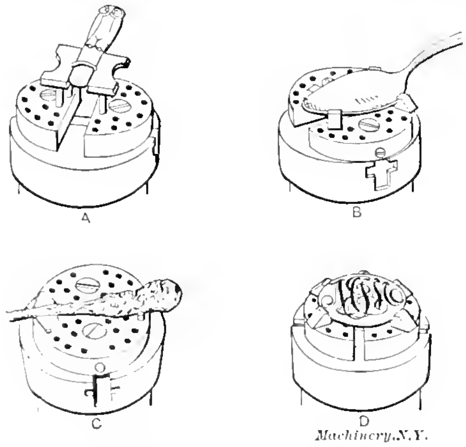

Fig. 9. The Way in which Irregularly Shaped Pieces are held by the Auxiliary Attachments

Most men who have worked in the big watch factories have a strong liking for split chucks, and Mr. Muehlmatt is no exception, as will be evident by examining Fig. 3. This complete set of spring chucks, both expanding and contracting, types, together with the quill and rod shown, were made for use on the Jones & Lamson lathe, to do this special work. It

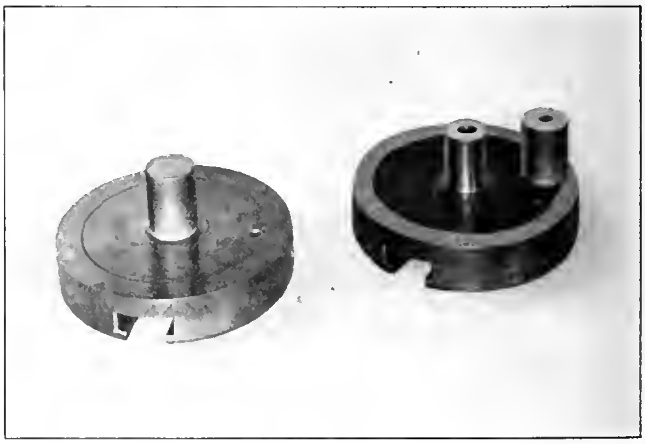

Fig. 13. Method of Protecting Turntable Bearings from Plating Solutions

is seldom that work of this kind is done on a lathe of this type, so that it is worthy of more than passing notice.

Centering, Drilling and Tapping

After placing the base on the expanding chuck, the first operation is to center it for starting the drill, as shown in Fig. 4, using the usual form of flat centering tool. The hole is then drilled, and tapped as shown in Figs. 5 and 6.

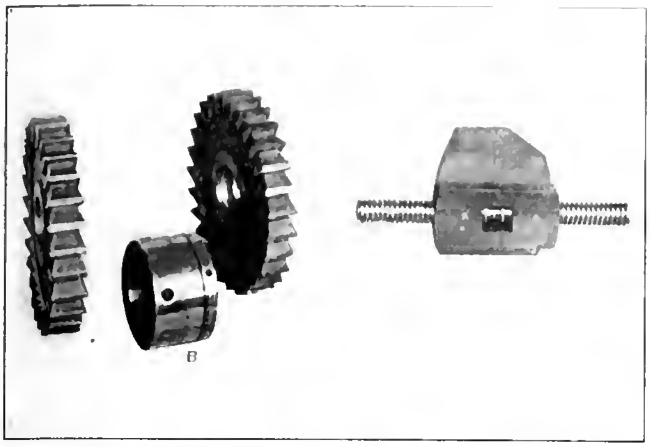

Fig. 14. Micrometer Spacing Collar—Jaws ready to be Machined

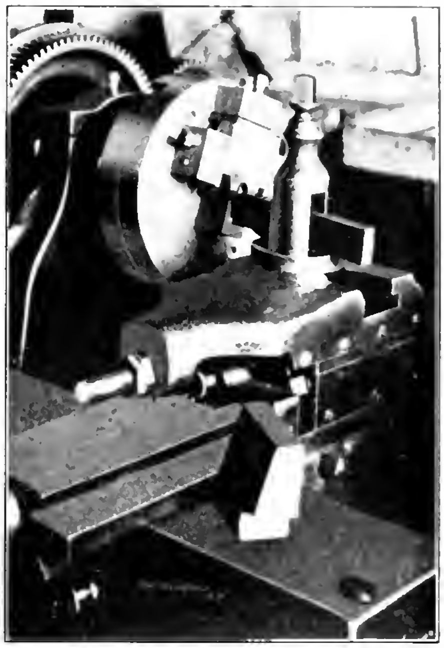

Fig 18. Boring, Threading and Facing Jaws in a Lathe

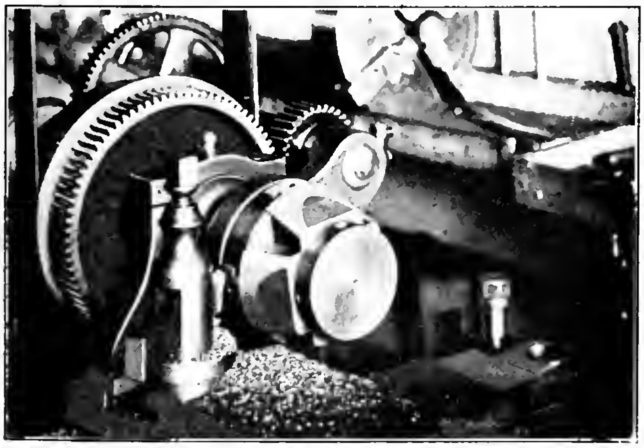

Fig. 19. Turning the Outside of the Jaws in the Lathe

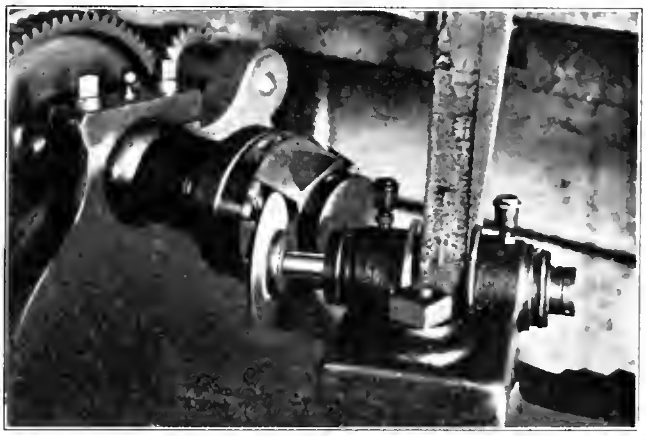

Fig 20 Grinding the Outside of the Jaws

Turning the Hemisphere

The next operation consists of turning the spherical surface, using the device shown in Fig. 10, which was designed by Mr. Muehlmatt. As will be seen, the device consists mainly of a circular-shaped rack or gear-segment carrying a tool-post and tool, which is turned by means of a small pinion, meshing with the gear teeth. This pinion is fastened to an upright shaft having two ratchet hand levers on the upper end. These ratchets are very convenient as they not only allow the levers to be in any position while they are being used, but also allow them to be swung out of the way during the other operations.

After the bases are removed from the lathe they have a small hole drilled in the flat or top part for a stop-pin that locks the turntable and base together when the swiveling motion is not desired. They are then ground and polished ready for the nickelplater.

Machining the Turntables

The turntables C, Fig. 1, a rough casting of which is shown at A, Fig. 11, are first held in a regular chuck, the bottom and stem turned and the small hole for the screw that holds the hardened washer drilled and tapped. The stop-pin hole

is next drilled, using the jig shown at *B*, which slips over the turned stem. This jig is also used to drill the hole in the base just referred to, a collar on one side just fitting the large hole in the base. In this way the stop-pin holes in the two parts are sure to line up. Two small bushed holes are in the jig shown because it is used for two different sizes of engraving blocks. The partly machined turntable is next held in the split chuck *C*, which fits the Jones and Lamson lathe, and the face and outside diameter is turned. The chuck *C* has a face-plate attached to it which has a pin in it fitting the stop-pin hole of the turntable; this pin acts as a driver.

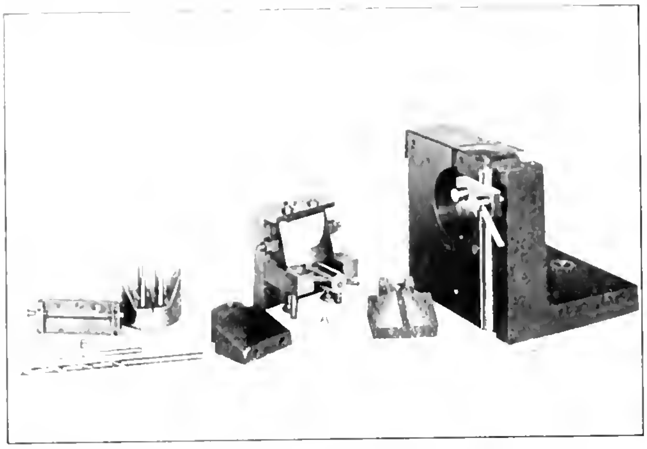

Fig 21. Two Jigs and a Fixture used in the Construction of the Block

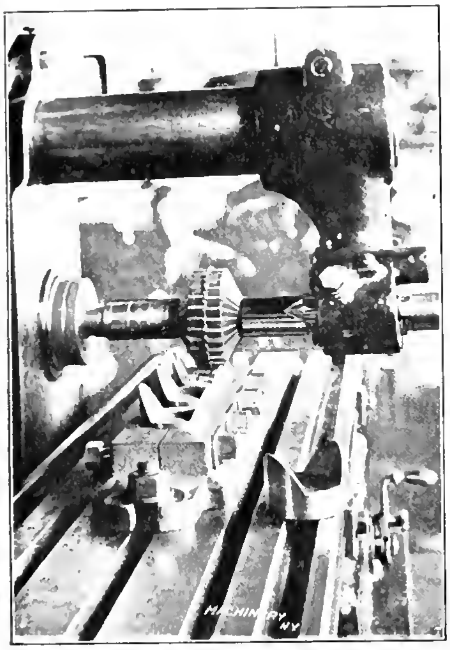

Fig 23. Milling the False Jaw Blanks

Milling the T-slot for the Chuck Jaws

When the turntables go to the milling machine to have the T-slots for the chuck jaws cut in them, they are placed in the fixture shown in Fig. 16 and channelled out. They are then transferred to the angle-plate jig, Fig. 12, and the T-slot finished. The edges of the slot are next rounded with the milling cutter lying on the table; the parts are then ready for the final grinding and plating.

In plating, it is undesirable to have nickel or copper deposited on the stem as it is a bearing, so small metal caps, Fig. 13, are placed over the stems to keep off the solutions.

Fig 25. Tools for Laying Out Holes in Jaws F, Fig. 1

Damaskeening the Turntables

The fancy spotting or damaskeening of the turntable tops is done on a small drill press (Fig. 17), the turntable being revolved on its own stem, which is set into a socket in the special base. The spotting tool used is simply a piece of steel rod, to the end of which is cemented a disk of leather. In doing the work the top of the turntable is smeared with fine emery and oil and it is turned with the left hand while the right works the rapidly revolving tool up and down by means of the hand lever.

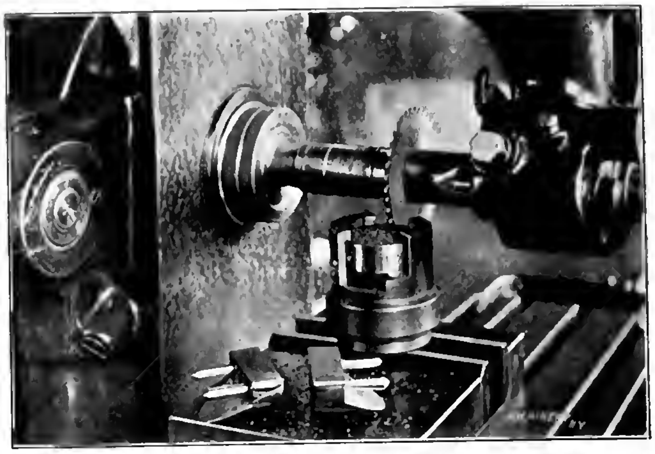

Fig. 22. Splitting the False Jaws in the Milling Machine

Machining the Jaws

Most of the ordinary straight milling on the chuck-jaws, such as facing off the top and sides, is done by holding the piece in the regular vise, but for truing the face of the jaw and boring and threading the clamping screw hole, they are held in the lathe by the fixture shown in Fig. 18. After a pair of jaws have been screwed together, as at *A*, Fig. 14, they are "squared" all over and stamped as mates. In the final fitting to the turntable the idea is kept in mind that while the fit must be good, the parts must work freely and easily with no bind anywhere.

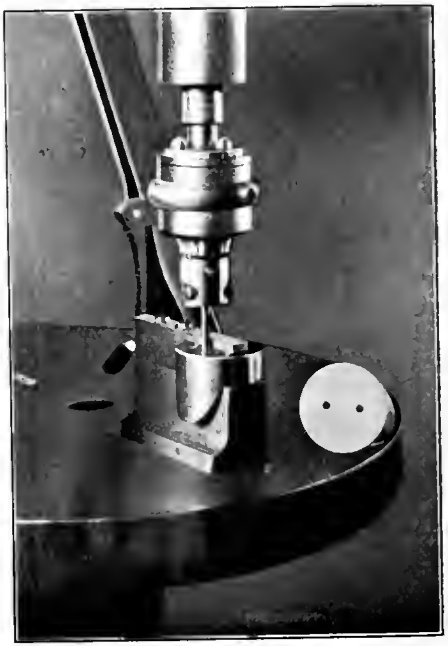

Fig. 24. Jig and Tapping Head for the False Jaws

A micrometer-adjustment spacing-collar is shown at *B* in Fig. 14, which is very convenient for straddle-mill work.

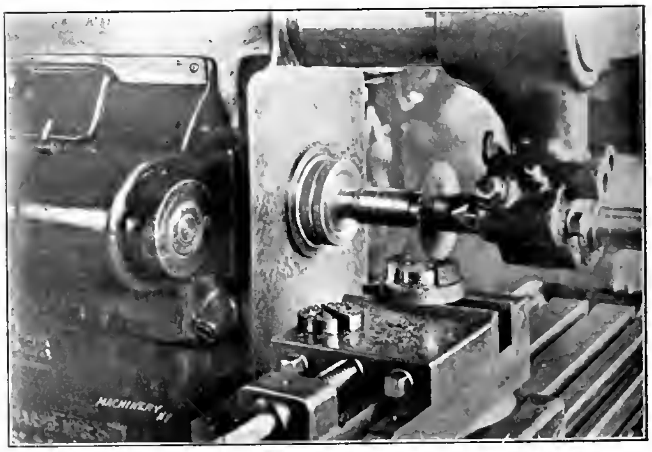

Fig. 26. Splitting the Jaws F, Fig. 1

In Fig. 15 is shown the fixture used for holding the jaws while milling the bevel on them, which is done with a bevel side-mill. Fig. 19 shows the way four of the jaws are held in the lathe while turning them, and Fig. 20 shows how the same fixture is used to hold them while they are being ground.

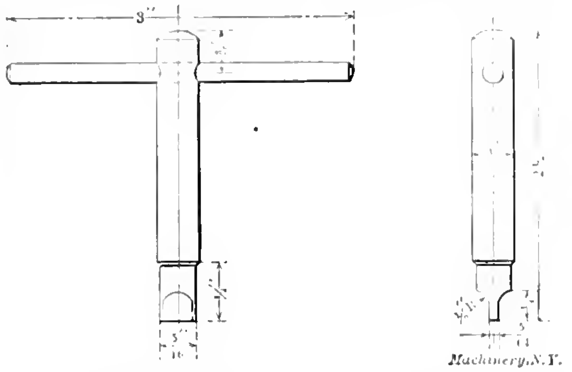

Fig. 27. Key used for Tightening the Jaws

When drilling the holes for the pins which hold the false-jaws in place, the chuck-jaws are placed in the jig shown at *A*, Fig. 21.

The False Jaws

The false jaws are both cast in one piece with a pin or stem on them similar to the one on the turntable, which is used to facilitate handling. The false-jaws are chucked by this stem, the outside turned and the stem is then cut off and the piece faced off at the same time. The blanks are next placed in the fixture, Fig. 23, and milled as shown. The slot which is sawed down the middle is put there to act as a guide for the drilling jig *B*, Fig. 21, used to drill the pin holes and the holes for the upper jaw screws, the jig having a tongue which exactly fits this slot.

The jig and geometric tapping head shown in Fig. 24 are used while tapping the screw holes in the false-jaws. The jaws are then placed in a fixture and split in the milling machine as shown in Fig. 22.

The upper or swivel jaws *F*, Fig. 1, are at first only flat pieces of steel, which are placed, one at a time, into the box-like piece *A*, Fig. 25. The part *B* is then placed on top and a blow given it under the hammer, with the result that all the holes to be drilled in the piece are "spotted" at one stroke by the blunt punches in the bottom; the piece then appears as shown at *C*, while at *d* its appearance is shown after all the holes have been drilled and the piece split. This splitting is done as shown in Fig. 26.

By referring back to Fig. 7 it will be seen that the screw that clamps the jaws together has a rather peculiar arrangement in the ends for the key. Instead of having a square hole, drifted out as usual, it has a piece, *A*, pressed into it.

The way the screw-blank is held while the ends are drilled for this piece is shown at *C*, Fig. 21. After the holes are drilled the small pieces are forced in with a hand-press as shown in Fig. 28, the holder and shape of the punch used being shown in Fig. 29. The style and shape of the end of the key used is shown in Fig. 27. The way these small key-pieces are held while being slotted is shown in Fig. 30. Three other gang jigs are also shown on the table in this halftone. The forcing in of the slotted key-pieces necessarily swells the ends of the screw-blanks to some extent, but as the thread is cut afterward no harm is done. This thread is cut with a Rivett-Dock threading tool. One-half the screw is held in a split chuck with the outer end steadied by the tail-stock center, as

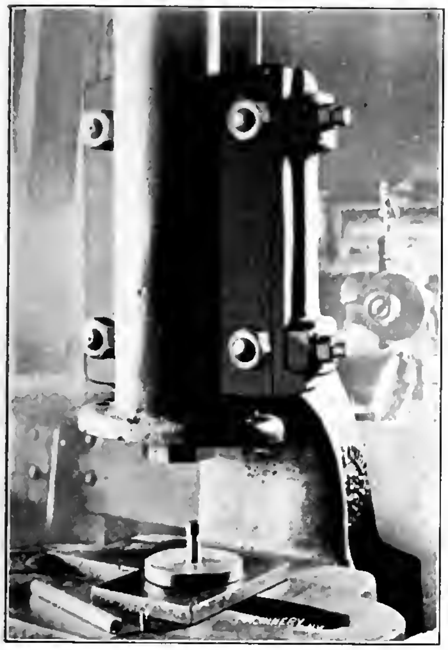

Fig. 28. Forcing the Piece A, Fig. 7, into Place

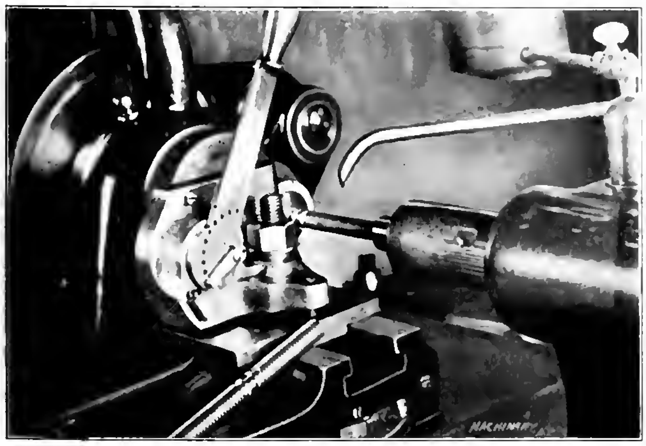

Fig. 31. Threading the Clamping Screws

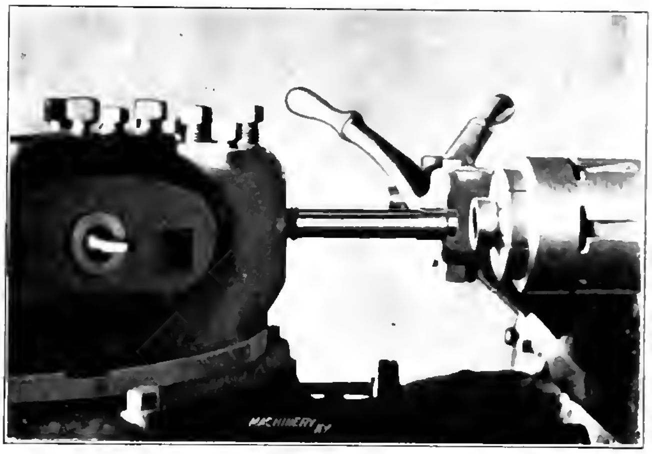

Fig 32. Boring the Turntable Bushings

shown in Fig. 31, the blank having, of course, been previously turned to size.

Bronze bushings are set into the base of the engraving-machine, as a bearing for the stem of the turntable. In machining the inside of these bushings they are held in a draw-in chuck in the Jones and Lamson turret lathe, rough bored, and then finished to size with a Schellenbach-Hunt adjustable boring-bar, as shown in Fig. 32. The use of a boring-bar seems to be the best way to secure accurately bored bushings in this case, as any attempt to finish bore with a tool depending on a carriage stop will not give uniform results.

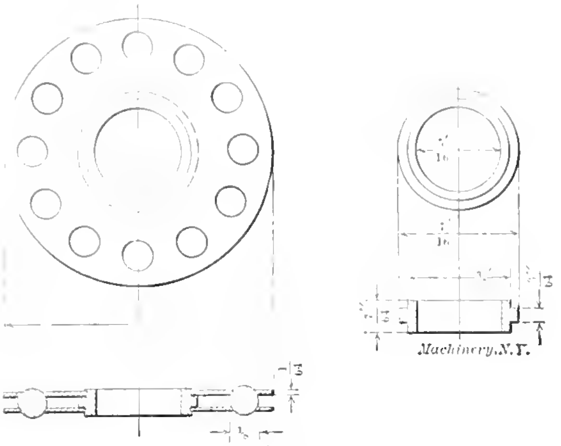

Fig. 33. Detail of the Ball Bearing for the Turntable

At the bottom of this bronze bushing as it rests in place in the base, is a special form of ball bearing which is shown in detail in Fig. 33. The cage consists of two punched disks held together by a hub onto which they are pressed and riveted fast. The manner in which this cage works between two hardened steel disks may be seen by referring to Fig. 7.

* * *

Reinforced concrete is rapidly coming into use as a building material and for making engineering structures of all kinds. It is a material admirably adapted for permanent structures, being practicably indestructible and gaining strength with age. It is not a material easy to handle, however, and special apparatus and experience are required to make a concrete structure secure. Some who are of the idealistic type, are dreaming of an ideal building material which can be molded into form without the difficulties and drawbacks of concrete, and one of the great developments of the future may be a partial realization of these dreams. It is possible that water will be the principal part of the new building material. Suppose that the normal temperature were at or below zero. Water would then make an ideal building material, provided, of course, that it could be readily obtained and that the interior temperature of the building would never rise above the melting point. Ice blocks would then be as good as concrete blocks, and finely divided ice could be used for the bond or mortar at the joints; or water-tight forms could be used to give the desired shape, the water being poured in, and allowed to freeze. Ice structures have been built in northern countries, and used for a variety of purposes, including exposition buildings of large size. The dreamers of an ideal building material have thought of the possibility of discovering a material which added in small proportions to water would cause it to crystallize and take permanent form having strength and heat-resisting qualities equal to cement. When we consider how little solid matter is required to make a firm jelly, it does not seem inherently impossible that the dream may be realized. Granting realization, then, monolithic construction would be reduced to the simplest terms, and the cost of transportation of the greater bulk of the material in cities would be eliminated, save that the charge for water is partly due to the cost of piping to the spot.

A great many women students are, at the present time, studying at the German engineering schools. According to a consular report, 1 230 female students are enrolled at the nine leading German engineering schools.

PATENT LAWS AND THE COST OF MANUFACTURE

In the new British patent act a clause is inserted requiring that articles patented in Great Britain shall be manufactured in that country to "an adequate extent." The United States Consul J. M. McCunn of Glasgow, states that he has been informed that under this law parts of patented machines and devices could be manufactured in the United States and then simply assembled in Great Britain. The ground on which this view is taken is that each part of a machine considered separately is not a patented article, and that the patent merely applies to the machine as a whole. As no test case has been brought into the courts, the Consul states that the previous opinion is the generally accepted reading of the law until a test case has been brought. Should this be a sound opinion it would mean that the new British patent act would be valueless in bringing about the results for which it was framed, and the construction of the law along the lines indicated would be entirely out of harmony with ordinary common sense. From an engineer's point of view assembling in itself cannot be considered manufacturing. A manufacturer of patented articles would at least be expected to make the majority of the integral parts. It is admitted, of course, that it is difficult to draw a distinct line between actual manufacturing and assembling. Many automobile firms, for instance, buy a large proportion of the parts ready-made from manufacturers of specialties in that line, yet, these manufacturers are generally and properly considered makers of automobiles. When assembling pure and simple is referred to, however, it is clear that no engineer would refer to the process as manufacturing, and the British lawyers who would interpret the new law to that effect are likely to find it rather difficult to convince an intelligent court, and even more difficult to secure expert testimony to support their view of this matter.

Taking larger views of the question, however, and considering from the productive engineer's point of view the benefit derived fom a law requiring patented articles to be manufactured in every country where the patent is granted for the article, there is considerable chance for difference of opinion with the framers of the new British patent act. While it is reasonable to require that every inventor or firm owning an invention should make use of it if a monopoly in the manufacture of the article in question is expected, it is not so clear that it is reasonable to require that every patented article should be manufactured in every country where the patent is in force. Such a requirement is simply an indication of the narrow sphere of thought from which mankind is slowly emerging, and is distinctly uneconomical from the productive engineer's point of view. It requires a duplication of plant and special machinery at great expense; in the end no actual benefit is derived by anybody, and the productive capacity of a great number of people is merely turned into wrong and useless channels. The engineer is concerned primarily with the reduction of the cost of production, and to him the question of prime importance should be to what extent any special law reduces this cost. From the engineer's point of view it would evidently be best that the whole world's supply of a certain article be manufactured in one or a few places where the cost of production of that certain article is the lowest. Of course, the economic gain from centralized manufacture would be lost in cases of exceptionally bulky or heavy manufactures, where increased freight charges would become a serious item. In this connection tariff duties between different countries ought to be considered, but as these are artificial and not natural barriers, the engineer may disregard them for the moment when he endeavors to arrive at a law governing the most economical methods of production. In the final analysis, of course, the results of tariffs between different countries must also be considered, as they increase the cost of production of the world's total supply of any one article, and consequently work in opposition to the constant aim of the engineer of decreasing the cost of production and devising means for producing the largest amount of goods at the smallest expenditure of labor.

MACHINE SHOP PRACTICE*

TWIST DRILL GRINDING

The drill is one of the most common tools used by the machinist and it is also the tool which, perhaps, receives the most all-round maltreatment, as will be evident by examining the supply in the average shop. Broken drills and poorly ground points are very closely related, as one is often the effect of the other. An improperly ground drill also means that the quantity and quality of the work is affected; hence, the mechanic should know what the requirements for a correctly formed drill point are, for while it is impracticable to grind a drill theoretically correct by hand, such knowledge will enable one to more closely approach the true form. A machine especially designed for this purpose is, however, to be recommended. The requirements, briefly stated, are as follows: The two cutting edges should be equi-angular with the axis, and of the same length; the angle of clearance for each cutting edge should be the same, and the clearance should increase toward the center of the drill.

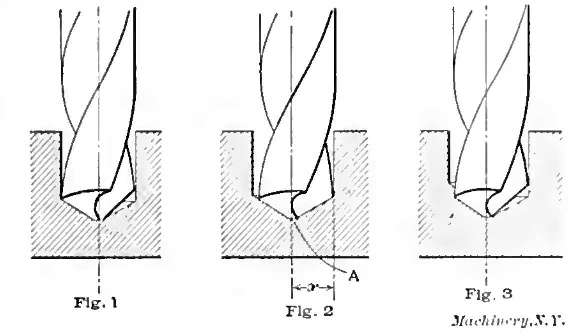

Fig. 1 Fig. 2 Fig. 3

Figs. 1, 2 and 3, illustrating the Effects produced by Drill Points improperly ground

In Fig. 1 is shown the relation of the drill point to the hole bored, when the cutting edges are not at the same angle with the axis. As will be seen, one side will do all, or at least a greater part of the work, thus subjecting the drill to an unbalanced torsional or twisting strain, which does not occur when each cutting edge is in action, as then the tendency of each side to spring away from the cut is counterbalanced by the opposite side. The drill will also be forced against the side of the hole, resulting in an enlargement of the latter.

The effect produced when the lengths of the cutting edges are unequal is illustrated in Fig. 2. As the drill, when it is fed into the metal, revolves about the center *A*, the horizontal distance *x*, from this point to the longest side, will be equal to the radius of the hole, which will, of course, be larger than the drill diameter if the point *A* is not central; hence, if holes of the correct diameter are to be drilled, each cutting edge must be exactly the same length. In Fig. 3 is shown a drill point having cutting edges inclined at different angles to the axis, and of different lengths, thus combining the disadvantages mentioned in the foregoing.

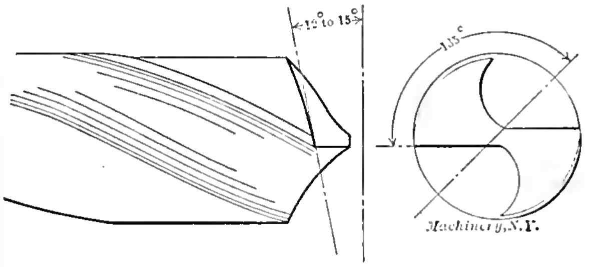

Fig. 4. Clearance Angle at the Periphery and Angle that the Point should make with the Cutting Edges

The clearance for the cutting edge is a very important feature of drill grinding. Drills split through the web are usually an indication of improper clearance or excessive feed. If the end of the drill conformed exactly to the shape of the bottom of the hole, obviously it would not cut, as the lack of clearance would make it impossible to sink the cutting edges into the metal; consequently, when there is insufficient clearance for a given feed, the drill binds back of the cutting edges, thus subjecting it to an excessive torsional strain. Theoretically, the clearance should be just enough to permit the drill to cut freely, in order to give the cutting edges the maximum amount of support. The Cleveland Twist Drill Co. advocates a clearance angle of 12 degrees at the periphery of the drill, with a gradual increase toward the center until the point or line joining the two cutting edges is at an angle of 135 degrees, as shown in Fig. 4. When soft material is to be drilled and heavier feeds are used, the angle of clearance may be increased to 15 degrees, while for hard material such as tool steel, for example, the amount of clearance can be diminished as the feed must necessarily be light, and a strong cutting edge is required.

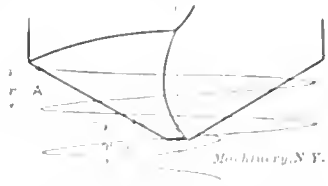

Fig. 5. The Angles of the Helical Paths described by the Points A and B show why the Angle of Clearance should increase toward the Drill Point

As previously stated, the clearance should gradually increase toward the drill point. The reason for this will be apparent by considering the movement of two points *A* and *B* (Fig. 5) on the cutting edge, as the drill is fed downward, one point being much nearer the center than the other. Assuming that the feed is constant, the path described by each of these points will correspond to that indicated by the helical lines shown. As the vertical distance *x* that each point moves per revolution of the drill will be the same, the angle of the smaller helix or spiral will be greater than that of the larger one. The angle of the helix, in each case, indicates the minimum clearance necessary at that particular point, for a feed per revolution equivalent to the distance *x*. The amount of feed indicated has been greatly exaggerated in order to make the comparison clearer.

There is a difference of opinion concerning the exact shape of a drill point, both in regard to the form of the end and the angle between the cutting edges. The Sellers grinder (the operation of which is described in the Shop Operation Sheet accompanying this issue) so controls the drill in relation with the grinding wheel that the surface of each lip conforms to the segment or part surface of a cone, as shown in Fig. 6. The axis *a-a* of the cone is inclined to the axis *b-b* of the drill, and also lies in a different plane, as shown in the view to the right, thus giving the cutting edge the required clearance which, obviously, increases toward the drill point. If we assume this hollow cone to be a grinding wheel revolving about the axis *a-a* with the drill point held against it as shown, the surface of one lip will evidently be ground to the desired conical form. It is not necessary, however, in order to grind each lip to this form, to resort to such a method. In the drill grinding machine referred to, this same surface is produced by turning the drill, which is held in a suitable chuck, around the axis *a-a* of the cone, while an emery wheel having a flat surface tangent to the surface of the cone, grinds the point.

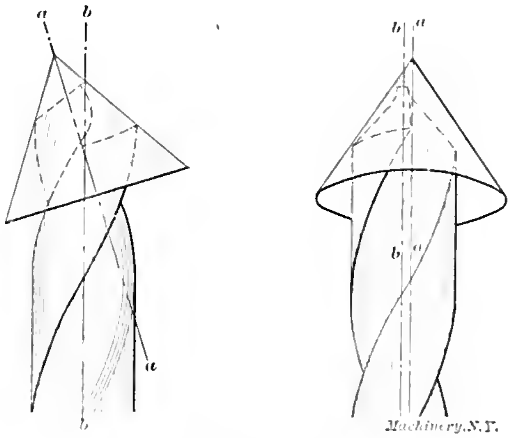

Fig. 6. Form given to the Lip of a Drill by the Sellers Drill-grinding Machine

As to the angle of the point, recent tests (the results of which are given in this and the May issue) have demonstrated that an included angle of 118 or 120 degrees is about right. The pressure required to force a drill through the metal be-

---

* With Shop Operation Sheet Supplement.

comes less as the angle of the point is diminished, but the power required to turn it increases; therefore it is not advisable to have the angle of the point too acute, as then the power consumption will be too great, and, on the other hand, the point should not be too blunt, owing to the excessive end-thrust and the resulting strain on the machine.

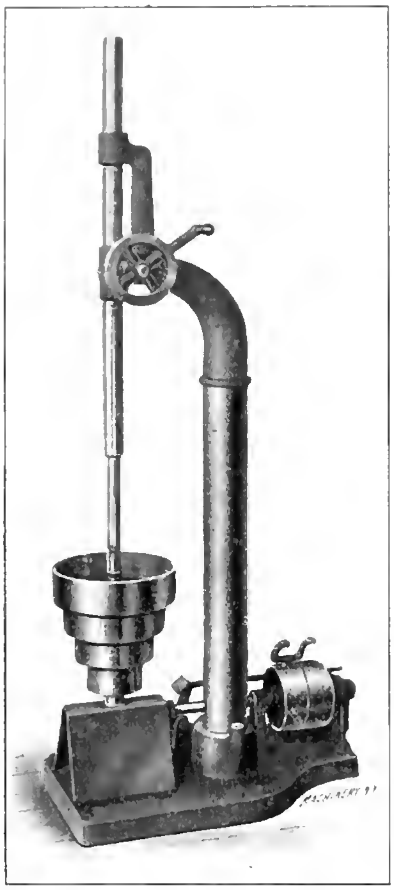
REAMING MACHINE FOR CHAMBERED HOLES IN PULLEYS AND SPINDLE SLEEVES

The difficulty of obtaining a true hole when reaming in a lathe or drill press, particularly when the parts to be reamed have chambered or relieved holes, is well known; in the latter case it is almost impossible to get the two ends of the hole to line up, even though floating reamers be used for this purpose. In order to overcome these difficulties the Hoefer Mfg. Co., of Freeport, Ill., has built, for use in its own shop, the reaming machine shown in the accompanying illustration.



Machine for Accurate Reaming of Long Holes in Pulleys, Sleeves, etc.

The base and column are the same as used for the company's regular 16-inch drills. The metal cover fastened to the base encloses a bracket carrying a bevel gear and pinion transmitting the power from the pulleys shown, to the spindle of the device. The key or drift hole of this spindle is shown just below the cone pulley. The end of the spindle which points upward, fits a No. 3 Morse taper and holds the shank of the reamer arbor. On this arbor an adjustable shell reamer is placed, and at the upper end of the arbor, just above the reamer, a small pilot is provided which enters into the guiding arbor above it. This guiding arbor is, in turn, held in the non-rotating spindle carried by the column. As shown in the illustration, a rack is attached to this spindle by means of which it can be raised and lowered by the wheel and lever shown.

The device is used for reaming spindle sleeves, pulleys and the holes in various gears. These holes are first bored in a drill press by means of a special boring bar extending through the cored hole of the sleeve into a revolving bushing in the base of the jig. The boring bar is provided with two double-ended cutters placed about one inch apart, one cutter being used for roughing, and the other for finishing the hole about 0.010 inch under the standard size. The guide bar of the reaming machine (held in the upper non-rotating spindle) is ground to a sliding fit for the bored pulley or sleeve.

In operating the reaming machine, the upper non-rotating spindle with its guiding arbor is raised, and the pulley is slid onto the arbor. The spindle is then lowered until the guiding arbor engages the pilot on the end of the reamer bar, and the operator starts up the machine, meanwhile holding the cone pulley with both hands on opposite sides of the rim. As the lower spindle rotates, he exerts a slight pressure on the pulley, thereby feeding it over the reamer until the latter comes through at the top. Since the guiding bar above and the shank of the reamer arbor below quite closely fit the hole before and after reaming, respectively, any error in the alignment of the hole is hardly possible. The upper and lower corners of the reamers are stoned off by a small oil stone, and a very smooth hole results in the work. The reaming is done by the drill press operator, who performs the reaming operation while a hole is being bored in the drill press, the two machines being placed near together. In the illustration a pulley is shown finish reamed, the reamer being visible at the upper end of the pulley, which is supported by the shank of the reamer arbor.

OFFSETTING CYLINDERS IN SINGLE-ACTING ENGINES*

A great deal has been said recently about the offsetting of cylinders in single-acting engines and many claims of superiority are made by those who employ this form of construction. About twenty-five manufacturing establishments in the United States are building engines in which the cylinders are offset, chiefly those of the automobile type, and one company is formed for the purpose of making engines in which the offset is equal to the crank radius and the connecting rod length is about 3¾ times the crank radius. Among the claims made by manufacturers for offset engines are: greater power, less side-pressure of the piston on the walls of the cylinder, better turning effort, less vibration, smoother running qualities and when one cam shaft is used, a more convenient mechanical arrangement.

The author of this paper gives a complete mathematical analysis of the effect on the length of stroke, turning force, side-pressure of piston on cylinder, etc., under various conditions of ratio of length of crank to length of connecting-rod and amount of offset, the latter ranging from zero to an amount equal to the length of the crank. The mathematical expressions by which these conditions are investigated take into account the length of the crank, the length of the connecting-rod, the amount of offset, the area of the piston head, the weight of the reciprocating parts and the revolutions per minute. The engines of various manufacturers are made by means of these mathematical expressions, and the effects on side-pressure, vibrations, etc., are all tabulated. In brief, the results of these investigations may be summarized as follows:

Offsetting increases slightly the length of stroke and the crank angle passed over during the stroke toward the crank shaft.

The maximum value for the side-pressure of the piston on the cylinder walls decreases as the offset increases up to the value of one-half the crank radius for any ratio of $L \div R$.

The work lost in friction due to the side-pressure of the piston on the cylinder walls decreases as the offset increases up to a value of 75 per cent of the crank radius.

Both the maximum value of the side-pressure and the work lost in friction increase as the value of the ratio $L \div R$ decreases.

Offsetting decreases the height and weight of the engine.

Offsetting increases the life of the cylinder and piston.

Offsetting improves the thermal cycle.

The author makes the following comparison of the importance of these various considerations:

Improvements due to offsetting, (1) in the thermal cycle, (2) in the mechanical arrangement, (3) in the turning effort curve, and (4) in lubrication, are very slight and may be neglected. The real advantages are:

a. A reduction of the frictional losses due to the pressure of the piston on the walls of the cylinder, resulting in a slight increase in mechanical efficiency and less wear of the piston, piston rings, and cylinders, and consequently longer life.

b. A reduction of the maximum value of the side-pressure of the piston on the walls of the cylinder allowing the use of shorter connecting rods, shorter pistons, and shorter cylinders, resulting in a shorter and lighter engine and in lower inertia-forces due to the reciprocating parts.

The most important of these advantages would be a considerable saving in weight.

The disadvantage of offsetting lies in the fact that the reduction in average side-pressure and maximum side-pressure grows less as the speed and inertia-force increase, so that for a speed of 1,400 to 1,500 R. P. M. there is either no reduction at all or an increase.

---

BORING MILL GAGE AND A SWAGE HOLDER

A short time ago B. W. Cooper, general manager of the Danville Foundry & Machine Co., showed me a handy little attachment used on their big boring mills for sizing large pulleys and fly-wheels. The device (shown in Fig. 1) consists of a bar of one-inch cold-rolled steel about three feet long, fastened by cast-iron brackets to the inside of the housing of the mill and back far enough to clear the cross-rail nicely. On this bar is a sliding cast-iron bracket carrying a measuring rod, as shown in Fig. 1. Rods of suitable length for sizing every standard-size pulley or fly-wheel made in this shop are kept in a rack close to the mill, and when a job is put on, a rod numbered to correspond to the number of the casting to be turned is put into the socket in the bracket and shoved in as far as it will go. It is then locked in place by turning the little hand-wheel screw shown. With this device, work can be brought to size with the mill running at full speed, as the right diameter has been obtained when the point of the measuring rod will just swing past the piece. When the gage is used with the machine revolving it should be swung against the work from the rear side or against the direction of rotation to prevent it from being forced past and bent. This tool may be used effectively on any large circular work, the outside of which is turned on a boring mill, as anyone who has had to use calipers on such work will understand.

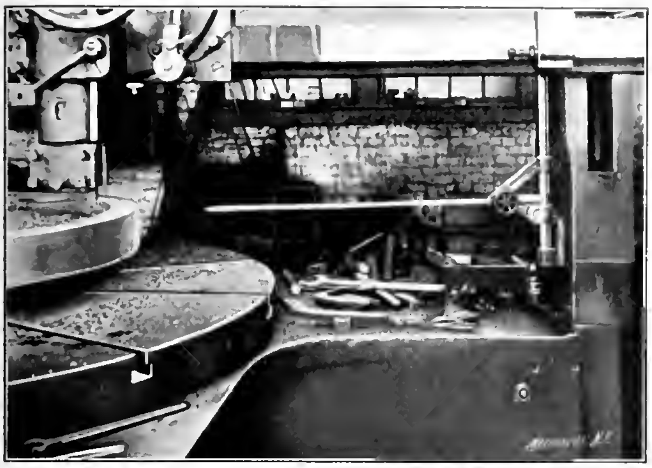

Fig. 1. Device for Measuring Circular Work on the Boring Mill

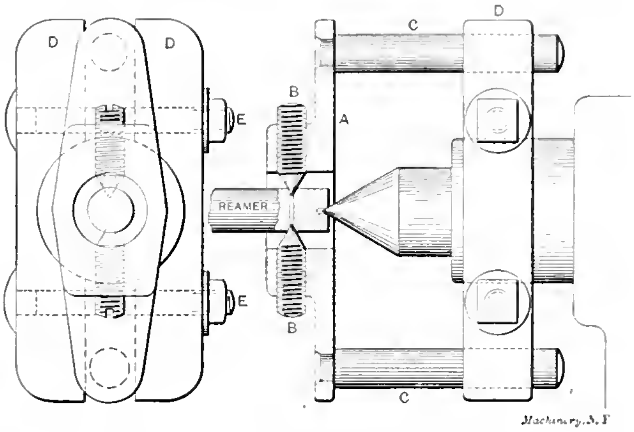
Fig. 2. A Steam-hammer Swage-holder or "Deadman"

Another very good thing that I saw in this shop is the "deadman," or swage-holder for the steam hammer, shown in Fig. 2. For the blacksmith, with only one helper who must be used to operate the hammer, this tool is extremely useful. As will be seen, the holder is made to take almost any style of spring-swage and is adjustable for height by means of staggered holes in the upright piece and a pin in the socket on the base-strap. The base-strap can also be moved around the block by loosening the clamping bolt, which allows the swage to be placed in different position on the anvil. E. V.

AN IMPROVED REAMER HOLDER

When reaming in the lathe the tendency for a reamer to slip off the center is not due to any inclination of the reamer itself to draw into the hole faster than it is fed in, but due rather to the fact that there is very little stock being removed, and that the reamer is usually held from rotating by a dog or holder of some kind which acts on one side only, thereby tending to pry the reamer off the center. When a reamer is held in this way there is also a liability of its reaming different size holes owing to the fact that sometimes it may have a little more stock to remove than at others, and that it may be fed faster in one hole than another; which in either case would tend to spring the reamer a little more out of line in one hole than another, thereby causing the holes to vary in size. This is especially true with small reamers with long shanks.

To overcome these difficulties the writer devised the holder shown in the accompanying illustration. The idea in part was borrowed from Prof. John E. Sweet's double-tailed dog. Referring to the sketch, *A* was made from a piece of machinery steel about ⅞ inch x 1½ inch x 5 inches. The clearance hole for the reamer shank is 1 inch and it will take reamers up to 1⅛ inch in diameter and some larger ones, this depending, of course, on the size of the shank. The holes for the pivot screws *B* should be drilled and tapped clear through from one way before the clearance hole for the reamer is drilled, so as to bring them nicely in line. The pivot screws are made from tool steel and hardened; the included angle of the points is 60 degrees. The studs *C* are ½ inch cold rolled steel. The driver *D* which is clamped on the tailstock spindle, is made from hard maple, which answers the purpose just as well as though it were made of cast iron or steel. A good way to make it is to bore a hole in a block of wood to fit the tailstock spindle, and drill the holes for the carriage bolts *E;* then cut enough out through the center of the block so that the studs *C* will be a loose fit in the slots when the driver is clamped in place as shown.



Machinery,N.Y.

Holder which prevents a Reamer from Sliding off the Center

To get the female centers in the reamer shank approximately in line to receive the pivot screws, drill a small hole through the shank of the reamer and countersink with a center reamer. It is not necessary that the hole should pass exactly through the center of the shank. The shanks of most reamers will be found soft enough so that they may be drilled readily. The studs *C* fit loosely in the blocks *D*, but when the reamer tries to rotate they come against these blocks, and being on opposite sides of the reamer and self-adjusting, the reamer will be held without any cramp, and there will not be any tendency for it to lift off the center. In using this holder all that is necessary for safety is to pass a string or belt lace around the holder and driver and hold it with one

hand, well out of the way, while feeding with the other. Another point of advantage is that the shanks of the reamers will not become marred or bent.

Syracuse, N. Y. **George G. Porter.**

DISTINCTIVE COLORS FOR PIPING IN A MANUFACTURING PLANT

The question of using distinctive colors for the various lines of piping in a manufacturing plant is one that has scarcely received the consideration that it deserves. The fact that a pipe is a pipe and that the line gives no trouble is enough for a great many superintendents and works managers. If there be any trouble there are the plumbers and pipe fitters who put up the job; let them look after it. They have made all of the changes and put in the new connections and know practically the exact location of every valve and union in the system. The thing that the superintendent does not stop to consider is this: There is the possibility that the men who did the work may leave the employ of the compuany before new men have been on the job long enough to have learned all of the details of the system, the result of which might be, should an accident occur to, say a water line, considerable damage before anyone unfamiliar with the system could trace the line through a network of piping to a valve controlling the supply. With the different lines of piping painted distinctive colors, it would be a comparatively easy matter for anyone to trace the particular line to a valve, shut the valve and stop the flow of water before any great amount of damage had been done.

Color Board giving List of Pipes and Wire Moldings with Name and Sample of Color

The best example of a color scheme for piping that has come under my notice, is the one in use at the Hawthorne plant of the Western Electric Co. They not only use distinctive colors for the different pipe lines throughout the plant, but they have extended the use of the color scheme to the moldings of the wiring system. Moreover, I noticed that there were "color-boards" upon the walls of the different buildings. The boards were about six or eight inches wide and probably eighteen inches long, and had a list of the lines of piping and moldings, the name of the color distinctive of each line of pipe or molding, and a small rectangle painted with the particular color, as indicated in the accompanying illustration. Thus there was no possibility of a workman mistaking the line unless he was unable to read or was color-blind.

This color scheme is not standardized by any means, but it has the advantage of covering a wide range—more than most shops would need—and it was carefully worked out, the idea being to get colors that would "hold" and still not be so near alike in shade as to be confusing to the workmen.

Columbus, Ohio. **C. E. Bliven.**

LUBRICANT FOR LATHE CENTERS

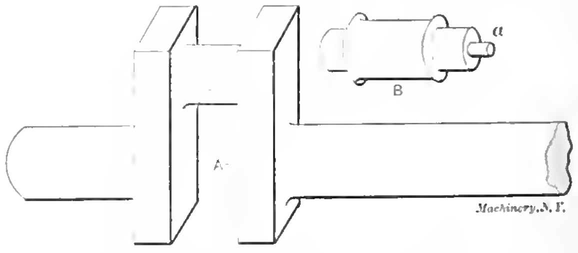
Until recently I have had considerable trouble with lathe centers, especially on small work when using high speed steel, as the work is revolved so fast that it is almost impossible to keep the centers from cutting. White lead is used by many to remedy this trouble, but I do not know what advantage white lead has over ordinary machine oil, unless it is the odor that is given off when the centers become heated, as this acts as a sort of warning. It may not be generally known that dry or powdered red-lead, mixed with a good grade of machine oil to about the consistency of cream, is an excellent lubricant for lathe centers. Since using this mixture I have never had a center cut, though they get very hot sometimes.

In order to test the efficiency of this lubricant as compared with a mixture of graphite and white lead composed of equal parts of these materials mixed with the best grade of machine oil, a piece of machinery steel 7/16 inch in diameter was placed between the lathe centers (which were lubricated with the graphite mixture) and revolved at a speed of 490 revolutions per minute for five minutes without stopping. After the piece had been revolving about two and a half minutes I could not bear my hand on it, and it was necessary to loosen the tail-stock spindle in order to give the lubricant a chance to work in between the bearing and center. At the end of four minutes the lubricant was smoking badly, and at the end of five the piece was taken out of the lathe, and the center examined. There was a slight burr thrown out around the hole, and by the aid of a glass it could be seen that considerable cutting action had taken place. The red lead and machine oil mixture was then used for lubricating the centers, with the result that when the piece was removed from the lathe at the end of five minutes, the hole did not show any cutting action whatever, but instead was very highly polished.

Geneva, N. Y. **Roy B. Demino.**

REPAIRING A LARGE CRANK-SHAFT

Some time ago I was called upon to repair the crank-shaft of a large pumping engine, which had a crank-pin broken as indicated in the engraving. This shaft was 18 feet long, 14 9/16 inches in diameter and had two cranks with pins 10¼ inches in diameter by 10 inches long. It was a solid forging and weighed 10,880 pounds. The broken ends of the pin, attached to each web, were first drilled and planed off smooth. Each piece was then placed in a horizontal boring mill and roughly bored for the new pin which was to be fitted. The two faces *A* were then bolted together with the webs exactly in line, and placed in the mill a second time and bored, thus bringing the two holes absolutely in line. The webs, still bolted together, were next put on the planer and key-seated, and in this way both key-seats were also kept in perfect alignment. The pin was then forged and turned to the required



Large, Solid Crank-shaft which was broken as indicated, and repaired by Forcing a Pin into the Webs

size, as shown at *B*. After it was finished in the lathe it was placed between the centers of the milling machine, and key-seats were cut into each end. A small part *a* was left on one end as shown, so that the pin could be turned in the lathe, and key-seated, without changing its position on the centers, thus keeping both key-seats and fittings in perfect alignment. Ninety tons was decided to be the proper pressure for forcing the pin into place, so, for an experiment, I used the formula and factor curve in the Data Sheet of August, 1903, by Stanley H. Moore, and found it to be correct. The formula given in this Data Sheet for determining the required pressure in tons is:

$$P = \frac{A\,D\,(P\,F)}{2}$$

where *P* equals pressure in tons, *A* equals area of fitting in square inches, *D* equals difference in diameter between plug and bore, *PF* equals pressure factor taken from the Data Sheet chart. The required pressure or the value of *P* was 90 tons, so transposing the formula and solving for *D* it became:

$$D = \frac{2\,P}{A\,(P\,F)}$$

The holes in the webs for the new pin are 8 inches in diameter and 7 inches long, and by referring to the curve in the Data Sheet the value of *PF* for an 8-inch fitting was found to be 55, so, substituting the known values:

$$D = \frac{2 \times 90}{8 \times 3.1416 \times 7 \times 55} = 0.0186 \text{ inch.}$$

As the hole was counter-bored a short distance, thus cutting down the area, I increased the allowance for the fit to .019 inch, with the result that the pressure required to force the pin into place was approximately 90 tons. A hydraulic press was used for this purpose and the pin was forced into the lightest half of the crank first. After the shaft was tested in the lathe and found true, the ends of the pin, which were made 3/16 inch longer than the web thickness and hollowed out on the end, were riveted over into the countersink in the web. The bearings were then turned true, and the job was finished.

Augusta, Ga.

SUB-PRESS DIE FOR SPECIAL SPRINGS

The die described in this article was designed and made for the manufacture of a special spring used in connection with a heat regulator. This spring is of an irregular shape, and it was conceded that the only proper way to obtain these springs at a reasonable cost was through the medium of a punch and die. The first set of dies for this work was made in the ordinary way, without applying the sub-press principle, but these tools were soon found to be of little value, as the steel used in the springs was a special grade, hard to punch, and it was essential that the blanks must come from the press straight. The tools just mentioned would not leave the blank straight, and only a few could be punched before the die would be sheared and thereby rendered useless. The sub-press die described in the following was then designed, and, after being made and put in commission, proved satisfactory. A large number of blanks have already been punched, and the die is still in good condition. The spring shown in Fig. 1 is 18¼ inches long × 1⅜ inch wide on central part of the spring, and ⅞ inch wide on the wings; two ½-inch holes are pierced in the central portion, and a ¼ inch hole in each wing. The thickness of the stock used in the spring is 0.055 inch. The width of the stock is equal to the length of the spring. The springs are cut from the end of the sheet to allow the stock to be fed through the die from front to back.

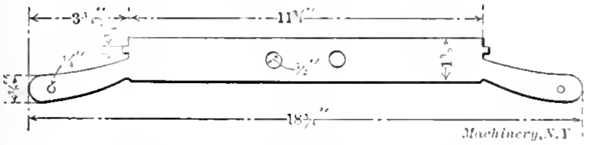

Fig. 1 Spring to be made in Sub-press Die in Fig. 2

The die holder *A* shown in Fig. 2 is made of cast iron, finished on the top and bottom and on all bosses. The top is recessed to fit the die, which is 1 inch thick × 6¾ inches wide. More will be said about the die holder subsequently. The die is a sectional die, consisting of four pieces; the two pieces *C* and *D* are 1 inch thick × 3¾ inches wide × 10¼ inches long; the two pieces *E* and *F* are 1 inch thick × 3½ inches wide × 10¼ inches long. The four pieces are finished on all sides, and are then placed in position on a surface plate, and the form of the spring is scribed on the surface. The stock is then removed to within 1/16 inch of the scribed line. The screw and dowel holes *G* are next drilled, there being three screw and two dowel holes in each of the four pieces. Each of the sections is next fitted tightly into its proper position in the die holder. The die holder is then placed under a drill press, and the holes are transferred into it from the sections. The screws used are ½-inch filister head cap screws; the dowels are made from ⅜-inch drill rod. With the die still in position, the four square key slots shown are laid out, one-half of the slot, which is ⅜ inch square, being in each section of the die. These keys serve to keep the four sections of the die in an accurate position, and thus prolong its life.

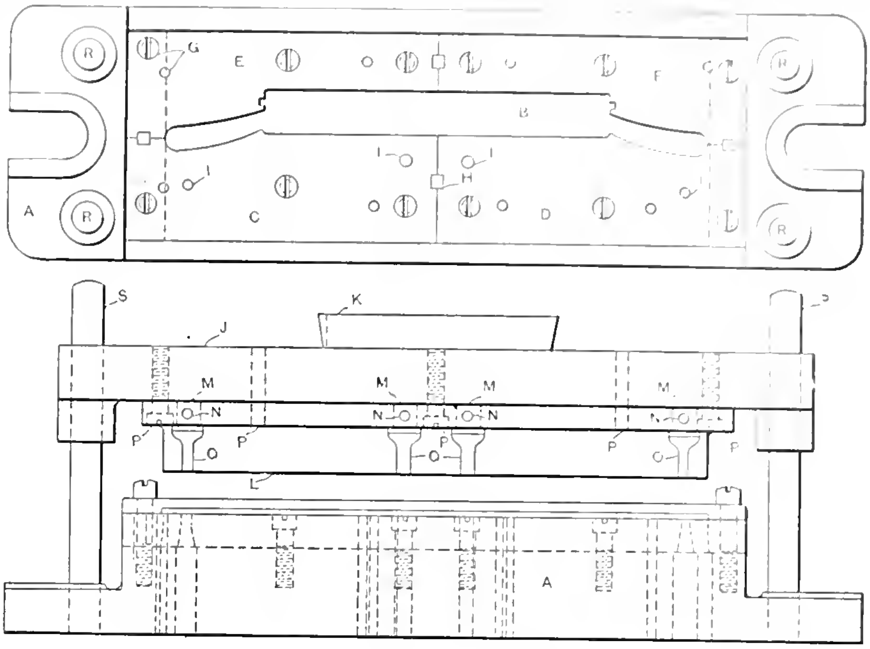

Fig. 2. Plan and Elevation of Sub-press Die for Making Spring shown in Fig. 1

Before removing the sections, the templet of the spring is laid on the top surface of the die, and with a scriber the outline of the templet is scratched on the die. The sections are now removed and the keyways *H* are machined accurately to the lines, and the form of the spring, which has already been roughed out, is finished. The holes *I* to be pierced in the blank are now laid out, drilled, and reamed. This work finishes the machine work, and the sections are now ready to be hardened and tempered in the usual manner.

The reason for making this die in four sections was that the die, being 20½ inches long over all and the hole for the blank 18¼ inches × ⅞ inch, it was impossible to harden the die successfully in one piece. The sections being hardened, and the temper drawn, the edges of the sections are ground to a true surface, a very small amount of stock being removed.

When the bottoms of the sections have been ground, they are again placed in position in the die holder. With a scriber the hole for the blanking punch, as well as the four holes for the piercing punches, are scratched through the die on the die holder. The sections are then removed, and the stock in the die holder machined out to allow the blank and piercings to fall through. The sections of the die are then

replaced and fastened in place by the screws. The dowels are fitted and driven in place, as well as the square keys. The die is now ready to receive the punch shown in elevation in Fig. 2. This is made as follows: The punch holder *J* is of cast iron, machined on the top, bottom, and on the bosses. The dove-tail *K* is fitted to the ram of the press. The punch *L* is of tool steel 2½ inches thick, 6¾ inches wide, and 19½ inches long. This piece of steel is machined on all sides, and the punch fitted to the die. The holes for the piercing punches *M* are now transferred through the die into the base of the punch; after these holes are drilled and reamed, the punch is removed from the die. The set-screw holes *N* are drilled and tapped. The punches *O* are turned and fitted into the base of the blanking punch.

The punch is now ready to be fastened to the punch holder. In order to do this, the punch is placed in its working position in the die; the holder is then placed on top of the punch, and the bosses for the guide pins lined up in position. With a scriber the outline of the base of the punch is scratched on the punch holder; the punch is then removed and the screw and dowel holes *P* drilled and counter-bored in its base. The punch holder is then placed in position to receive the punch, which is placed on the holder between the lines already scratched, and the screw and dowel holes *P* are transferred through the punch to the holder. The holes are then tapped, and the punch holder is now ready to receive the punch, which, after being fastened by the screws, has the dowels fitted, and driven in place. This punch is not hardened, but left in its soft state, to allow for staking and cutting in the die in case it wears small.

The piercing punches *O* are now fitted; the shank is fitted to the punch base, and the opposite end to holes in the die. These punches are then hardened and tempered, after which they are placed in position in the blanking punch, and fastened by set-screws *N*. The punch is now complete, and placed in working position.

The punch and die is then fastened on a horizontal boring mill, and the four guide pin holes *R* are bored, great care being taken to have these holes exactly in line. After boring, the holes are reamed, using a lining reamer, which insures perfect alignment. The guide pins *S* are next turned to 1.015 inch diameter, and 11¾ inches long. After turning, the pins are hardened and tempered, and then ground the entire length. The ends fitting the die holder are a driving fit, the remaining part being a sliding fit in the holes in the punch holder. The punch and die are then ground on the cutting surfaces, and, after driving the guide pins in position, the punch is placed on the pins and gently lowered to the face of the die, to test the accuracy of the tools. If the punch enters the die equally free on all sides, and the piercing punches are found to be in line with the holes in the die, the punch and die are pronounced ready for use.

This tool proved satisfactory from the start, and nearly 25,000 springs have been blanked to date, the blanking punch having been staked and cut in once, which operation required about one hour's time. NOTROH.

ISOMETRIC PERSPECTIVE

I must take exception to one or two statements of Mr. Honey in MACHINERY for August, 1907, as regards isometric perspective. In the first place, "perspective" is not in this connection "an erroneous expression." According to the first definition in the Standard dictionary, perspective is "the art or theory of representing, by a drawing made on a flat surface, solid objects or surfaces seen as not lying in that surface; delineation of objects as they appear to the eye; specifically, in mathematics, a branch of projective geometry."

Isometric projection certainly fills this bill as far as the first part of the definition is concerned; and if we consider objects as they appear to the eye, their appearance depends entirely on the point of view. In the so-called "painter's" or "diminishing" perspective, the object appears to no two observers the same. It just happens that in isometric perspective or projection, the point of view is an unusual one—namely, one in a line passing through the object at an equal angle to all three co-ordinate axes; an angle best expressed in familiar language by saying that it corresponds to that of the greatest diagonal of a cube. If a cube be so tilted that the line of sight passes through this greatest diagonal, the outline presented will be a regular hexagon, with the nearest corner of the cube in the center of the circumscribed circle. This is the exact isometric projection of the cube. A photograph taken of a cube with this greatest diagonal in the axial line of the camera lenses would exactly coincide with an isometric perspective of the same cube, care being taken that the scale was the same.

The isometric representation is by no means "distorted." The fact that such a body as a cube, which is symmetrical with regard to every axis, is reproduced isometrically as a perfectly symmetrical drawing, whereas the "diminishing" or "artistic" perspective or projection of the same cube may have no two sides or angles alike, shows that the isometric projection is in fact the only one which is *not* distorted.

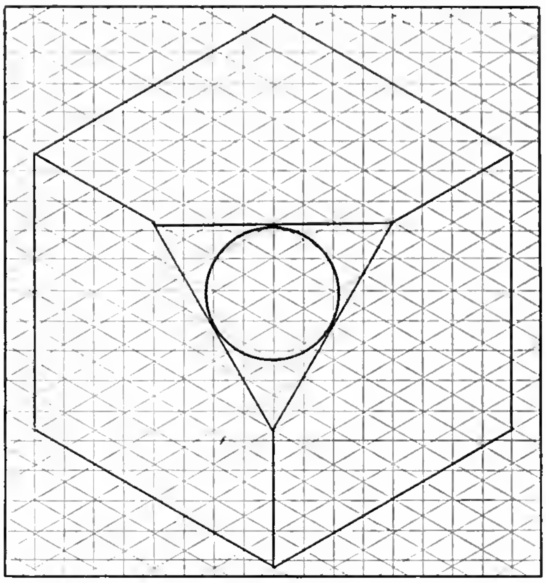

Fig. 1. Example showing that Objects are not distorted when drawn in Isometric Projection

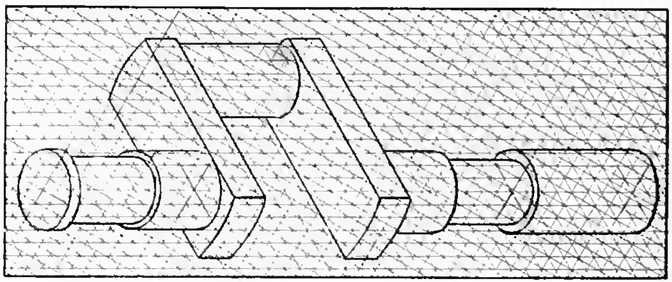
It is also not strictly correct to say that "whenever it is necessary to represent circles in this kind of projection, the drawing of ellipses is unavoidable in whatever position the object is placed." It depends entirely on the object. If its shape be such that every circular outline therein lies in one of the co-ordinate planes, ellipses will be necessary whenever the object is supposed to be viewed along the line of sight above referred to—namely, at equal angles to all the co-ordinate axes; and the major and minor axes of such ellipses will bear to each other the proportion of 1 to $\sqrt{3} = 1 : 1.732$; that is, considering 1 as the diameter of any circle, the major and minor axes of the corresponding ellipse, projected isometrically in the same manner, are respectively 1.225 and 0.707. Most other circles, not lying in these co-ordinate planes, as, for instance, in the faces of a cube, will also be ellipses. But if we have a circle lying in a plane at right angles to the greatest diagonal of the cube, and view it along this diagonal, not only will it appear as a circle; but it can appear as nothing else. Further, the isometrical projection of a sphere cannot be anything else than a circular outline, no matter from what point of view, in what plane projected, or from what distance viewed.



Machinery,N.Y.

Fig. 2. A Crank-shaft shown in Isometric Projection

It is also not true that "this distortion increases with the increase of the dimensions of the object"; because in the first

place there is no distortion; in the second, the isometric projection being supposed to be taken with rays of light that are parallel to each other, that is, taken at an infinite distance from the object, dimensions have nothing to do with the case; it is a matter of proportion only.

Fig. 1 shows an isometrical projection of a cube projected at right angles to its greatest diagonal, and with a circle inscribed in the triangle produced by this section.

In this connection allow me to say that the popularization of isometric drawing in Germany and America is due to me, it having been facilitated by the isometrically-ruled paper patented by me in Germany in 1902, and a sheet of which was sent, for the purpose of patenting it, to the American publishers who are now pushing the system. As far as I know, no patent was applied for, but some of the material used in an American pamphlet on the subject is taken, without credit, from my "*Leitfaden für die Isometrische Projektion*," published by Gebr. Jänecke, Hanover, in 1902. One of the illustrations (shown in Fig. 2) used by the American publishers for advertising purposes, over some such inscription as "Can you draw this?" is Fig. 132 of my German book. I send you my original drawing. Although nothing has been paid me for the use of my material, I like to have the satisfaction of being properly credited. ROBERT GRIMSHAW.

Dresden, Germany.

FORMULA FOR MILLING V-SHAPED GROOVES WITH INCLINED TOP AND BOTTOM

The accompanying formula and table will be found very useful in making patterns and broaches for brackets, such as are used on bicycle lamps, automobile speed indicators, etc. These brackets, in order to fit into each other, must have the top and bottom of the teeth inclined at the same angle, as shown by the lines KA and KG in the engraving.

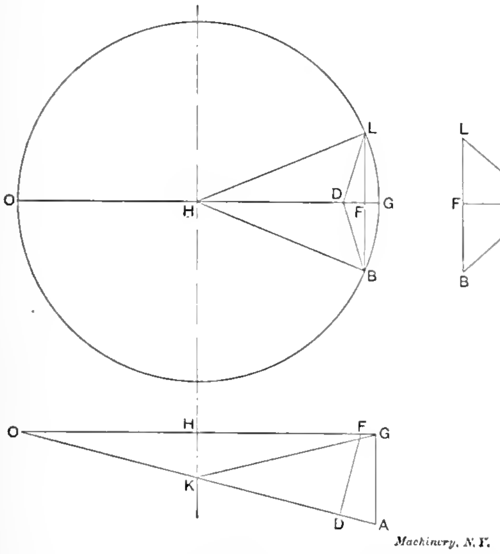


Diagram for Deriving Formula for Setting Index-head for Cutting V-shaped Groovee

Assume that the number of teeth is N, that the cutter angle LDB is given, and that the radius HG equals 1. The angle LHB, which is the angle of one tooth, is bisected by the radius HG. Draw LF perpendicular to OG. The line KA represents the bottom of the tooth; the plane in which the angle of the cutter for milling the tooth must be measured is perpendicular to KA. Assume, therefore, that the angle is measured in a plane FD. (See lower view of engraving.)

$$\text{Angle } LHB = \frac{360 \text{ degrees}}{N}$$

Since HG bisects angle LHB,

$$\text{Angle } LHG = \frac{360 \text{ degrees}}{2N} \text{ and } LF = \sin\frac{360^\circ}{2N}.$$

The triangle LFD shown at the right in the engraving is in a plane perpendicular to OA. In this triangle

$$FD = LF \cdot \cot LDF = \sin\frac{360}{2N} \cdot \cot LDF$$

But FD also lies in the plane containing the right triangle ODF.

$$OF = OH + HF = 1 + HF;\ \text{but } HF = \cos\frac{360}{2N}.$$

consequently

$$OF = 1 + \cos\frac{360}{2N}$$

and

$$\cos OFD = \frac{FD}{OF} = \frac{\sin\frac{360}{2N} \times \cot LDF}{1 + \cos\frac{360}{2N}}.$$

The angle OFD equals the angle OAG, or the angle to which to set the index head.

TABLE OF ANGLES FOR SETTING INDEX HEAD WHEN MILLING V-SHAPED GROOVES

No. of Teeth	Included Angle of Cutter		No. of Teeth	Included Angle of Cutter	
	60°	90°		60°	90°
10	74 5'	80 53'	31	84 57	87° 5
11	75 35	81 53	32	85 6	87 11
12	76 50	82 26	33	85 16	87 16
13	77 52	83 2	34	85 25	87 21
14	78 45	83 32	35	85 32	87 26
15	79 31	83 58	36	85 40	87 30
16	80 11	84 21	37	85 47	87 34
17	80 46	84 41	38	85 54	87 38
18	81 17	84 59	39	86 0	87 42
19	81 45	85 15	40	86 6	87 45
20	82 10	85 29	41	86 12	87 48
21	82 34	85 42	42	86 17	87 51
22	82 53	85 54	43	86 22	87 54
23	83 12	86 5	44	86 27	87 57
24	83 29	86 15	45	86 32	88 0
25	83 45	86 24	46	86 37	88 3
26	84 1	86 32	47	86 41	88 5
27	84 13	86 39	48	86 45	88 8
28	84 25	86 46	49	86 49	88 10
29	84 37	86 53	50	86 53	88 12
30	84 47	86 59	.	.. ..	..

The formula above expressed in words would be:

The cosine of the angle to which to set the index head equals the sine of one-half of the tooth angle, multiplied by the cotangent of one-half of the cutter angle; this product divided by 1 plus the cosine of one-half the tooth angle.

Belvidere, Ill. IRVING BANWELL.

CAM-OPERATED PRINTING PRESS MECHANISM

It was desired, on a printing press, to remove the printed sheets from the cylinder at the rate of fifty a minute. The cylinder was 6 inches in diameter and rolled back and forth over the type bed. The type bed also moved back and forth the same distance as the cylinder, one moving forward while the other moved backward. The sheets extended two-thirds around the cylinder and were held by grippers at the front edge. When the cylinder reach a position in which the front edge of the sheet was at the top—after having made one complete revolution—the sheet was to be taken off the cylinder and carried 23 inches horizontally. The object of this article is to describe the means by which this was accomplished.

The movement of the press will be understood from Fig. 1. The crank A drives the carriage or type bed by means of pitman B acting on bracket C. Bracket D is bolted to the under side of the carriage, and at its lower end engages with lever E. This lever is pivoted at its center F, and its upper end engages the cylinder, thus securing the same movement of type bed and cylinder, but, as stated above, in opposite directions. The sheet is fed to the cylinder in position G and is gripped for removal at the take-off position H. J represents the extreme throw of the cylinder forward.

An interesting point to be noted here is the surface speed of this cylinder. When near the take-off position the cylin-

der center moves approximately one inch for each 10-degrees revolution of the crank. If it had simply a rolling motion, the same as a cart wheel, a point on the top of the cylinder would move 2 inches in this time. Being geared to the carriage and the carriage moving backward an inch—the same distance as the cylinder center moves forward—causes the point on the top of the cylinder to move another inch, or 3 inches in all. The paper is therefore unwound from the cylinder at this rate of speed or about 9 feet per second, and mechanism had to be designed to take it as fast.

The figures 1, 2 and 3 represent the position of parts of the mechanism after a 10-, 20- and 30-degree revolution of the crank from the take-off position 0. The movement of the take-off is as follows: *K* represents a pair of racks which slide in ways and mesh with gears *L*. These racks are connected by rods which carry the grippers *M*. The pinions *N* are fastened to the same shaft as *L* and mesh with the stationary racks *O*. This shaft is journaled and has a horizontal movement of 7¼ inches by means of the connections *P* and lever *Q*. Lever *Q* is reciprocated by means of the cam on the crank shaft through connection *R*. The driving of rack *K* is another variation of the cart-wheel principle. The distance the rack *K* will move for each inch of movement of the center of the gear and pinion, equals the ratio of the radius of the pinion to the sum of the radii of the pinion and gear. The pinion and gear are 2¼ and 5 inches respectively. The ratio is therefore 1⅛ to 3⅝.

Since most draftsmen do not have proportional dividers, and as it often happens that they cannot be adjusted fine enough even when the draftsman does have them, a convenient way in which to find proportional dimensions is shown in Fig. 2. Make a right-angled triangle having the base equal to one member of the proportion and the altitude equal to the other and draw the hypothenuse. A proportional to any given dimension may be found by laying off the given dimension from 0 on the horizontal and erecting a perpendicular to the hypothenuse, which will be the required dimension.

Scraps of tracing cloth are very useful in plotting out movements on the drawing board. The laying out of cams is made easy by having the cam shape on the cloth in pencil; the cam may then be given the same motion as in the machine, and the shape altered to produce the required movement. This, of course, only applies to face cams.

The points 1, 2 and 3 were the most essential in the design of the cam, and were laid off along the center line of the connection *R* at 1′, 2′ and 3′. This was done by means of the strip of cloth as explained above. It is evident that as connection *R* moved out, its end *S* would drop, thus raising the roller slightly at each ten degrees of revolution of the cam. The exact positions of the roller are indicated by short lines at 1″, 2″ and 3″.

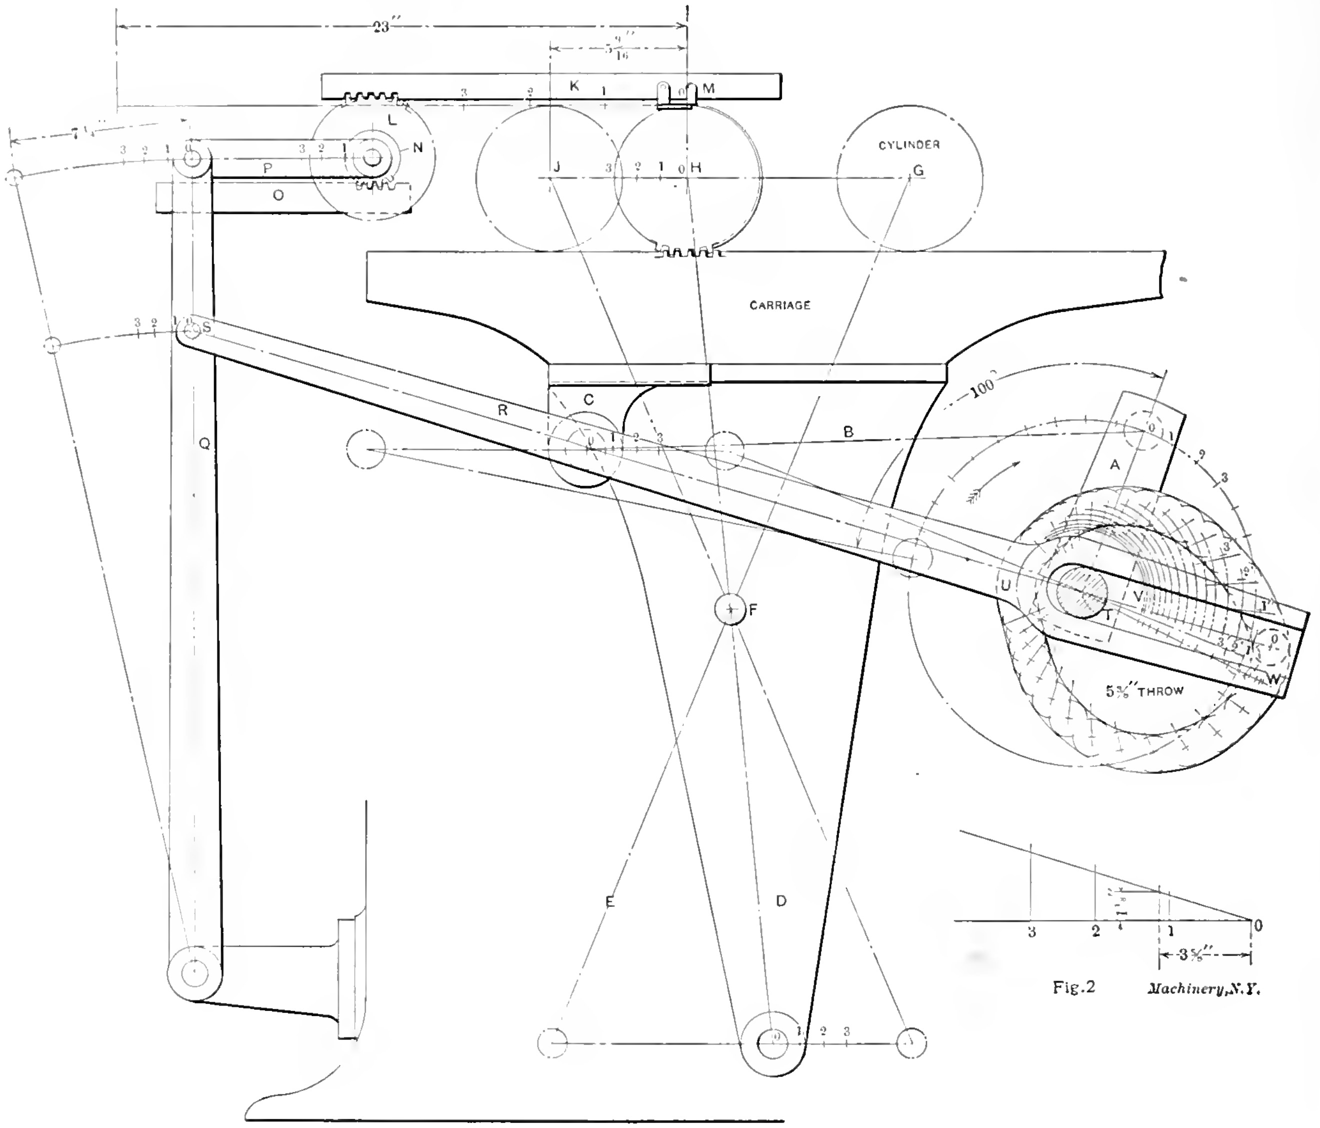

Fig.2

Fig.1

Figs. 1 and 2. Lay-out of Cam and Cam Motions for Printing Press

Spaces of ten degrees were laid off about the center *T* either side of the center line *T*0, with the exception of 70 degrees "dead" time at *U*. Circles from the points 1′, 2′ and 3′ were scribed about the center *T* to their respective radial lines, allowing for the increments at 1″, 2″ and 3″. Circles were drawn with these centers the size of the cam roller, and curves were drawn tangent, thus giving the contour of the cam walls.

When this most important part of the cam was determined, the remaining ten degrees spaces on the upper half of the cam were twelve in number. The space along the center line from 3′ to *V* was divided into twelve parts decreasing in

size so as to produce a gradual movement down to the "dead" part of the cam. When these points were described about the center T onto their respective ten degree radial lines, the cam walls were drawn in.

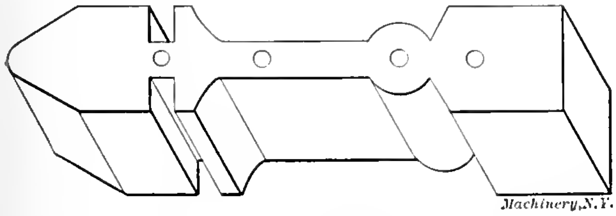
The lower half of the cam from U to W was simply to produce a return movement. On the center line TW the movements for this part of the cam are shown. The 5⅜ inch of throw from V to W was divided into thirteen parts—the number of ten degree spaces—which were graduated so as to start the roller slowly from the inactive portion of the cam, increasing to obtain the greatest movement at the center, and slowing down again for the reversal of motion. The ten degrees from W to 0 was to allow an opportunity for a better curve to reverse the motion. The movement of the cam from 0 to W gives ¼ inch movement along the center line. This causes the take-off at the cylinder to run by and reverse its motion and be on the return stroke when it grasps the paper. In the portion of the cam from 3" to U the slight variation due to the dropping of the connection at S was neglected as being of no importance. The same was true regarding the lower part of the cam from U to 0. Both these portions of the cam might have been laid out according to either the gravity, simple harmonic or elliptic formulas. The eye proved to be a sufficient guide in this case. It is good practice to lay off the increments along the center line as shown in the diagram. The relative movement or time of the cam may then be seen at a glance.

This cam was cut in the lathe, a former having first been filed up. By putting the cam and former on an arbor, removing the screw from the cross slide and putting a weight on the slide to keep the tool against the former, the cam was roughed out. A roller of slightly smaller diameter than the finished size was fitted to the tool to bear on the former. The cutting edge of the tool was kept even with this roller. A finishing cut was taken with a rather odd tool. It consisted of a piece of tool steel the same diameter as the roller to be used, squared on one end to fit the tool-post. This piece was left round for a sufficient length to bear on the former. At the end, teeth were cut in it the same as a file, and the tool, when hardened, was ground to size. After taking a finishing cut with this tool the cam and roller were a fine fit.

New York City. DAVID J. WALSH.

EFFICIENT TYPE OF BLANKING AND FORMING DIE

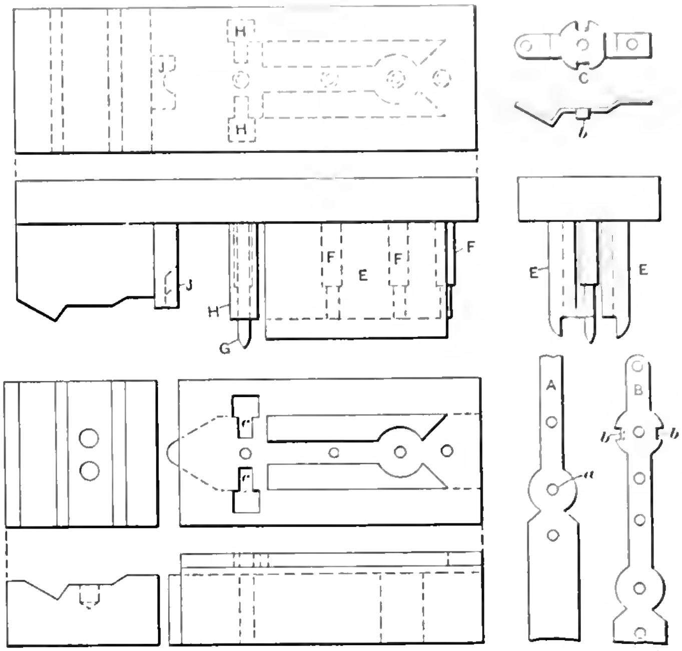
A novel design of die which will appeal to progressive manufacturers, as well as die-makers, is shown in the accompanying illustration. Ordinarily the blank is punched out and then put through the successive bending operations until it is completed. The type of die shown herewith, which can be employed on most classes of work, does not cut out the blank, but trims off the metal on the outside, leaving the blank attached to the strip until the last bending operation is completed, when it is cut off. All these operations are successive. While the bending operation is taking place, piercing and blanking punches are preparing another blank. The die proper, which is shown in Fig. 1, does not look familiar to the average die-maker, as he is accustomed to dies having holes cut through corresponding to the shape of the piece to be blanked. In this case, the outside of the die is used as a cutting edge for shearing the stock to the required shape.



Machinery,N.Y.

Fig. 1. A Die in which the Outer Edges are used for Shearing the Metal when Blanking

The first thing to be done when constructing such a die would be to develop or determine the shape of the blank before it is bent to shape. The best and surest way known to the writer is to carefully ascertain the shape as near as possible and then cut out two blanks, by hand, exactly alike, marking each with the same symbol. One of these blanks is then bent to the required shape, and if the piece is too long or too short after all the bends are made, the duplicate can be referred to when making another pair of blanks with the required changes. By following this method of always making two blanks, then bending one and retaining the other to refer to until the desired shape is obtained, we have, finally, a straight blank which is useful for laying out the blanking die. The bending die should almost invariably be made before the blanking die, as it is much easier to change the shape of the templet, than to change the blanking die. After the bending dies are completed so that the finished blank is correct, the duplicate templet can be used to lay out the blanking die. This is almost universally made by cutting a hole the shape of the templet, through the die and filing it to size. This method means that we must make a blanking die and punch and two or three bending dies and punches, which also means that there are to be two or three presses in use. Compare, mentally, the cost of producing 1,000 blanks made under such conditions, with the cost of producing the same number made with one die and with one press that produces a finished blank at each stroke. When the nature of the work will allow slight variations on the outside of the blank, there is no comparison whatever between this type and the older style of die.



Machinery,N.Y.

Fig. 2. Diagrammatical View of Blanking and Forming Die for Producing the Piece shown at C

Referring to Fig. 2, A and B show the stock after the first and second blanking and piercing operations, respectively, and the finished piece is shown at C. During the first operation the piece is blanked by the punches E and pierced by the three punches F. As the blank is moved along for the second operation, it is located by the pilot-pin G which enters the hole a. The lugs b are formed by the punches H on either side, after which the piece is ejected by spring-pins located at c, so that it may be fed along. The blank is then cut off by the punch J.

It might be well to add that with clever designing, this die might be advantageously used for work requiring more accuracy than that here illustrated.

Pittsfield, Mass. F. E. SHAILOR.

* * *

The *Mechanical World* gives an account of the amount of money expended on aerial navigation by various governments during 1908. In Germany, the amount of public money spent was about $660,000. The French government spent $235,000, and Austria Hungary $27,000; Great Britain expended about $25,000. Besides the large public expenditure in Germany, over $1,300,000 was privately subscribed in that country in connection with the Count Zeppelin fund.

SHOP KINKS

PRACTICAL IDEAS FOR THE SHOP AND DRAFTING-ROOM

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary

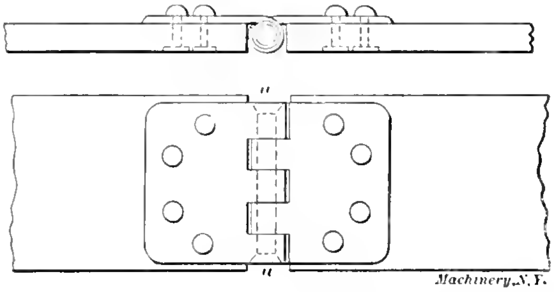
TO TURN SOFT RUBBER

Mount the rubber roll on a wooden mandrel, if the size of the hole will permit, or on an iron mandrel if the hole is of small dimension. Drive the work at about the same speed as for finishing brass. For a turning tool use a worn-out half-round file, without drawing the temper. Grind out nearly all the teeth but leave a sharp burr on the cutting edge. This saw-tooth edge is what does the work. Give the tool plenty of clearance. **E. B. Gafkey.**

Lakewood, Ohio.

BELT FASTENER

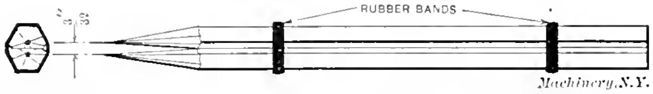
The accompanying sketch shows a belt fastener, attached to a 3-inch double belt, that will more than equal the strength of the belt itself, and last as long. It is made of a common T-hinge of the proper width, which is secured to the belt by eight 3/16-inch copper rivets, as shown. The pin hole should be countersunk in the ends as at *a*, and the edges of the hinge nicely rounded. A brass pin should be inserted in place of the steel one and riveted over on the ends. As will be seen, the knuckle part of the hinge comes between the ends of the belt. On wide belts, two or three hinges may be used. **A. I. Linsley.**



Cleveland, Ohio.

SPACER FOR LETTERING

A spacer for giving the proper height to the lettering on the body of a drawing is shown in the engraving. As will be seen it is made by fastening together, with rubber bands, two flattened pencils. As a rule these letters are about 3/32 inch high, but if higher or lower spaces are desired, a set of two or three spacers could easily be made which would answer all the requirements of a drafting-room. The leads are easily sharpened by simply removing the bands.



Three Rivers, Mich. **E. G. Peterson.**

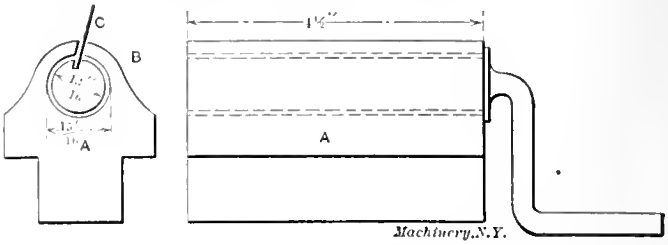
TO PREVENT THE BREAKAGE OF INCANDESCENT LIGHT GLOBES

Many readers of Machinery have doubtless been annoyed by the continual breakage of incandescent light globes hung near some rapidly moving belt. Of all the electrical phenomena whose exact nature we really know so little about, none manifests itself to us more frequently than the static charge residing on the surface of a moving belt. An observing person will notice that the filament of a lamp in proximity to a charged belt is distorted until it touches the glass, even though no spark is visible. Now, when the current is turned on, as soon as the filament becomes incandescent the glass cracks and the lamp is on the retired list. Here is a simple preventative: Attach to the lamp, in the ordinary manner, any one of the numerous wire protectors on the market. To this protector fasten a fine wire, say number 16 bell wire, and run it to an overhead I-beam, water pipe, or other metal body that is grounded. Through this path the static charge passes away without affecting the lamp. It is understood, of course, that the protector is insulated from the lamp circuit by being fastened to the insulated socket. **Donald A. Hampson.**

Middletown, N. Y.

DEVICE FOR ROLLING TIN-PLATE TUBES

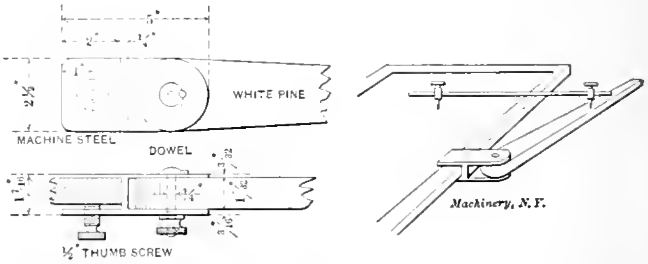
A rush order came to my department for several thousand tin-plate steam heater floor tubes. The shop rollers were too large in diameter for the job, and the usual method of manufacture, that is, bending the pieces of tin-plate around an iron rod in a groove in the creasing stake, was too slow. Consequently, I made an appliance similar to the one shown in the illustration. The device consists of a cast iron block *A*, which is bored to receive the roller *B*, having a slot throughout its length, as shown, which holds the metal plate when the crank is turned and the roll is being formed. When one edge of the plate *C* is inserted in the slot in the roller, the crank is turned two or three times, when the roller and tube can be withdrawn. With this simple tool, the output was increased to 500 per hour, as against 50 per hour with the creasing stake.



Manchester, England. **T. Iles.**

ATTACHMENT FOR THE DRAWING-BOARD

In laying out work, it is often necessary to locate a center or some other point beyond the scope of the average sized drafting-board. The accompanying sketch illustrates a simple device that has been found to meet the requirements when such occasion arises. If the attachment is made according to the dimensions given, it will fit any board up to 1⅛ inch in thickness. **W. L. Van Ness.**



Toledo, Ohio.

TWO TYPES OF BACK TOOL REST

Fig. 1 illustrates a very poor back tool rest which may be seen on some new screw machines. The tool lacks support, breakages are frequent, and the efficiency is thereby greatly diminished. Fig. 2 shows what these machines need —a rigid tool rest. **F. Rattek.**

NEW MACHINERY AND TOOLS

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP

CHAMPION DOUBLE BACK-GEARED LATHE AND IMPROVED GEAR BOX

In Fig. 1 is shown the head-stock end of an engine lathe built by the Champion Tool Works Co., 2422 Spring Grove Ave., Cincinnati, O. The special feature of the design lies in the use of a three-step cone for a high power belt, which may be connected with the spindle either directly or through double back gears. The throwing in of the back gears or the changing from one back gear ratio to the other may be effected from the front of the machine by the use of conveniently placed levers and handles. The drive will be understood from a study of the half-tone engravings, Figs. 1 and 2, and the line engraving, Fig. 3, which shows the mechanism.

The cone pulley *A* has driven into it a sleeve *B*, having pinion teeth cut in its outer end. A second gear, *C*, is driven onto a seat turned just behind the flange. Gears *B* and *C* mesh with corresponding gears *D* and *E*, which are normally free to revolve on back gear quill *F*. The latter is supported by shaft *G*, which passes through the length of the head-stock and bears at opposite ends in the eccentric hubs of levers *H*, which are journaled in bearings in the head-stock casting. The outer ends of levers *H* are connected by bar *J*, which may be reached from the front of the machine. By swinging this bar *J*, the eccentric hubs of levers *H* throw the back gear quill forward or backward, so that gears *D* and *E* are thrown in mesh with gears *B* and *C*, while the pinion formed on quill *F* is thrown into engagement with driving gear *K*, keyed fast to the spindle.

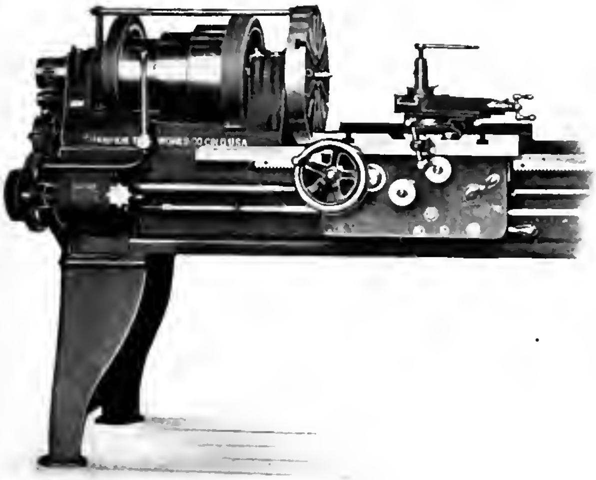

Fig. 1. Double Back-geared Head-stock for Champion Lathe

As stated, gears *D* and *E* normally revolve freely on quill *F*. The hubs of these gears have key slots cut in them, and are recessed on their inner hubs to furnish a clearance space for key *L*, which may be shifted axially in a cross slot in *G* by means of a bar *M* pinned to the external sliding collar *N*. In the central position, when *L* is resting in the recesses of the hubs of *D* and *E*, both these gears are disconnected from the shaft. When sleeve *N*, and with it *M* and *L*, is moved to the right or left, the key is forced into one of the opposing pairs of slots in the hubs of the gears *D* or *E*. By this means the two back gear speeds are obtained. Sliding collar *N* is operated by a yoke and rock-shaft provided with a handle, shown at the front of the head-stock in Fig 1.

Great belt power is obtained by this drive. The smallest step is 8¼ inches in diameter for a 3½-inch belt, and the largest is 11½ inches in diameter. The operator has perfect control of the back gears without moving from his position, and may make changes from single back gear to double back gear, or *vice versa*, without stopping the counter-shaft. This double back gear does not interfere with the driving of work in which the spindle is directly connected with the cone. The speeds are positive, and no friction or other connections are used, clutches being relied on for the various changes. This double back-geared drive is an invention of Mr. John C. Pflanzer, superintendent of the shops of the makers. It is applicable to 16-inch lathes and larger.

The new feed box is shown applied to the lathe in Fig. 4. The gearing connecting the spindle and the gear box is exceptionally well guarded, as shown, standing comparison in this particular with the lathe of any other American maker. The guard has a spring catch which may be released to swing it back for oiling the gear bearings. If desired, it may be easily lifted off the machine entirely. The use of a substantial guard is made possible by the fact that a large number of screw cutting and feed changes are provided by the gear box, without requiring the removal or replacing of any change gears. The quick-change gear mechanism gives forty different threads or feeds in all.

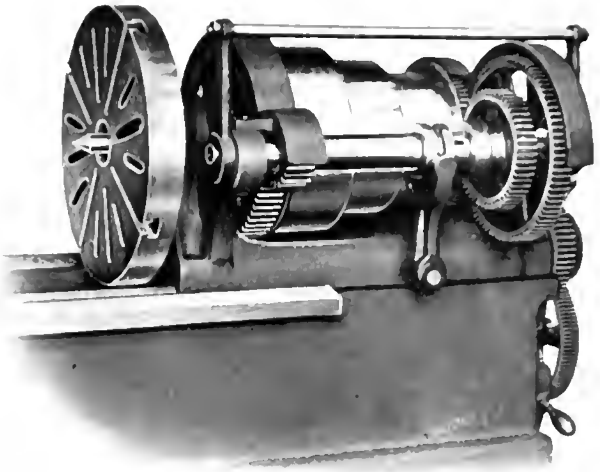

Fig. 2. Rear View of Head-stock, showing Arrangement of Double Gearing

Provision is made for reversing the feed by the lever at the end of the head-stock in the usual way. A double train of gearing is provided between the spindle and the gear box, either side of which may be thrown into action by a push pin, thus giving two rates of speed to the driving shaft of the feed mechanism. This driving shaft has formed on it a pinion extending the full length of the feed box, meshing with an idler carried on a swinging arm, so that it may be adjusted to engage with either one of a cone of eight gears on the variable speed shaft above it. This construction is, of course, a familiar one. The variable speed shaft is in turn geared to an intermediate shaft, which is connected with the lead-screw by a cone of three gears. A sliding key operated by the vertical knob shown at the right-hand end of the feed box, throws either one of these three sets of gears into action. These have ratios of 2 to 1, 1 to 1, and 1 to 2 respectively. The knob for making these changes is retained in each position by a ball forced by a spring into a depression placed opposite

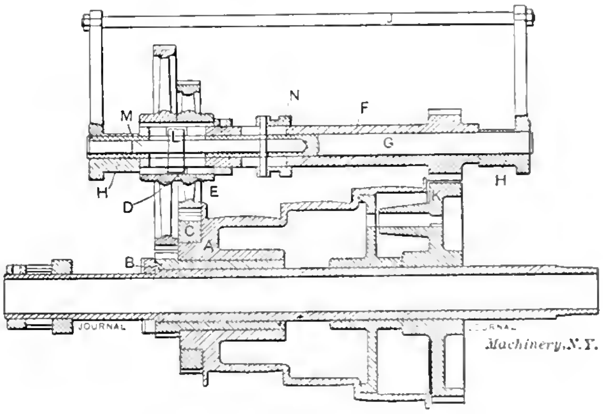

Fig. 3. Plan View of Driving Mechanism

each one of the three stopping points. This prevents the shifting key from working out of position except when the knob is turned by the operator.

There are thus forty-eight combinations possible, derived from the two changes controlled by the pull pin in the outside gearing connections, the eight changes furnished by the swinging idler and the main cone of gears, and the three changes controlled by the vertical knob. Of these forty-eight combinations, forty are non-duplicates, giving that number of separate thread pitches without change of gearing. Provision is made in the connection between the head-stock and gear box for change gears for odd or fractional pitches as required. The forty threads available range from 2 to 56 per inch, including 11½. The forty non-duplicating feeds give 3½ times the number of turns per inch for the corresponding thread.

The lead-screw is driven from the lead-screw shaft in the gear box by a clutch, which may be thrown out if desired when the rod feed is in use. The latter is connected with the feed-screw shaft by gearing inside the box. The splined feed rod has a provision for axial movement against the pressure of springs in either direction. These springs hold it normally in central position, where suitable clutch teeth engage with corresponding internal teeth on the loose gear by which it is driven from the lead-screw shaft. Stop collars are provided as shown, on each side of the carriage. When the automatic feed forces the carriage against either of the stop collars in either direction, the feed rod is thereby shifted longitudinally and the clutch is thrown out of engagement, stopping the feed. When the carriage is returned by hand to the starting point again, after releasing the friction in the apron, the spring automatically throws the splined rod back to the central position, so that the feed rod clutch is again in engagement.

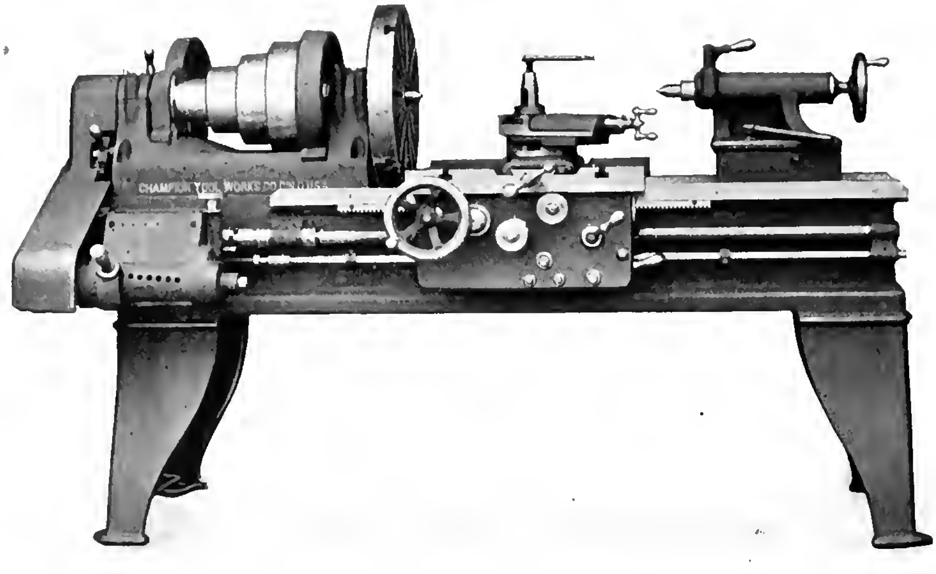

Fig. 4. Sixteen-inch Champion Lathe with Gear Box Mechanism giving Forty Changes

The pinion in the apron may be withdrawn when chasing threads, and provision is made in the apron feed reverse for interlocking with the lead-screw half-nut, so that the rod and screw feeds cannot be engaged at the same time. The rack pinion has an inside bearing, so that the apron is virtually of the double construction so far as this vital feature is concerned. The gears and longitudinal feeds are controlled by independent frictions.

The compound rest slides have taper gibs, and the swivel is graduated in degrees. Both compound rest and cross feed screws have dials graduated in thousandths. The carriage has a chasing dial connected with the lead-screw, which permits the cutting of threads without reversing the spindle. By its use the operator is informed of the proper time to throw in the half-nut. This permits using the two belts of the counter-shaft for giving two speeds in one direction, so that with the single back-geared four-step cone drive, sixteen spindle speeds are obtainable or, similarly, eighteen speeds are obtainable with the head-stock mechanism shown in Figs. 1, 2, and 3.

The quick change gear device is applicable to the 12, 14, 16 and 18-inch lathes manufactured by the Champion Tool Works Co. It is the invention of Mr. William Donaldson, secretary and designer of the firm. The lathe shown in Fig. 1 has a simpler feed gearing, which will be furnished if desired by the customer. With it three changes of pitch or feed are obtainable without altering the change gears.

BROWN & SHARPE NO. 12 PLAIN GRINDING MACHINE

The plain grinding machine illustrated herewith is built by the Brown & Sharpe Mfg. Co., Providence, R. I. In the broad lines of its design it resembles the larger plain machines of the same make, being intended for rapid and accurate manufacturing of such parts as spindles, shafts, rolls and other work (either straight or taper) capable of being finished on dead centers. It will take work up to 8 inches in diameter and 36 inches long, being thus intermediate between the makers' No. 11 and No. 13 plain grinding machines; the former of these is of different design, built especially for small work. The No. 12, which is here under consideration, will take in the major portion of the grinding work of the ordinary machine shop, and handle it with a rapidity and accuracy corresponding to the highest present attainments in the art of grinding.

General Construction of the Machine

The base supports the entire mechanism on a single casting; it rests on the floor or foundation on a three point bearing, one at either end of the front view of the machine in Fig. 1, and the other at the center of the base in Fig. 2. This three-point bearing gives assurance that the machine will always be supported under the same conditions as when it was planed and scraped, so that the original accuracy of workmanship is preserved. While this compensates for any unevenness in the floor, a solid, steady support is desirable, and a cement foundation will be found a valuable factor in increasing the output in manufacturing work. The base is hollow, and is fitted with

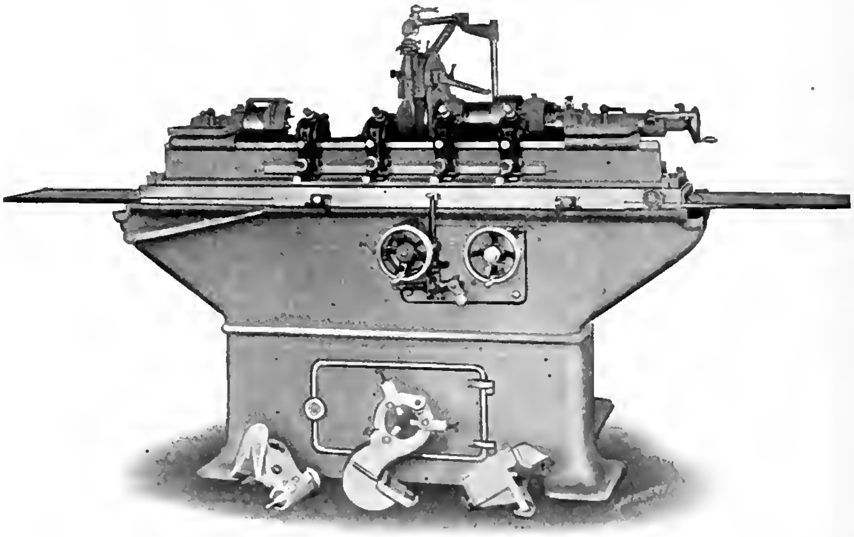

Fig. 1. Brown & Sharpe No. 12 Plain Grinding Machine

shelves to receive small tools and accessories. A tank and pump for wet grinding are also located inside the base. The pump is of the centrifugal type, with bearings above the water line. It is self priming, and no packing is required. (See Fig. 3.) A complete set of water guards and pans protects the floor and returns the waste to the settling tank and pump. On the carriage is mounted the swivel table, carrying the head- and foot-stocks, to provide for grinding tapers. A quick adjustment and graduated scale is provided for obtaining the taper desired. The head- and foot-stocks are adjustable on ways on the inclined face on the swivel table. These ways are protected from the water by adjustable guards. The universal back-rests furnished with the machine for supporting long slender work or splined shafts, are supported on independent ways of their own on the vertical front face of the swivel table, as is plainly shown in Fig. 1. The head- and foot-stocks are adequately protected from water and grit. The foot-stock has permanently attached a device for holding a carbon point in truing the wheel, which can thus be done without removing the work.

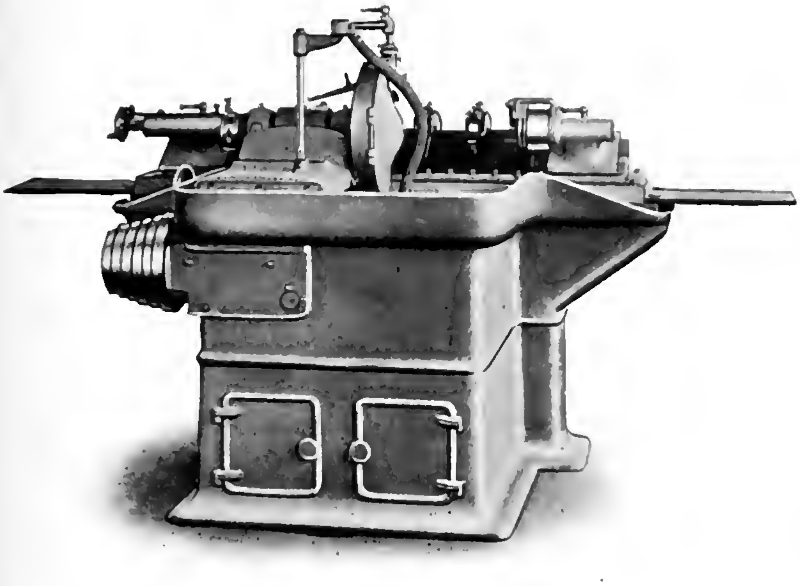

Fig. 2. Rear View of Grinding Machine

Improvements in the Cross-feed Mechanism

Fig. 3 shows a section through the wheel spindle, and illustrates an improvement in construction which makes possible the rapid traverse of the wheel spindle slide. The cross adjustment is effected by a vertical pinion on shaft *A*, meshing with rack *B*, which is firmly screwed to the slide. To *A* is pinned the clutch *C*, which engages a corresponding clutch member screwed and doweled to worm-wheel *D*, which in turn is operated by worm *E* controlled from the cross-feed hand-wheel at the front of the machine. By turning the short lever shown below and between the two hand-wheels on the front of the bed in Fig. 1, cam *F* is rocked into the position shown in Fig. 3, thus raising shaft *A* and disengaging clutch *C*, leaving the slide free from worm-wheel *D* and from connection with the cross-feed adjusting hand-wheel at the front of the machine. Hand-wheel *G* at the side of the slide is mounted on a short pinion shaft engaging a stationary rack on the stand. This may now be operated to give a rapid movement to the slide. Rocking cam *F* downward again by the lever at the front of the machine again throws clutch *C* into engagement and gives a fine cross adjustment from the regular hand-wheel.

The rapid movement thus provided is useful for moving the wheel slide quickly from one extreme of its travel to the other, so as to thoroughly distribute the oil along the ways of the wheel slide. This is very important, particularly in starting the machine after it has been idle over night, or for some time during working hours. If these bearings are not thoroughly lubricated it is impossible to get the fine adjustments required, which often have to be made as close as 0.000125 inch. This quick movement is also useful in altering the adjustment of the wheel for considerable changes in the diameter of the work.

Another point of interest shown in Fig 3 is the method of gibbing the wheel slide to the stand. Gib *H* is fitted into position by scraping, and is drawn down tightly into place by means of the bolts shown. This construction does not permit the operator to tamper with the adjustment. If it becomes necessary after years of service to compensate for the wear at this point, this is done by removing the gib and scraping its upper surface until the desired closeness of fitting is obtained.

The spindle construction is shown quite plainly in Fig. 3. The spindle is of one diameter throughout the main part of its length, and is exceptionally heavy. Suitable oil wells with felt distributing pads are provided, and the boxes are self-aligning and adjustable for wear. The thrust of the spindle is taken by two washers, bearing in spherical seats in the hub of stationary sleeve *J*. This construction makes possible a much closer fit, so far as end movement is concerned, than can be obtained in any other way. A two-step cone pulley is provided to keep up the speed as the wheel wears down. A safety belt stop shown at *K* attached to the adjustable cap of the wheel guard, makes it impossible to shift the belt on to the smaller step until the wheel has worn down to a point that makes it safe to do so.

The automatic cross-feed is of the standard design developed by the makers. The simple pressing of a thumb latch sets the feed for any desired size, automatically stopping it when the required depth of cut has been reached. The feed can be set to give the full amount at either or both ends of the stroke. The same movement also, if desired, may be used for giving a fine hand feed. The hand-wheel is graduated to read to thousandths of an inch on the diameter of the work.

Improvements in the Table Traverse Mechanism

Figs. 4 and 5 show quite plainly the mechanism of the automatic traverse for the table. The reversing device is of the "load and fire type," which has been used for many years by the builders. Arm *K* in Fig. 4 is keyed to a rock-shaft extending through to the front of the machine, where it is actuated by the adjustable reversing dogs at the front of the carriage. As the carriage approaches the end of its movement, arm *K* is rocked to the right or left as the case may be. If rocked to the left in Fig. 4, by means of the connecting rod and tappet *L*, spring M_1 on rod *N* is compressed, bringing block O_1 against the catch on latch P_1. Continued movement of *L* to the left finally raises latch P_1, allowing O_1 and *N* to fly to the left under the impulse of compressed spring M_1. Latch P_2 then drops in behind block O_2. The movement of *N* to the left, by means of fork *Q*, throws feed-shaft *R* to the left, and with it the reversing clutch *S*, which is keyed to it. The table traverse is thus reversed. At the end of the stroke

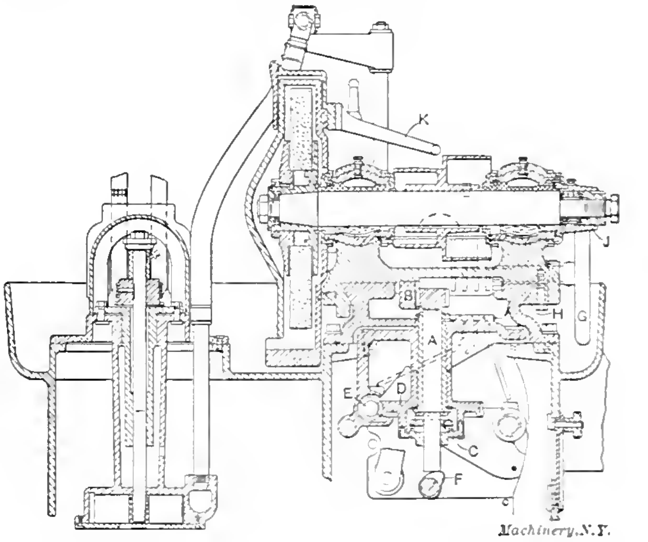

Fig. 3. Cross-section through Grinding Head Spindle, showing Centrifugal Pump and Improvements in Cross Feed

in the other direction, L is moved to the right, spring M_2 is compressed, latch P_2 and N, Q, R, and S are thrown to the right, thus again reversing the table. This mechanism avoids the possibility of stopping the clutch on dead center.

An improvement in the design makes it possible for the operator to stop the traverse at the end of the stroke if he desires. This is clearly shown in Fig. 5, where the same reference letters apply as in Fig. 4. A knob T in the center of the traverse movement hand-wheel X, by means of the connections shown passing through the hollow shaft, operates the plunger U. By pressing the knob T, U may be held under spring pressure against the surface of revolving clutch S. When the latter, at the end of the stroke, flies over under the influence of springs M_1 and M_2, latch U drops into the groove turned in the periphery of S, holding it in the central position. The workman may thus at any point of the stroke of the machine set knob T to stop the traverse at the end of the stroke. This requires less watchfulness and care, and leaves the operator free to concentrate his mind on the matter of making accurate measurements. The spring detent at V holds the knob T in either its open or closed position. The withdrawal of the knob again starts the traverse without requiring any further movement on the part of the operator.

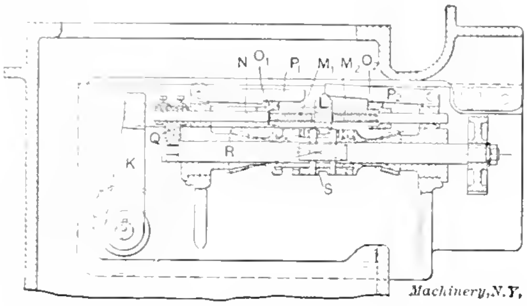

Fig. 4. The "Load and Fire" Reverse Mechanism for the Table Feed

Knob T serves another purpose simultaneously with that of stopping the machine at the end of the stroke. It is pinned to the shaft which receives the movement from the feed gearing, and is provided with clutch teeth engaging corresponding teeth on the hub of hand-wheel X. The latter thus hangs free during the operation, and is only thrown into engagement with the table traverse gearing when the operator stops the power movement. This is advantageous in the production of accurate work. The nature of the grinding operation requires the operator to stand close to the machine for the delicate adjustment of rests, etc., during the movement of the table. This is inconvenient and dangerous with a revolving hand-wheel having a handle protruding from it. Besides this, the hand-wheel is necessarily geared up to give an easy and accurate movement to the table when facing a shoulder on a piece of work. This means a comparatively high speed, so that its momentum becomes a serious factor in reversing the direction of the table feed mechanism. Since with this improved arrangement the hand-wheel never reverses, it can be made much larger in diameter than has hitherto been possible. Throwing it into engagement, as explained, requires no further movement on the part of the operator than that of stopping the machine.

Another improvement in the table feed mechanism is effected by the gearing shown at Z, in Fig. 5. This gives two rates of table feed, controlled by a hand lever (shown just above the table hand-wheel in Fig. 1), mounted on shaft B. When this lever is set for the slow movement and the belts on the counter-shaft cones are properly set for roughing out a piece of work, the shifting of the feed gearing to the fast movement makes the proper change in the table feed for the fine finishing cuts desired for bringing the work down to size. It is thus possible to have the proper feeds for roughing and finishing without requiring the shifting of belts during the progress of the work.

Improvements in the Driving Mechanism

The counter-shaft of this machine has been re-designed so as to make the wheel and work speeds and the table feeds entirely independent of each other, so that either of the three may be changed without affecting the others. This feature, particularly in relation to the work speeds and table feeds, is an important factor in commercial grinding. By this arrangement it is possible to obtain a correct table feed for any work speed, so that when it is desired to remove stock rapidly, a slow speed and fast feed are available. Any of the changes can be made without stopping the wheel, work or table.

A further convenience in the drive is afforded by the horizontal lever shown at the left of the bed in Fig. 1. This is for starting and stopping that portion of the overhead works that feeds the table back and forth and reverses the work. This lever replaces the shipper arm generally employed for this movement, and changes the tiresome horizontal movement over the workman's head to a vertical movement in a convenient position where his hands would naturally be in operating the machine. As this lever is moved every time a piece of work is calipered or removed from the grinder, the relief to the operator becomes an important factor in increasing the output of the machine. The connection with the counter-shaft is by means of a piece of wrought iron piping not shown in the engraving. This improvement has been found of so much importance that all of the grinding machines in the shops of the builders have been equipped with it even when it was not provided for in the original design.

General Dimensions and Specifications

The machine takes work 8 inches in diameter and 36 inches long. It takes a wheel 16 inches in diameter, 1 inch or 1½ inch face. The automatic cross-feed ranges from 0.00025 to 0.004 inch at each reversal of the table. The scale for the swivel table reads up to 8 inches per foot and 3½ degrees taper. The ways of the table are provided with roller oil distributors, and are protected by metal covers. The table movement is controlled by quick shifting dogs with micrometer adjustment. Six changes of wheel speed are provided, ranging from 1,200 to 2,400 revolutions per minute. There are twelve changes of work speed, from 42 to 312 revolutions per minute, and twelve changes of table feed, from 8 to 100 inches per minute in two series, available for any work speed. The counter-shaft is driven by tight and loose pulleys 14 inches in diameter for 4-inch belt, and should run about 400 revolutions per minute. The floor space occupied is 144 inches by 51 inches. The net weight of the machine is 5,050 pounds. The equipment includes one plain back-rest, four universal back-rests, a center rest, center grinding attachment, water guards and a set of dogs. Two grinding wheels are also provided, together with wrenches and complete overhead works.

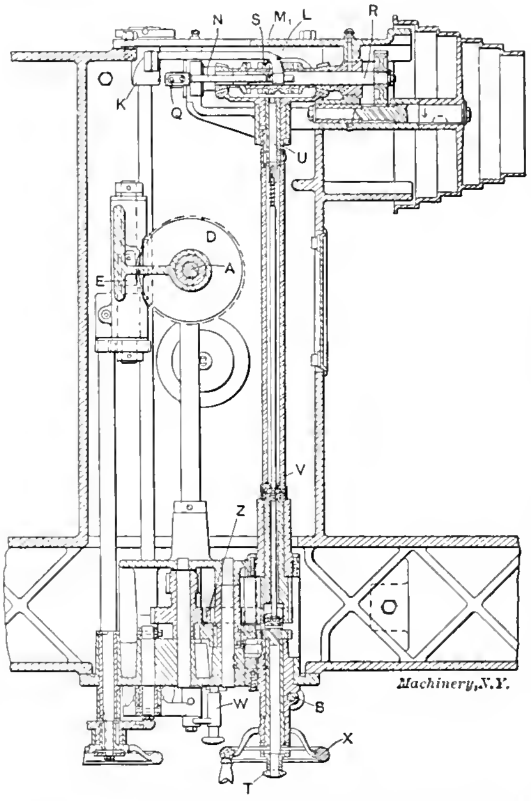

Fig. 5. Horizontal Section of the Feed and Traverse Mechanisms

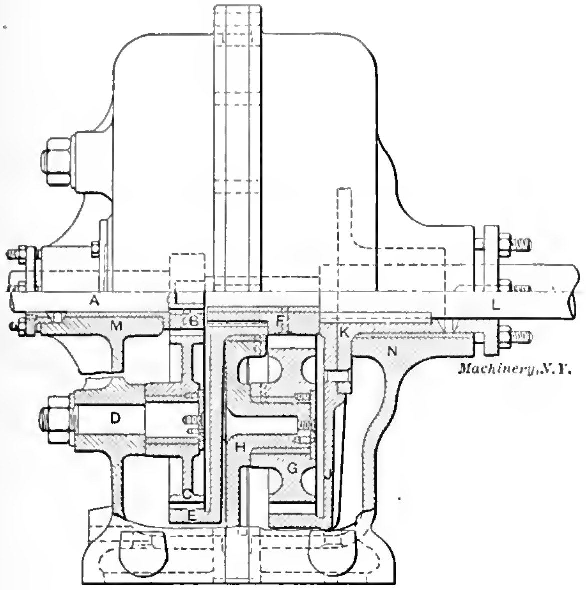
FOOTE BROS. SPUR GEAR SPEED REDUCER

The Foote Bros. Gear and Machine Co., 44-50 No. Carpenter Street., Chicago, Ill., have devised a very neat form of speed reducing gearing, intended particularly for direct connection to electric motors. As may be seen from the engraving, the casing of the mechanism in itself closely resembles a motor, so that the combination of the two on the same base plate gives a pleasing mechanical appearance to the apparatus. In laying out the design it has been the endeavor to get the reduction for the horse-power required as nearly as possible into the same center height as the motor, thus avoiding raising strips on either the reduction or the motor.



An Enclosed Spur Gear Reduction Mechanism of Rigid and Pleasing Design

This reducer employs spur gears only, the two larger members being of the internal spur gear type. The driving shaft at *A* has keyed to it a steel pinion *B*, meshing with a series of four intermediate gears *C*, of which one only is shown. This intermediate runs on a stud *D*, fast in the casing head *M*. It meshes at its outer diameter with the first internal gear *E*, which is journaled in a bearing in diaphragm *H*. The hub of *E* is keyed to pinion *F* and the latter is bored and bushed as shown, to furnish a bearing for driven shaft *L*, so that *L*, *F* and *E* support and stiffen each other. Pinion *F* engages with a second series of intermediate gears, of which one is shown at *G*. These are journaled on bearing studs integral with the diaphragm *H*. Pinions *G* mesh with the second internal gear *J*, riveted to flange *K*, which is in turn keyed to the driven shaft *L*.

It will be seen from the engraving that the design provides for a mechanism of high class, especially as relates to rigidity and durability. All the bearings throughout the casing are bushed with phosphor bronze, and are of ample length and diameter. The studs for the idlers are rigidly supported, so that there is no chance for springing or loosening to cause cramping of the teeth, with consequent breakage. It will be noticed also that the driven or slow speed shaft is supported at the center of the diaphragm, as well as at the outer bearing. The internal gears, which are the only ones rotating in the oil, have long hubs, preventing them also from tipping sideways and cramping the teeth. These internal gears distribute the oil effectively over the whole driving mechanism. The shafts are provided with glands, as shown, packed to prevent leakage of the oil. Since the high speed shaft does not pass through the slow speed internal gear, it is not necessary to turn this shaft down. Stopping off the high speed shaft in this way allows the use of a more compact design to transmit the power the device is intended for.

In comparison with other spur gear reducing mechanisms, the makers call particular attention to the following points: Strong central support of the shafts, and particularly of the idler studs in the diaphragm; smooth frictionless action of the parts in the oil bath, instead of the thrashing and consequent loss of power resulting from the rotating of idler plates or disks at high speeds; no rotating parts so constructed as to be liable to get out of balance, so that the machine runs smoothly and is not racked to pieces. These speed reducers are made in three styles, one of them with a compound idler for extreme reductions. The ratio of reduction may be made anything desired from 8 to 1, to 60 to 1. For ratios greater than 60 to 1, the makers prefer to furnish a worm gear spiral reduction as being better adapted to the conditions. These reducers are made in seven sizes, ranging from 1 to 50 horse-power capacity. They will be furnished, if desired, with a universal coupling between the motor and the casing, to obviate all danger due to misalignment of the armature and driving shafts.

REED 13-INCH SINGLE SPINDLE DRILL PRESS

The new single spindle drill press illustrated herewith is built by the Francis Reed Co., Worcester, Mass. It is noteworthy from the number of adjustments provided. It embodies a sliding head and sliding table, with provision for either tilting or swinging the working surface of the latter. The drive also is unusual in being set parallel with the machine, so that the latter faces the line-shaft, thus agreeing also with the makers' regular A style of drill press.

Straight belts only are used, all quarter turns and twists being done away with. The parallel drive is accomplished through miter gears, one of which is rawhide, connecting the counter-shaft with the vertical driving shaft. The latter runs on a step to prevent the gears from crowding together. The counter-shaft, which is a part of the machine, runs in a bushing on an extension of the frame. The loose pulley runs on a hub on the outside of the frame, and has no connection with the shaft, so that conditions are ideal so far as durability and lubrication are concerned. The changes of speed are obtained by three-step cones at the top of the machine. The main drive is down low enough to reduce the vibration to a minimum, so that with smooth belts no shaking is noticed at the highest speeds.

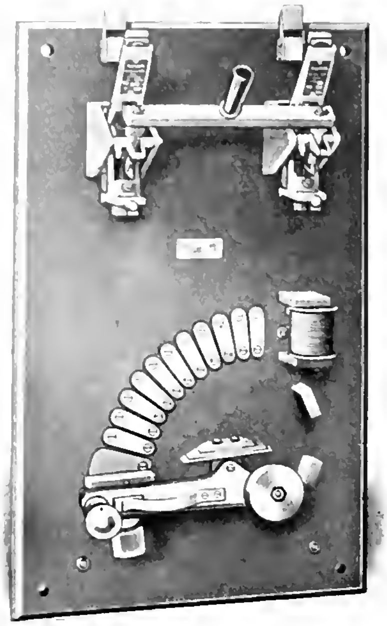
The Reed 13-inch Drill Press

The table is large and heavy, having a 12 by 12 inch surface with an angle plate 12 by 6 inches. This latter may be used to take a chuck for centering long work, making it unnecessary to throw the whole table around at right angles. The style of table shown tilts 45 degrees on each side of the center, the angle plate taking care of the other 90 degrees. Three styles of table will be furnished; the plain round table, a tilting and swinging table, or a plain swinging table. Cup and V centers are furnished with each machine to fit the lower arm. They are aligned with the spindle so as to center the drill properly.

The machine is furnished with either a No. 1 or a No. 2 Morse taper spindle. The spindle has a feed of 5 inches, and the vertical head is adjustable for 12 inches. The lower table has a vertical adjustment of 32¼ inches. The total height of the machine is 70 inches and the weight is about 280 pounds. The machine has a capacity for drills up to ½ inch, and is capable of extremely high speed.

WESTINGHOUSE STARTING PANELS FOR DIRECT-CURRENT MOTORS

The illustration shows one of a line of starting panels recently placed on the market by the Westinghouse Electric & Mfg. Co., Pittsburg, Pa. This panel has been found better than the usual separate starting boxes for many installations, since it insures a more satisfactory location for the rheostat, switches and fuses or circuit breaker than when these parts are mounted separately. Each panel consists of a slate slab, on which the parts are mounted. In the smaller sizes the resistance is mounted on the back. The terminals are so plainly marked that there is little excuse for anyone making mistakes in the wiring, even though unfamiliar with apparatus of this kind.



Westinghouse Starting Panel, equipped with Circuit Breaker

The engraving shows what is known as the type "ZB" starting panel, on a carbon break circuit breaker. Other styles are provided with fuses in place of the circuit breakers. All of them have a low voltage release coil, independent of the field circuit so that any panel may be used for shunt, series, or compound motors. All the contacts are protected from burning by a quick arcing tip on the front of the panel, or by a blow-out coil on the rear, which also prevents burning the contact on opening the circuit.

As stated, these panels are furnished with either fuses or circuit breakers. Both have their advantages. The fuse will carry currents in excess of its capacity for brief intervals, so that it may perhaps be considered preferable for motors that are liable to very brief over-loads, and have expert supervision. The circuit breaker opens immediately, as soon as the circuit reaches the strength for which it is set. It can be reset in less time and less trouble than is required to replace burned-out fuses. Either the circuit breaker or the fuse opens the circuit of the low voltage release magnet, so that the motor is protected from over-loads at all times.

This line of starting panels is furnished in a wide range of sizes, for motors from ¼ horse-power at 110 volts, up to 120 horse-power at 220 volts. A wide range of panels for 500-volt circuits is included in the list. They are made in several different styles, either for mounting on wall brackets, or provided with tubular supports resting on the floor.

LEEDS & NORTHRUP HARDENING AND ANNEALING PYROMETER

In the department of New Machinery and Tools of the March, 1909, issue of MACHINERY, we published a short note describing a pyrometer placed on the market by the Leeds & Northrup Co., 4901 Stenton Ave., Philadelphia, Pa. The distinctive feature of this pyrometer was its use of a pure platinum conductor exposed to the heat to be measured, in place of the usual thermo-electric couple. The resistance of this conductor was measured by an instrument of the same type as an ordinary ammeter. This arrangement combines the convenience of a pyrometer of the ordinary type with the easy reading and durability of the standard electrical measuring instruments. The current used is obtained from any direct current system, and the readings are practically independent of voltage fluctuations.

In the apparatus previously described, the operation of measuring consists in adjusting a resistance for about the desired temperature (within 200 degrees) and then reading the finer calibrations on the ammeter dial. The improvement consists in furnishing a form of direct reading resistance or "indicator," as it is called, which may be set exactly to the temperature desired. Then the pointer of the deflector or ammeter will stand at 0 when the furnace has been brought to this temperature. There are 100 divisions on either side of this 0 point. When the temperature is 50 degrees too high, the needle stands approximately on the + 50 mark; when it is 75 degrees too low, the needle stands approximately at —75, etc. By turning the index on the indicator, the temperature corresponding to 0 may be varied at will. Thus, if it was desired to treat a piece of steel at 1,380 degrees F., the index would be set at 1,380, and the temperature of the furnace raised until the needle stood at the center of the scale. If the next piece was to be heated at 1,420 degrees F., the index would be set at 1,420, and the needle again brought to the center of the scale.

The apparatus is shown diagrammatically in Fig. 2. *A* and *H* represent the terminal poles of the apparatus where it is connected to the shop lighting or power circuit, storage battery or other convenient source of current. From *A* the circuit leads to the shifting contact *C* of the indicator. From *C* the circuit flows through the resistance on either side, flowing out through *E* to *D* or through *F* to *D'*. *D* and *D'* are two coils of a balanced ampere meter, forming the deflector. When the current is the same in each coil, the dial indicates zero. When the current is stronger in one coil than the other, this condition is shown on the dial by a deflection to the right or left, as the case may be. The upper circuit of the divided current passes from *D'* through the bulb *B*, containing the platinum resistance member, which is subjected to the heat, and back to the minus binding post at *H*. The other half of the divided circuit leads from coil *D* of the ampere meter through the permanent resistance *G*, back to the binding post *H*.

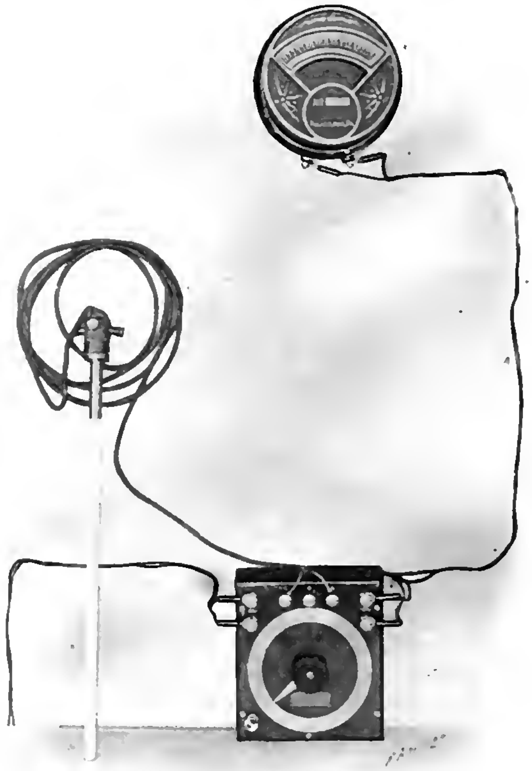


Fig. 1. A Pyrometer used on an Ordinary Lighting Circuit, which gives Magnified Readings for Minute Temperature Changes

The action of the apparatus will now be easily understood. The sliding contact *C* is set to indicate a desired temperature. When so set, as shown in Fig. 2, the resistance of the upper circuit is decreased while that of the lower is increased. (It should be mentioned that the permanent resistance *G* has the same resistance as the bulb *B* at normal temperatures, and it is made of a material whose conductivity

is unchanging for changes of temperature, so that no attention has to be given to the cold end of the apparatus.) Owing to the smaller resistance in the upper circuit, the needle of the balanced ampere meter will fly to one side indicating this condition. If now the element be subjected to heat, its resistance will be gradually increased until both branches of the circuit are again carrying the same amount of current, and the indicator dial, under the influence of coils *D* and *D′* again indicate a balanced condition. If contact arm *C* is again moved upward, so as to further increase the resistance of the lower circuit, the element *B* has to be heated to a still higher temperature to bring the ampere meter to balance again. It will thus be seen that each position of the contact arm *C* corresponds, when the ampere meter is in balance, to a definite temperature of *B*, no matter what the voltage of the current flowing in the apparatus. By indexing these definite temperatures with graduations on the resistance box, a very effective means of temperature control is provided.

The ordinary thermal couple instrument has crowded on its single 6-inch scale its total temperature range from 0 to 2,000 degrees F. In a given process with a given kind of iron or steel, at least 90 per cent of this scale is never used. On such an instrument, ⅛ inch on the scale corresponds to from 20 degrees to 50 degrees. On this deflection indicator, ⅛ inch corresponds to 5 degrees approximately. The workman does not have to remember at what temperature he is working. The deflector does not tell him what the temperature of the furnace is; it tells him that the furnace is so many degrees from the correct temperature. He can at any time, by looking at the index on the box, tell at what temperature the furnace is supposed to be held. Or, should it be desired, this index may be in the superintendent's office or kept from the furnaceman's sight. In any case, the first thing that strikes the furnaceman's eye is that the temperature is higher or lower than it should be, or that it is just right, depending on whether the needle is to the right or the left of the center or just in the center. When 30 degrees means a deflection half way off the scale of the pyrometer, even the most careless workman will get busy to correct the error, but when 30 degrees means only 1/16 inch to 1/8 inch motion, the average man naturally thinks "that little bit won't hurt."

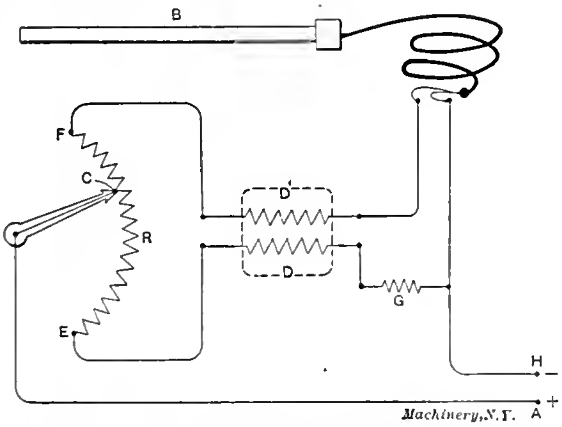

Fig. 2. Diagram illustrating Principle of Action of Leeds & Northrup Pyrometer

It does not require a deep knowledge of psychology to know that small things do not receive the consideration that big things do. With the average workman reading a pyrometer, it is the amount of space covered by the needle which counts; the scale receives scant consideration. An eighth of an inch is to him an eighth of an inch, regardless of whether that eighth of an inch stands for 5 degrees or 50 degrees. Hence a pyrometer on whose scale an eighth of an inch equals 5 degrees acts on the workman as an unconscious stimulant to accuracy.

It is also true that with a pyrometer readable to 2 degrees it is very much easier to control temperature within set limits than it is with an instrument readable to only 25 degrees, for the reason that as soon as the source of heat, be it gas, coal, oil or electricity, begins to vary, the change is immediately noticeable and may be immediately remedied. This does not give the furnace conditions a chance to get "a set" which necessitates radical action to correct, such action starting the temperature change too far in the other direction.

From what has been said it will be seen that this instrument is primarily designed for telling the operator whether or not his furnace is being maintained at the proper temperature; what this particular temperature is is really to the workman a matter of secondary consideration. In fact, it is occasionally desirable that he should be kept in ignorance of it. The usual construction of pyrometers emphasizes first of all the true temperature, often in unfamiliar units, and the workman must transpose this in one way or another to figure out how far his temperature is in error. The measurement of temperatures is in reality a problem in electrical measurement. The makers' long experience and high reputation in this work gives them confidence in introducing this new form of pyrometer for general use.

LANG TOOL-HOLDER FOR TRIANGULAR BLADES

The tool-holder illustrated herewith is made by the G. R. Lang Co., Meadville, Pa. The makers believe that they have succeeded in producing an inserted blade tool-holder which will effectively take the place of the solid forged tool in general work. The blade, as may be seen, is made from triangular steel, which is rolled in bar length accurate to size. The shape of the stock and the provision for clamping allows the use of a cutter of much larger section than is possible in the old style tool-holder.

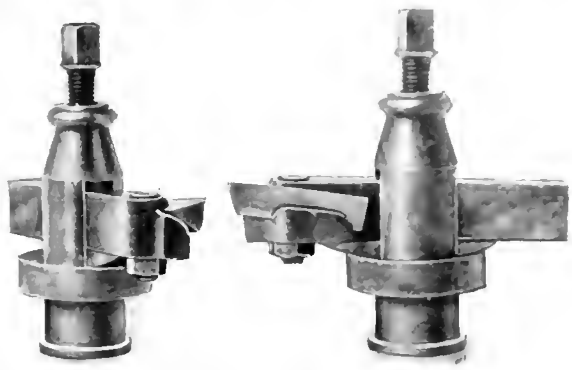

Fig. 1. A Simple and Rigid Tool-holder, using a Blade of Triangular Section

The seat for the blade and the way in which the point is ground gives it an angle of nine degrees back rake at the top, and fifteen degrees side rake. The clearance angles on the front and side are ground to about seven degrees, with very little waste of steel. To secure the same conditions with a cutting edge of square section would require stock about twice the area, and would necessitate the grinding away of a considerable amount of high-speed steel.

Fig. 2. The Holder with Blade Removed, showing Method of Holding

As an example of the heavy blades used, it may be stated that in the ⅝ × 1¼-inch tool-holder, a ¾ triangular steel bar is used, as compared with the usual ⅜-inch square. The cutter is supported entirely on the end opposite the direction of the thrust of the cut, and is held by a method which insures rigidity. There is no swell or head on the side to interfere with working close up to a shoulder, and there is no obstacle on the top to the passage of the chips. This makes it unnecessary to furnish offset tools. Severe tests have shown that the blades will not slip under the heaviest cuts. It is made in both right and left-hand styles and may be used as a side tool or as a drill starting tool, as well as for ordinary turning.

GRATON & KNIGHT CO.'S SPARTAN BELTING

The Graton & Knight Mfg. Co., of Worcester, Mass., has recently placed on the market a new brand of belting which they call the "Spartan." The special advantage claimed for it is pliability. This carries with it the advantage of dur-

ability, and closer gripping of the belt at less tension. The belting is also claimed to be steam proof, and to be unharmed with contact of lubricating oil. It is proof, also, against the action of hot water, coal gas, and acid fumes, so that it would seem to be able to stand almost anything it is likely to come in contact with. The makers give the strong guarantee that "it will, when used under the same conditions, outlast any other belting material."

WESTERN GEARED DRIVE PLAIN RADIAL DRILL

The radial drill herewith illustrated and described, is built by the Western Machine Tool Works, Holland, Mich. It is notable from the ingenious design of the geared driving mechanism, the thorough provision for automatic lubrication of all important members, and the wide range of feeds and speeds provided. Another noticeable feature is the maker's well-known method of driving the spindle from a gear at the lower end, as shown in Fig. 8.

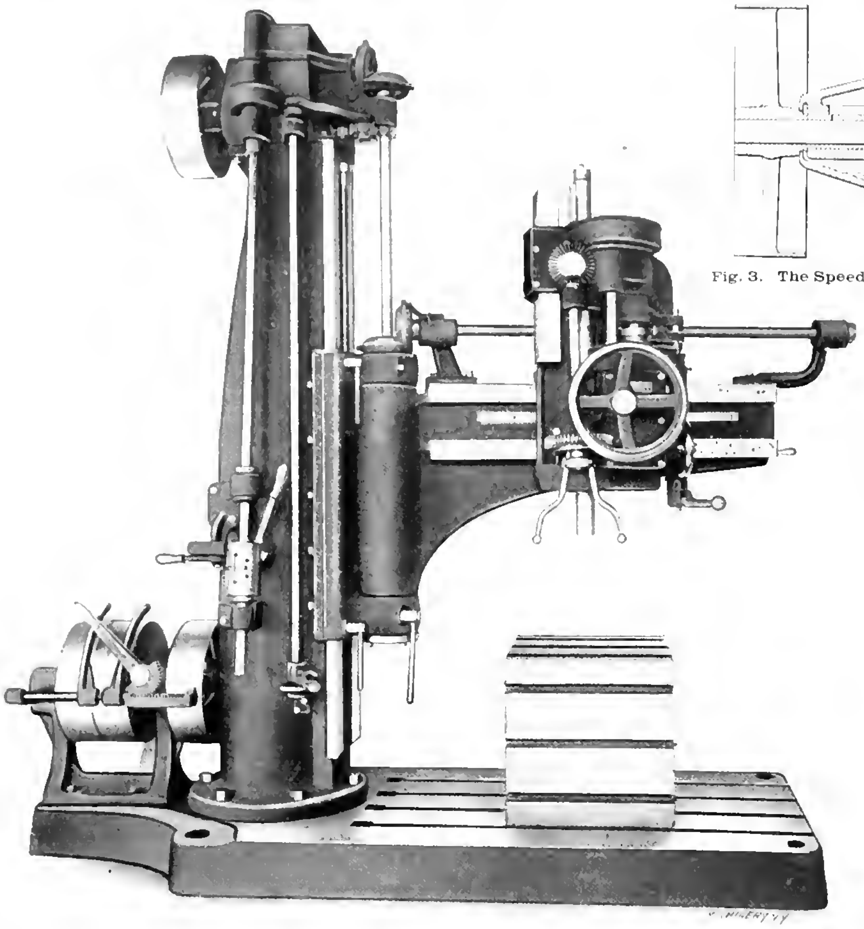

Fig. 1. The Western Plain Radial Drill, with Geared Speed Changes and Positive Feeds

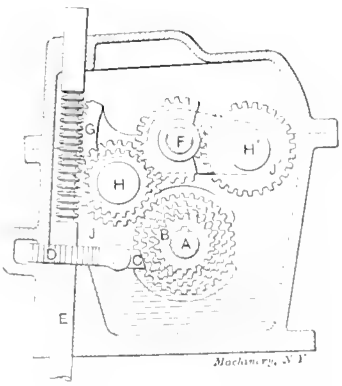

Fig 2. End View of Change Gearing, showing Control by Rod E

The Driving Connections

As may be seen in the front elevation, Fig. 1, the usual vertical shaft passing up through the column is dispensed with, a belted connection being made instead between the counter-shaft at the base of the column and the change gear box at the top. The counter-shaft has self-oiling journals and a self-oiling loose pulley. The individual oil reservoirs contain enough oil to last for a year of constant use. The loose pulley is of single piece construction with a reservoir cored around the bearing, packed with cotton and oil. In the reservoirs of the journals and the loose pulley, wicks are provided, leading from the bearing surface to the oil supply. A feature of the counter-shaft, which will be seen in Fig. 1, is the belt shifter. This, by means of the rack and sector construction shown, gives such a leverage that the shifting of the belt requires but a very light touch of the hand. If a motor drive is desired on the machine, a constant speed motor may be bolted on in place of the counter-shaft with very little trouble, being belted to the gear box at the top of the column in the same way.

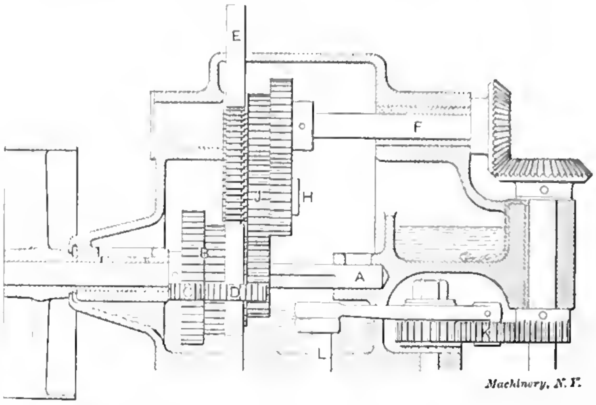

Fig. 3. The Speed Box, furnishing Eight Changes on the Selective Principle

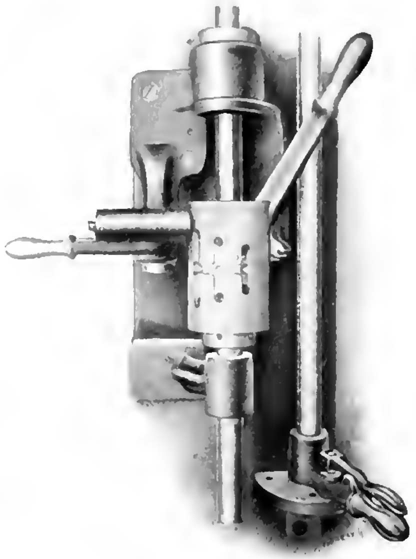

Fig. 4. Speed Changing Control at Lower End of Rod E

Figs. 2 and 3 show the construction of the speed change box. The constant speed shaft *A* is keyed to the pulley which, in turn, is belted to the counter-shaft or driving motor. A cone of 4 gears *B* is splined to shaft *A* and may be shifted thereon longitudinally, by means of fork *C*, sliding on the stud fixed in the gear casing. The rear side of the fork has rack teeth cut in its face, engaging a gear *D*, keyed to the vertical shaft *E* so that the rotating of the latter shifts the cone of gears *B*. The shaft to which the variable speed is transmitted is shown at *F*. This has mounted on it a rocker arm *G*, having two pivots *H* and *H'* supporting two intermediate gears *J* and *J'*. The latter is directly geared to pinion shaft *F*, while *J* is connected by compound gearing as shown. In the upper part of rod *E* are cut circular rack teeth, which engage corresponding gear teeth cut in the sector face of rocker arm *G*. Rod *E* may be both raised and lowered, and rotated to the right and left. Raising and lowering it rocks arm *G* and permits either *J* or *J'* to mesh with the corresponding gear on shaft *A*, as may be required. Rotating to the right or left shifts the cone *B* on shaft *A*, to bring either one of the four gears into position to engage either *J* or *J'*.

As may be seen in Fig. 4, a drum is mounted on the lower end of *E*, which is guided and locked in position by a lock bolt and lever shown. Raising or lowering this drum by means of the handle provided, brings *J* or *J'* into mesh with the mating gear *B*. Rotating the drum and shaft *E* brings either

one of the four gears on *A* into position to mesh with *J* or *J'*. By this means eight changes of speed are provided by a very simple mechanism, with no possibility of interferences or false moves. An inspection of Figs. 2 and 3 shows that at this point also the matter of lubrication has been carefully considered.

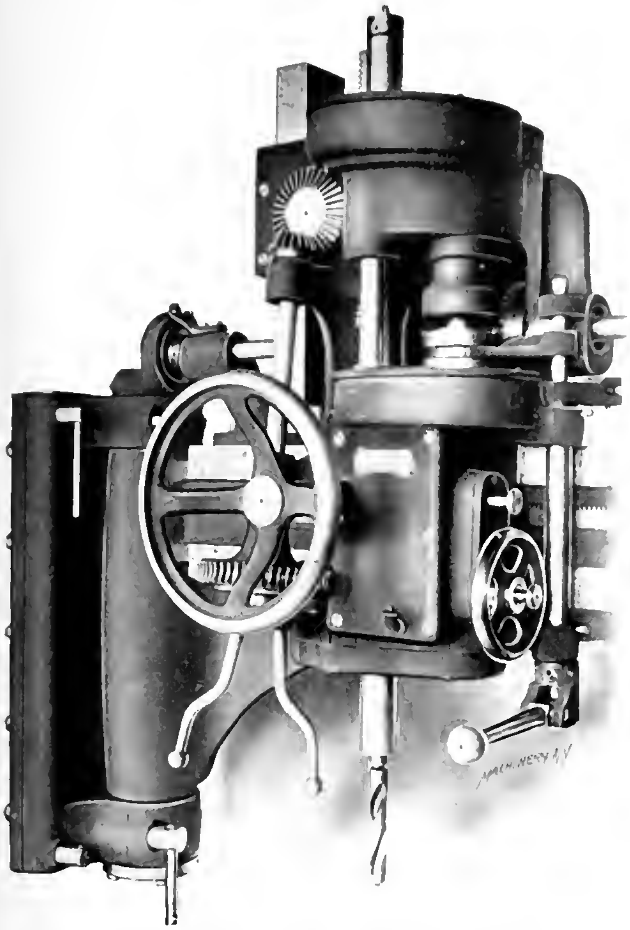

Fig. 5. The Spindle Head, showing Enclosed Construction

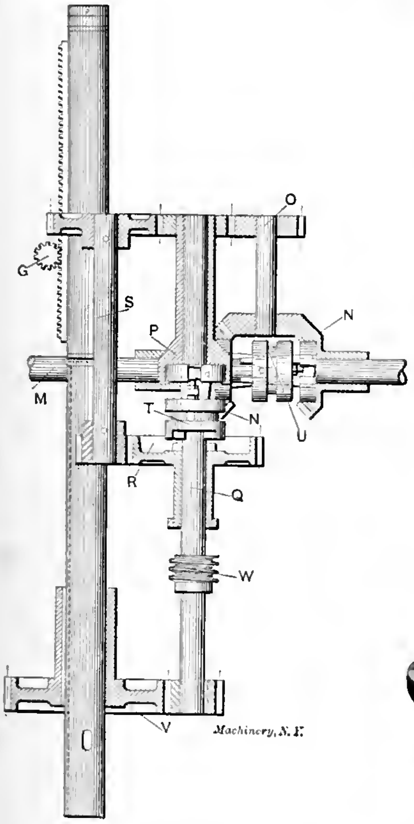

Fig. 7. Diagram of Driving Gearing in Head

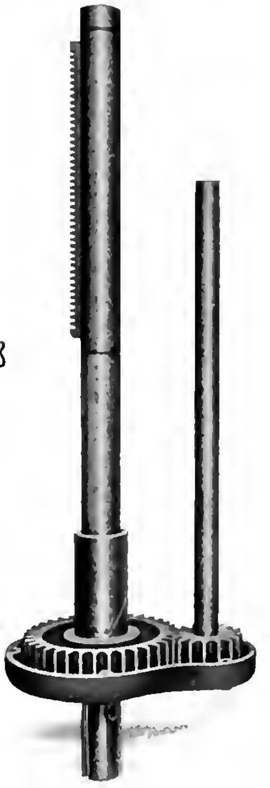

Fig. 8. The Spindle with Large Diameter Driving Gear, close to the Drill

The vertical screw for raising and lowering the arm is driven through the tumbler gearing shown at *K* in Fig. 2. This is operated by a handle attached to the vertical rock shaft *L*, plainly shown in Fig. 4. The arm rests and turns on ball bearings in the slide, giving the operator an easy and quick adjustment.

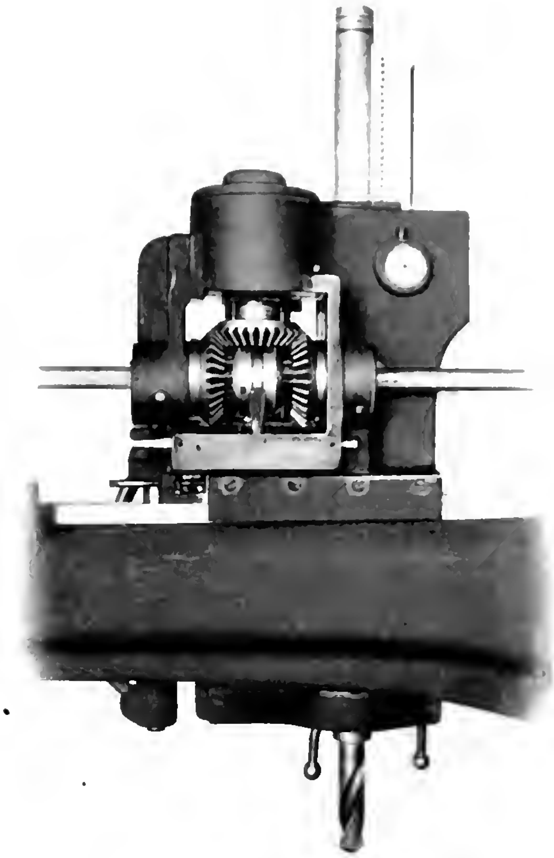

Fig. 6. Rear View of the Head, showing Tapping Reverse for Spindle Drive

The Driving Mechanism in the Head

From the speed box the power is transmitted through two sets of bevel gears to the horizontal shaft on the arm. Figs. 5 and 6 show front and rear views of the head respectively, while Figs. 7 and 10 show the details of the driving mechanism. *M* is the horizontal driving shaft. It has revolving loosely upon it bevel gears *N* and *N*. Either of these may be connected to *M* at will by means of the friction clutch shown in Fig. 9, so that short shaft *O* may be driven either forward or backward. The latter is geared with a loose quill *P* on spindle driving shaft *Q*. A second loose quill gear *R*, also mounted on *Q*, receives the movement from *P* through the back gear shaft *S*. *Q* may be clutched to either *R* or *P*, as may be required, by shifting clutch collar *T*. When this is dropped, *Q* is clutched positively to *R*. When it is raised, it is engaged with *P* by means of the friction clutch shown. This back geared drive, in connection with the speed box, gives sixteen changes of spindle speed, suitable for driving anything from a 3/8-inch drill to a 6-inch pipe tap.

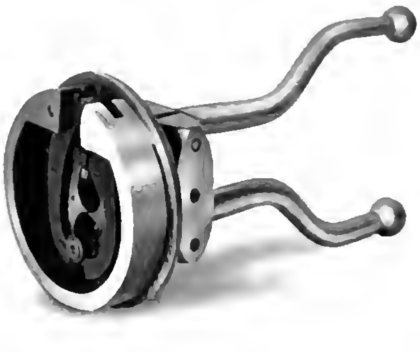

Fig. 9. The Friction Clutch for Connecting the Power Feed

The matter of lubrication of these members, seen most plainly in Fig. 10, should be noted. The driving gears are all enclosed in oil-tight casings, and are provided with reservoirs of oil for both the bearings and the gear teeth.

It should be noted that the same handle is used for the reversing clutch and the back gear clutch. This is shown at

the lower right-hand side of the head in Fig. 5. Raising and lowering this handle operates clutch *T* and controls the back gears. Swinging it to one side or the other operates clutch *U* for reversing the spindle movement. The starting, stopping, back gears and tapping device being thus controlled by one handle, it is possible to throw from one position to the other instantly, without danger of conflict or interferences.

The head is rigidly constructed, with webs of suitable thickness. The stiffness of the spindle drive is enhanced by the position of the driving gear *V* which is splined to the lower end of the spindle where it is driven by a pinion on shaft *Q*. The spindle and the driving gear are shown separately in Fig. 8. The spindle is thus driven in its large diameter and close to the gear, minimizing the torsional deflection, which is localized in a short, stiff length of spindle. In the ordinary construction, the power has to be transmitted through a long, slender spindle, cut down to pass through the feeding quill. It is stated that a torsional rigidity is obtained of from $2\frac{1}{2}$ to 3 times that given by the usual construction. This drive is, we believe, an exclusive feature of the Western machine.

The Feed Gearing

The feed mechanism is shown plainly in Fig. 10. The spiral gear *W* on shaft *Q* (Fig. 7) engages a mating gear *X* in the feed box. The shaft on which *X* is mounted carries also two gears, either of which may be connected with it by sliding the pull pin *Y* in or out, thus giving two rates of speed to the cone of gears *Z*. Gears *Z* in turn mesh with corresponding gears *A*, any one of which may be keyed to shaft *B* by means of the pull pin *C*. Eight feed changes are thus obtained, ranging from 0.008 to 0.060 inch per revolution of the spindle. These gears are enclosed in an oil-tight casing and run in oil.

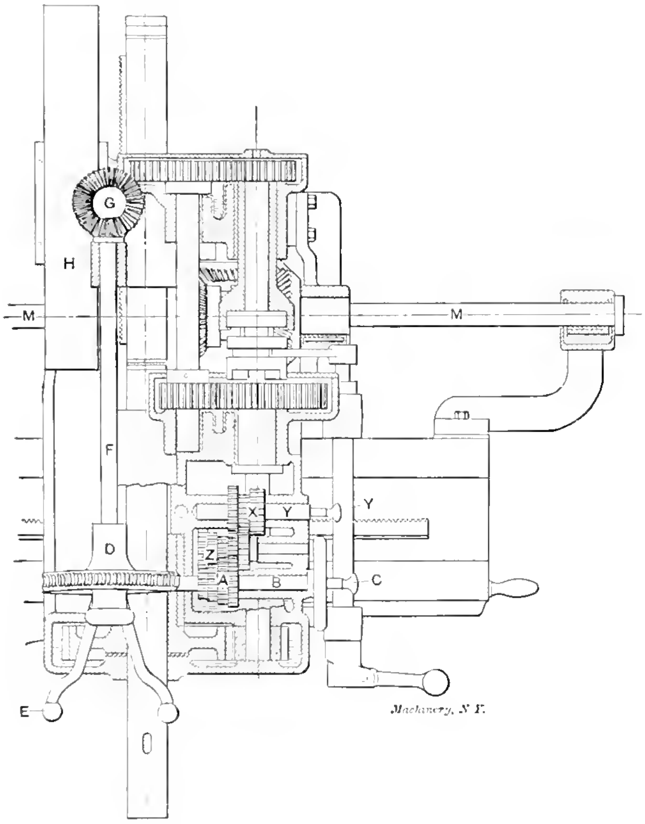

Fig. 10. The Positive Quick Change Feed

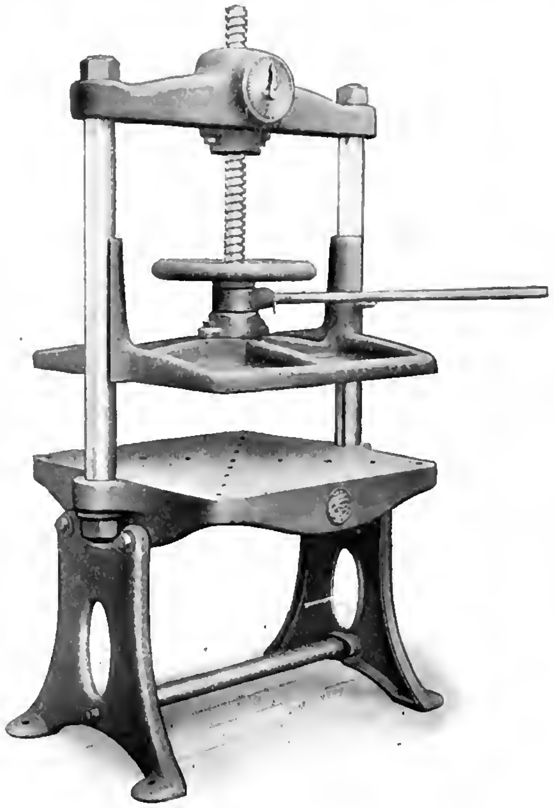
A worm on shaft *B* engages worm wheel *D*. This is clutched to the feed shaft by the mechanism shown in Fig. 9, operated by handles *E* (see Fig. 10). These serve to operate the clutch or to feed the spindle rapidly by hand when the clutch is disengaged. By pressing together handles *E*, a toggle joint mechanism expands the friction ring of the clutch, thus giving a powerful grip with easy operation. A suitable wedge is placed between the two fingers to vary the gripping pressure as desired. This clutch is keyed to the vertical feed rod *F*, which transmits the movement through a set of bevel gears to the pinion spindle *G*. This latter meshes on one side with the feed rack on the spindle quill, and on the other with the counter weight *H*.

The Western radial drill is built in four sizes having 3, 4, 5 and 6-foot arms respectively. As may be inferred from the illustrations and description here given, it is a strongly driven machine adapted to heavy work, and especially suitable for pipe tapping. Hill, Clarke & Co., of Boston, Chicago, and branch offices, are the selling agents.

FERRACUTE HAND SCREW PRESS

The tool illustrated herewith is a hand screw-press built by the Ferracute Machine Co., Bridgeton, N. J. It is designed for miscellaneous work of considerable area and height, having a bed 36 inches square and a maximum distance from the bed to the ram of 24 inches. It is designed for pressures of from 0 to 15 tons.



A Hand Press, provided with Dial for Indicating the Pressure Produced

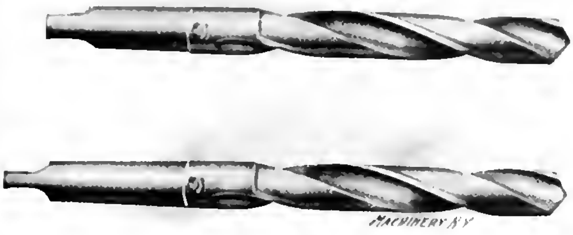
One of the features of novelty is the dial shown in the head of the press. The nut, set in the head, through which the screw runs, bears against a heavy steel spring, and the indicator hand on the dial is driven by a pin connected to this spring, giving the effect of a spring balance, which indicates on the dial the amount of pressure applied at any moment. Another point of interest is the combined handwheel and ratchet. Several tons pressure may be obtained by the hand-wheel alone. By connecting the ratchet lever, which may be done instantaneously, the maximum pressure is easily available. The ratchet is reversible, enabling the operator to start the ram upward with a minimum of effort.

The total height of the press with the screw raised is 98 inches. It occupies a floor space of 47 by 36 inches and weighs 2,300 pounds.

THE "STANTOOL" TAPER FOR DRILL SHANKS AND COLLETS

It seems to be practically agreed to that the old standard Morse taper shank and tang is too weak for the high duty required of it under modern conditions with modern cutting steels. The dimensions of the tang were settled on in days when the chips now taken with the twist drills would have seemed out of the range of the possible. To provide a stronger drive for new twist drills, and for giving added life to old ones from which the tangs have been broken, a number of devices and methods have recently been proposed. In the opinion of the Standard Tool Co., of Cleveland, O., all of these

devices have objectionable features. Some of them are complicated, some of them expensive, and some of them require a special preparation of the drill, which is only possible with the assistance of a skilled mechanic, and machines not found in every shop. This firm has therefore decided to meet the situation in a radical way. They are putting on the market drills having what they call the "Stantool" shank. While preserving the Morse taper, these shanks are shortened, thus permitting the use of a tang of much greater strength.



The New and the Old Standard Taper Shanks for Twist Drills

The upper drill in the engraving has the new shank, while the lower drill has the old standard. The difference in the strength of the tang will be seen at a glance. The dimensions are such that old drills on hand, whether broken or not, can be converted into the new type at very little cost and trouble. The makers furnish a gage which can be placed over the regular taper shank and used for scribing the size and location of the tang of the "Stantool" shank.

DIMENSIONS OF "STANTOOL" SHANKS AND TAPER HOLES

Number of Taper	Diameter, Small End of Shank	Diameter, Large End of Shank	Total Length of Shank	Depth of Hole in Socket	Length of Tongue to End of Socket Hole	Thickness of Tongue	Width of Keyway	End of Socket to Keyway	Length of Keyway	Diameter of Socket	Taper per Foot	Taper per Inch
	A	B	C	D	E	F	G	H	J	K		
1	0.378	0.484	$2\frac{1}{8}$	$1\frac{3}{4}$	$\frac{1}{4}$	$\frac{1}{4}$	0.263	$1\frac{5}{8}$	$\frac{3}{4}$	$\frac{25}{32}$	0.600	.05000
2	0.587	0.706	$2\frac{3}{8}$	$1\frac{15}{16}$	$\frac{5}{16}$	$\frac{3}{8}$	0.388	$1\frac{3}{4}$	1	$1\frac{1}{16}$	0.602	.05016
3	0.800	0.941	$2\frac{13}{16}$	$2\frac{1}{4}$	$\frac{3}{8}$	$\frac{1}{2}$	0.520	2	$1\frac{1}{4}$	$1\frac{5}{16}$	0.602	.05016
4	1.050	1.244	$3\frac{3}{4}$	3	$\frac{9}{16}$	$\frac{5}{8}$	0.645	$2\frac{11}{16}$	$1\frac{1}{2}$	$1\frac{11}{16}$	0.623	.05191
5	1.515	1.757	$4\frac{5}{8}$	$3\frac{3}{4}$	$\frac{5}{8}$	1	1.020	$3\frac{1}{4}$	2	$2\frac{7}{16}$	0.630	.05250
6	2.169	2.501	$6\frac{3}{8}$	5	$\frac{3}{4}$	$1\frac{1}{4}$	1.270	$4\frac{3}{8}$	$2\frac{1}{2}$	$2\frac{7}{8}$	0.626	.05216
7	2.815	3.283	9	$7\frac{3}{4}$	1	$1\frac{1}{2}$	1.520	7	3	...	0.625	.05208

The accompanying table gives the exact dimensions for all sizes of the new standard. Special sockets and sleeves are, of course, required, to adapt these tools to drill presses now in use. The makers furnish these sockets and sleeves with an outside taper to fit the spindles, and an inner taper suitable for the new shank. They are also made with the new taper both outside and inside. These latter interchange or nest into each other.

The use of a new standard, made stiff enough to begin with, would seem to be a logical way out of the broken tang difficulty.

JAEGER AUTOMATIC FRICTION CLUTCH

One of the many disadvantages experienced with the ordinary design of automatic pin clutches, such as are extensively used on power presses, is the heavy blow against the clutch pin, a fact which quite often causes injury to some parts of the clutch mechanism, and is accompanied by expensive delays while the broken parts are replaced. In order to overcome the difficulty of breakages, many press builders have designed their clutch parts very heavy, giving the clutch mechanism a clumsy appearance and, sometimes, a slower action.

Another disadvantage of the ordinary pin clutch is the necessity for a special brake for the crank-shaft. If this brake is not provided, the crank-shaft will not stop at its highest point after the fly-wheel has been released. The brake power acts constantly on the shaft, while the press is performing its work, and, therefore, a considerable amount of power is absorbed by the brake when the press is running continuously. Besides, the brake is rather unreliable, and requires frequent adjustment in order to do its work properly. Another disadvantage of many clutches is the loss of time. A number of clutches require that the fly-wheel at times make half a revolution before striking the clutch pin for engaging the crank-shaft.

In order to overcome the disadvantages referred to, Mr. M. Jaeger of 109 North Terrace Ave., Mt. Vernon, N. Y., has undertaken extensive experiments on a new design of automatic friction clutch, the results of these experiments being a device of the type shown in the accompanying illustrations. In Fig. 1 a clutch is shown as applied to power presses of smaller sizes. The main parts of this clutch are the eccentric *B* turned directly on the crank-shaft *A*, an expansion ring *C*, and a wedge *D*. The fly-wheel *E* is provided with a recess bored out in the hub in the side towards the press frame, and the whole clutch mechanism is placed in this recess. The eccentric in the design shown in Fig. 1 is turned directly on the crank-shaft, but it can, of course, be made as a loose ring and attached to the crank-shaft in any suitable manner. The fly-wheel revolves freely on the shaft, the hole in the fly-wheel being preferably lined with a bronze bushing.

The expansion ring *C* is originally turned larger than the recess in the fly-wheel. It is then cut open, pressed together, and then turned to fit the diameter of the recess, so that when laid inside of the recess and permitted to expand, it will closely fit the recess and at the same time press against the walls. Due to this pressure, the expansion ring will follow the fly-wheel when the latter rotates, whenever the stop *F*, acting against the pin *G* and operated by the foot-treadle, is removed; but when the stop *F* is in the position indicated in Fig. 1, the expansion ring *C* is prevented from rotating with the fly-wheel, and contracts so that the friction between the ring and the fly-wheel is reduced to a minimum.

It will be seen in Fig. 1 that the expansion ring has on the inside two projections. The wedge *D* rests against one, and the other has the same radius as the eccentric *B* on the shaft, there being only a very small clearance between the ring and the eccentric when the former is expanded, and no clearance at all when it contracts. A small spring *H* holds the wedge against the inside of the expansion ring.

The operation of the clutch is as follows: The fly-wheel runs continuously, but crank-shaft *A* does not rotate when the clutch is not in operation. When a stroke of the press is required, the operator, by means of a foot-treadle connected with the stop *F* by the link *K*, releases the expansion ring so that it follows the fly-wheel, thereby forcing the

wedge *D* between the inside of the ring and the eccentric, and imparting motion to the crank-shaft *A*. The expansion of the ring is still further increased by the wedging action of *D*, so that practically a positive drive is obtained. When the treadle is released, the stop *F* slides up in the position shown in Fig. 1 and the pin *G* strikes against the stop and prevents the ring from following the fly-wheel any further. The experiments undertaken with the clutch show that the blow against the pin is but slight, as the momentum of the shaft, pitman and other moving parts quickly releases the wedge and permits the ring to contract. The projection at *L* at this time also acts as a brake, stopping the crank-shaft at its highest point. If the foot-treadle is released immediately after being depressed, only one revolution will result.

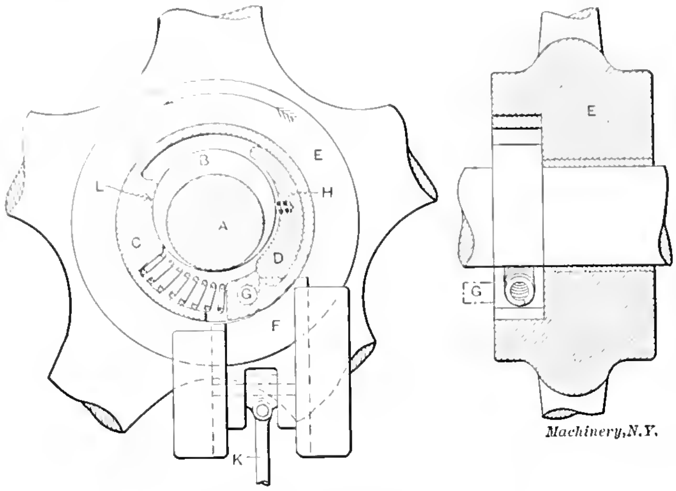


Fig. 1. Jaeger Automatic Clutch applied to a Power Press

The engagement is practically instantaneous as the clearance between the eccentric and the wedge is made as small as possible. An incidental advantage of this clutch is that the fly-wheel can be brought very close to the frame of the machine which, of course, is very important. A great many clutch designs make it necessary to place the fly-wheel a considerable distance from the frame and the bearings, thus producing bending stresses, and requiring larger shaft dimensions. A special brake acting on the crank-shaft is avoided. The design is very simple and reduces the cost of the clutch mechanism to a considerable extent. There is nothing in the design of the clutch that is liable to get out of order or break, and the experiments undertaken show that the efficiency of the design is very satisfactory.

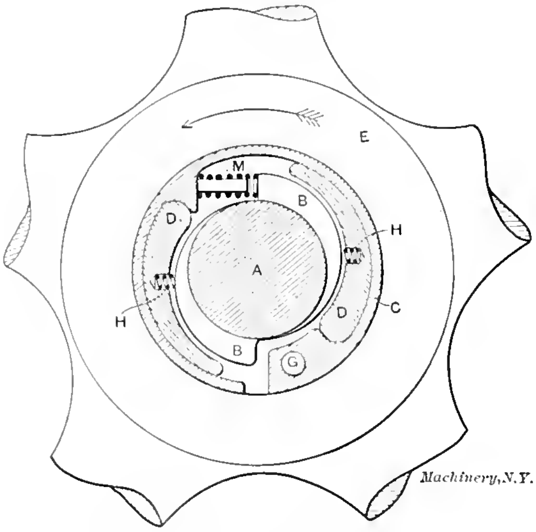

Fig. 2. Variation of Design of Jaeger Automatic Clutch, as used on Heavy Presses

In Fig. 2 is shown a modification of the design intended for heavy presses. Here two wedges are provided instead of one, and the eccentric or cam on the crank-shaft is provided with a double rise. In order to provide for a stop for the crank at the right position a spring *M* is provided, inside of which is placed a small rubber cylinder. This cylinder prevents the spring from bending sideways and at the same time acts as a final stop if the momentum is greater than that which will be taken up by the spring itself. The clutch is not limited to applications to presses only, but can, slightly modified, be used for a great many purposes where quickly releasing clutches are required.

BUFFALO FORGE CO.'S HAND I-BEAM AND CHANNEL PUNCH

While the tool here illustrated is a hand punch, it is designed, as a glance at its proportions will show, for far heavier work than is ordinarily considered feasible for hand operation. It will quickly and easily pierce a ½-inch hole in a ½-inch plate. Its maximum capacity by hand operation is for 1-inch holes in ½-inch plate. This would require a dead weight of about 40 tons on the plunger, considering the shearing strength of the material being punched as being 50,000 pounds to the square inch, which is about that found in the steel ordinarily used in bridges and similar structural work.

In the first place the construction of the frame is notable. It is composed of two sides of armor plate, rigidly bolted and riveted together in a box form of construction. The planed sides of the frame form guiding surfaces on two sides of the plunger, while the main guides are bolted between the sides and have adjustable gibs, which assure the permanent alignment of the punch and die. The die holder is a steel casting of a style designed to adapt it to working on the webs of channels, I beams, etc. It is mounted on the frame, and bolted on an extension machined to fit the frame space.

Hand-operated Punch of Large Capacity with Armor-plate Frame

The great force which this hand operated punch is capable of applying is due, of course, to the construction of the operating mechanism. This consists of a combination lever, ratchet wheel, and crank mechanism, which will be easily understood from a study of the engraving. It gives a leverage of 2,200 to 1 from the end of a 6-foot lever to the shearing edge of the punch; this does not include the power lost in the friction of the working parts, which is small for a machine of this kind. The lever bearing studs are bolted to the frame, making a very rigid support. The socket in which the lever is inserted is provided with three holes for the connecting links to the secondary lever, so that a movement of 1, 2 or 3 ratchet teeth for each stroke is obtainable.

The ratchet wheel is cut from solid steel, and is hardened. It can be turned by a convenient handle to quickly adjust

the punch to the work, and to run it back again as well after the completion of the operation. The plunger crank-shaft, on which the ratchet wheel is pressed, is supported by flanged bearings bolted to the main frame. The throw of the crank-shaft is ¾ inch, and the motion is transmitted to the plunger head by a steel one-piece connecting rod the full width of the frame space, bored from the solid and bronze bushed.

This is believed by its maker, the Buffalo Forge Co., Buffalo, N. Y., to be the only punch press with armor plate frame made in the country. Its portability, in connection with its great capacity, should make it a useful tool in many structural operations. As may be seen, heavy angle plates are riveted to the frame on both sides, making a substantial base plate when it is desired to mount it permanently. Otherwise it is provided with a truck for portable use. It weighs about 1,000 pounds.

ST. LOUIS MACHINE TOOL CO.'S GRINDING MACHINE

The plain grinding machine, or grinding head, is so simple a piece of mechanism that it is no wonder that little thought is ordinarily given to its construction. There is no complicated mechanism, and the parts required are few and simple. Nevertheless, it is possible to put thought into the design of a machine as simple as this, as will be realized from a study of the accompanying illustrations, which show one size of a line recently placed on the market by the St. Louis Machine Tool Co., of St. Louis, Mo.

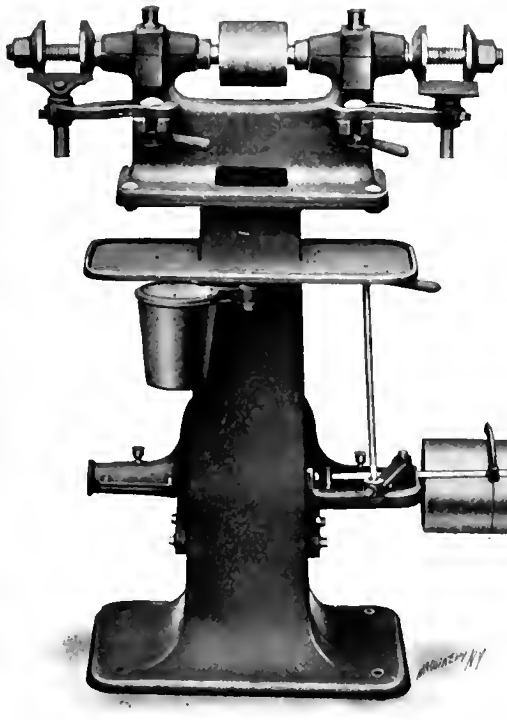

Fig. 1. Front View of the St. Louis Grinder

The points of advantage claimed for this grinder relate both to the workmanship and the design. Considering first the construction of the heads, the arbors are of 50 point carbon steel, with square threads coarser than standard, giving a strong and quick acting screw. The arbors for each size are of larger diameter than usual. The boxes are lined with a high grade of anti-friction metal, and are provided with oil reservoirs and felt oilers with a length four times the diameter of the arbor. The bodies are unusually long, extending out for their full size beneath the bearings, giving the latter a very rigid support. The arms supporting the rests are curved. This permits the use of a shorter fork than when the straight rest arms are used. This is very advantageous when large work is to be ground.

The column is of new design, being large and well proportioned to agree with the service it is called on to perform. The pan is 4 inches below the base of the machine, allowing more room than usual. All of the batter or slant of the column is at the back, thus setting the head as near the front of the base as possible, giving the tool somewhat the appearance of being braced toward the operator.

The column is furnished either with or without a self contained counter-shaft. The machines shown are provided with this counter-shaft, which is the most interesting feature of the whole machine. The lower half of the boxes (see Fig. 3) are cast integrally with arms extending backwards the full depth of the column, being pivoted at the rear end. Each arm is also clamped to the column at the side by a screw passing through an elongated slot. The top halves of the boxes are cast in one piece and connected by a strong yoke which passes over the driving pulley. This yoke is provided with a lug passing beneath a corresponding projecting lug on the column, into which an adjusting screw is tapped. The driving belt passes over the large pulley at the base of the counter-shaft up back of the machine, over the spindle pulley and down through a hole, into the middle of the column to the pulley again. The tension of this belt tends to draw the driving pulley and its shaft upwards, bringing the yoke against the adjusting screw. By screwing down on this, the counter-shaft is swung downward upon its supporting arms and the belt tightened. The screws passing through the slots in the arms provide means for holding the adjustment once it is obtained. This tightens the driving belt and the belt from the main line-shaft at the same time. The belt shifter is conveniently located, as shown, it being unnecessary to reach overhead for it as usual.

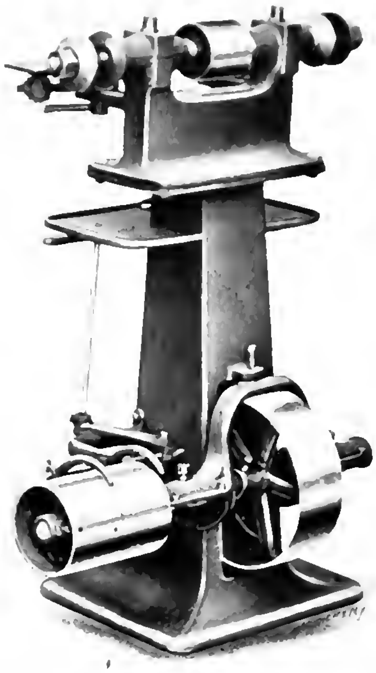

Fig. 2. Side View of the Grinder, showing Counter-shaft

This arrangement gives several advantages over the separate counter-shaft from the ceiling. One of the most obvious is the avoiding of the necessity for mounting the counter-shaft on the ceiling. Another is the advantage of bringing the driving belt down in an out-of-the-way position, which is often a great convenience in handling large work. The most important advantage, however, is the smooth running of the wheels which is the result of the direction of the belt pull, this being such as to draw the spindle down against the frame of the machine, instead of up against the caps.

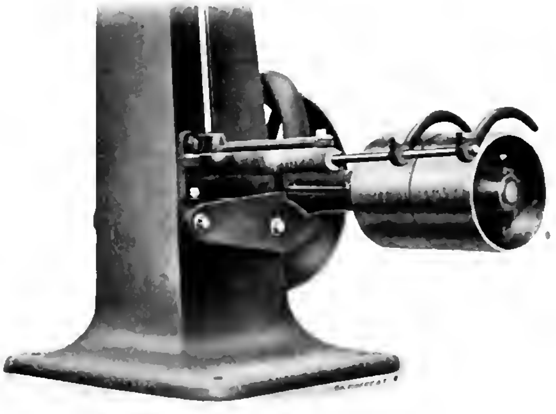

Fig 3. Detail View of Belt Tightener and Shifter

A short belt on a machine of this kind without a belt tightening device is impracticable. The only objection to the use of short belts is the matter of keeping them tight. In long belts the elasticity serves to allow considerable stretch without affecting the belt pull seriously. In short belts,

however, it is necessary to take up the stretch as fast as it occurs by some simpler means than by cutting and resplicing the belt. The use of the adjustable swinging supports for the counter-shaft does away with the great difficulty hitherto met with in furnishing a satisfactory self-contained counter-shaft.

These machines are made in five sizes, for work from the smallest to the heaviest which the workman is ordinarily called on to perform on a grinding wheel stand of this type.

TWENTY-FOUR-INCH FAY AUTOMATIC LATHE

The Fay Machine Tool Co. of Philadelphia, Pa., makes an automatic lathe especially adapted to the performance of turning operations on castings in large quantities. To the 14- and 18-inch swing sizes previously built, the makers have recently added the machine with a 24-inch swing shown herewith.

Without going minutely into the mechanism, the machine may be described as follows: The work spindle is driven by Hindley worm gearing from the high speed shaft extending across the top of the head-stock. This shaft is belted at the rear side to the counter-shaft, and at the front side to the feed-driving pulley at the left-hand end of the bed. This latter is geared to a longitudinal shaft carrying a series of cams controlling the cutting tools. By means of a clutch mechanism operated by adjustable dogs, the cam shaft may be given a slow feeding movement, or a rapid idle movement, over any desired portion of its periphery.

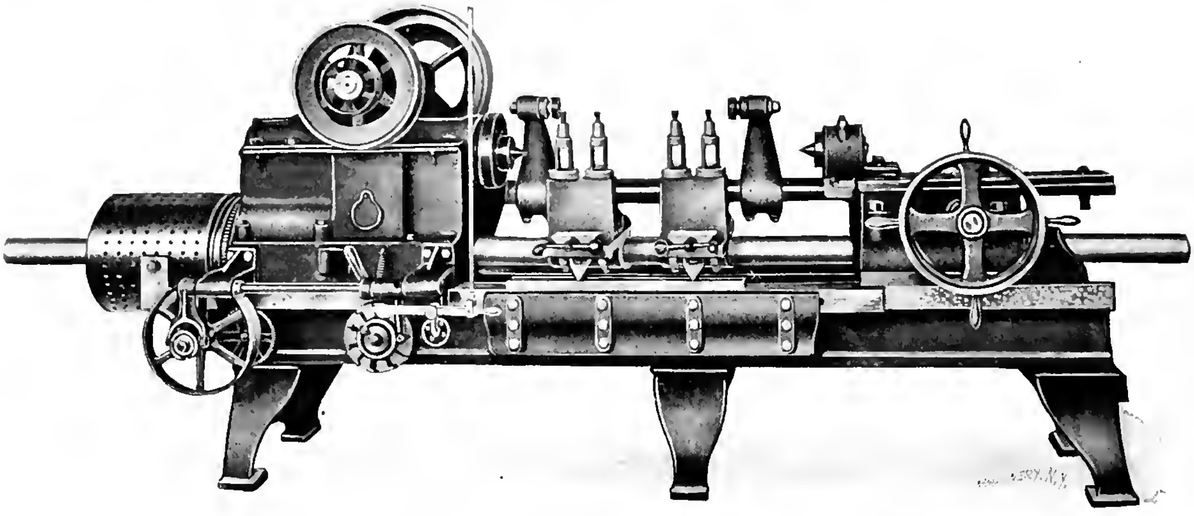

Fig. 1. An Automatic Lathe for Turning Pulleys, Gear Blanks, etc., on Centers

Two heavy bars extend the length of the machine, and on these the various carriages and tool holders are mounted. Each of these bars is controlled by the cam shaft, both as to longitudinal movement and the rocking movement about their axes. The rocking movement for the main bar at the front is controlled by a templet on the slide at the front of the bed, on which the outer ends of the carriages rest. This templet may be given any desired shape, which will be copied by the tool as the bar is fed longitudinally. On the other hand, if desired, the bar may be held against longitudinal movement while the slide carrying the templet is fed to the right or left, by means of its connection with a cam roll operated by the drum cam shown at the left of the machine. Cams of any required shape may be bolted on this drum to operate the former slide or the tool bar at the rear. The latter is rocked by a cam beneath the head-stock, while the main tool bar is operated by an internal cam surface within the cam drum.

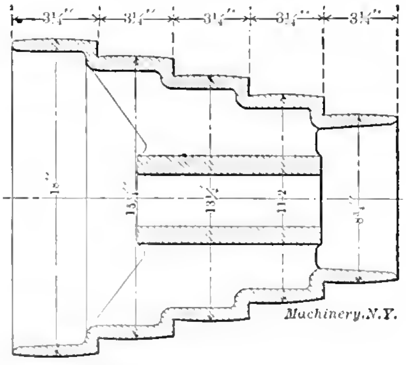

Fig 2. A Cone Pulley, which was roughed out and finish-turned Complete in Forty-two Minutes

The large machine here shown swings twenty-four inches over the ways, eighteen inches over the carriage and will take thirty-six inches between centers. The automatic feed of the main bar and its carriages is fourteen inches. The provision for turning between centers is unique in automatic machines, and permits the production of a quality of work comparable with that produced on the engine lathe. One operator can attend several machines, or can run one of these in combination with work on a regular lathe.

The 5-step cone pulley shown in Fig. 2 was turned in two operations, roughing and finishing in forty-two minutes. This included turning and crowning the five steps, and facing both ends of the pulley. The crowning was done by suitable templets acting on the carriages attached to the main bar, as described. Facing down the ends was effected by tool holders on the rear bar.

IMPROVED MURCHEY AUTOMATIC OPENING DIE HEAD

The machine shown in Fig. 1 is a double-head pipe and nipple threading machine, made by the Murchey Machine & Tool Co., 4th and Porter Sts., Detroit, Mich. This machine follows the general lines of the older design built by the makers, with the exception of the die heads, which are of radically new and improved construction. The mechanism of this new die head will be understood from a study of the line engravings, Figs. 2 and 3. Its purpose is to furnish a die head of rigid construction, wide range of adjustment, and strong, simple construction, and one that will operate readily and automatically and will preserve its accuracy through a long period of use. As may be seen, the head is composed of comparatively few members, and there are also few wearing parts and no light and delicate pieces in the mechanism.

The body *A*, which is of strong close-grained cast iron, is pressed on and keyed to the spindle *B* of the machine. In the face of the body are milled four large T-slots, carrying the steel die blocks *C*. These, in turn, are drilled and slotted to receive the dies *D* and the bearing pins *E*. These bearing pins are closely fitted in the holes in *C*, into which the slots for the die blocks are cut, so that there is a solid backing for the latter against the thrust of the cut.

On the hub of the body *A* slides a collar *F*. This is provided with lugs which are milled, drilled and reamed to form pivots for the die levers *G*. These latter are restrained from outward movement by a tapered bearing on the inner rim of the adjusting shell *H*. This adjusting shell is threaded to the collar at the rear end as shown, and is fitted at the front end to an internal flange on the rear face of the body *A*. When it is screwed in or out, the bearing of its taper surface on the four die levers *G* adjusts them inward simultaneously, or allows them to move out simultaneously as the case may be. These die levers bear at their front end on a seat cut to receive them on bearing pins *E*. When the sliding collar is moved to the right from the position shown in Fig. 2, the

ends of the die levers slip off of the seats on the bearing pins to a lower position, when the spring *J* forces the pins *E*, die blocks *C* and dies *D* outward, thus opening the dies and releasing the work. When the adjusting shell is moved to the left, levers *G* ride up on the cam surface onto the upper bearing on pins *E*, closing the dies. The turning of the adjusting shell *H* evidently affords means for setting the dies accurately to any desired diameter within the range of the adjustment.

The sliding collar *F* is moved to the left to close the dies by hand through a lever connection with the handles shown between the two work-slides in Fig. 1. The die is opened automatically when the desired length of thread has been cut. This is done through the reaming mechanism shown in Fig. 3. It will first be necessary to describe the operation of this mechanism in reaming a pipe. The reamer holder *K* is of malleable iron with a squared socket for receiving the squared pipe reamer shanks. The reamer is held in place by a single set-screw. The holder is supported on rods *M*, which pass through holes in the body *A*. It is free to move outward, but its backward movement is resisted by plunger *N* and spring *O*. The latter may be compressed to give more or less tension by means of threaded adjustment collar *P* (seen also on the spindle between the head-stock bearings in Fig. 1) which bears against collar *Q* and plunger *R*, furnishing the rear abutment for the spring. After the work has passed far enough into the dies to secure a good hold on the thread, the continued feeding forward of the pipe brings it in contact with the reamer *L*, pressing it back against plunger *N* and spring *O*, thus giving sufficient pressure for taking the chip. Owing to the construction the extra tension which may be applied by adjusting collar *P* affects the thread only when the work is well through the dies, where a heavy chip will not cause a thin thread.

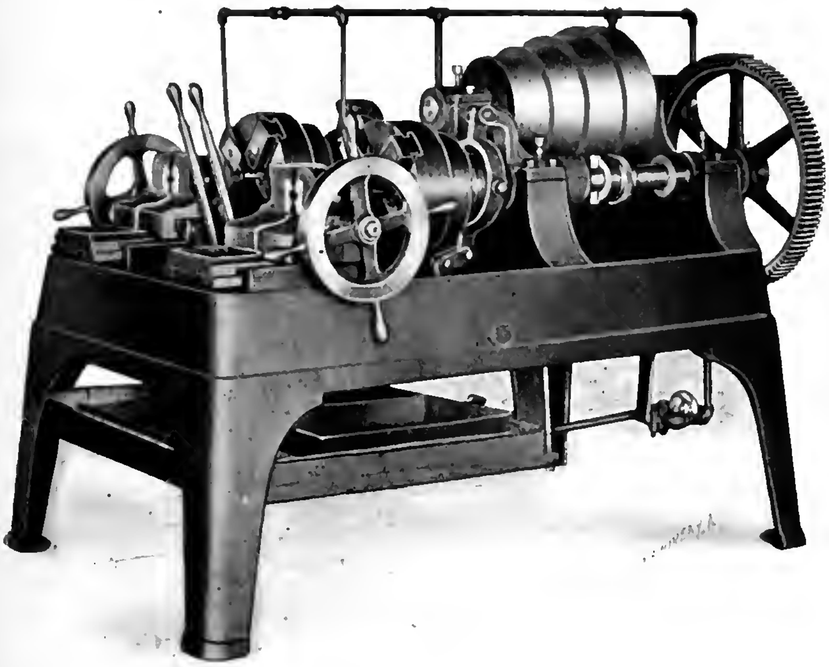

Fig. 1. Murchey No. 2 Pipe and Nipple Threading Machine equipped with Improved Opening Die Heads

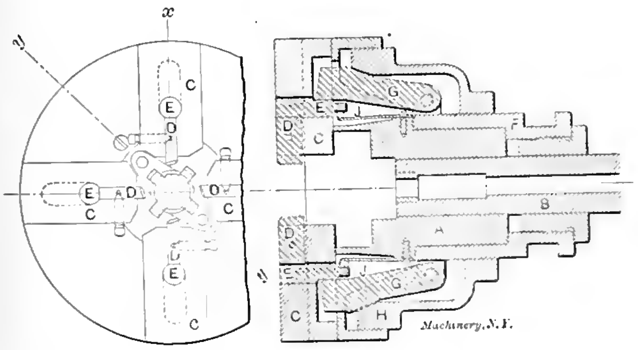

Fig. 2. Face View of Die Head and Section on Line x—x, through Die Blocks, with Reamer Removed

The automatic opening of the dies is effected by the longitudinal movement of reamer holder *K*, caused by the pressure of the work on the reamer. This forces back *K* and rods *M* against sleeve *S*, which is threaded into sliding collar *F*. As *F* is thus forced backward, levers *G* are withdrawn from their seats on bearing pins *E*, allowing the dies to open. By screwing sleeve *S* in or out, the length of the thread on the work can be shortened or increased. Spring *O* being set up tight enough so that the reamer faces the end of the pipe, it will be seen that the stop movement is governed by the end of the pipe itself, so that the threads come to a uniform length. Shoulders are provided on reamer rods *M*, which strike against the shoulder on the sliding collar *F*, in case *S* is adjusted out too far. When the die head is open, the reamer holder with the rods may be drawn out, allowing long or "running threads" to be cut.

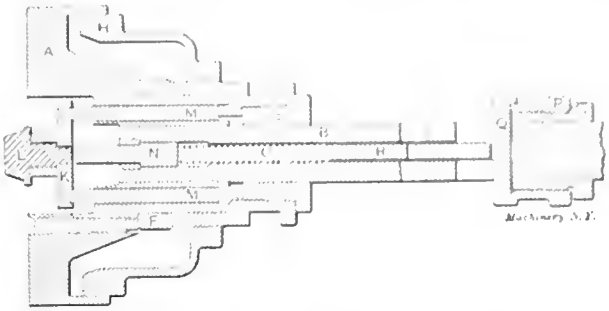

Fig. 3. Section on Line y—y of Fig 2, showing Reaming Mechanism

The adjustments for this die holder are few, simple and quickly made. They are the adjustment of shell *H* for the size of the thread, of sleeve *S* for the length of the thread, and of sleeve *P* for the depth of internal reaming. The large amount of adjustment of sleeve *H* makes it easily possible to re-hob dies in this head. The workmanship is of a high grade, the tool being made with jigs and fixtures throughout on the interchangeable plan. The die blocks are of case-hardened machine steel, the bearing pins *E* are of tempered steel, and the bearing levers *G* are of tool steel. Attention has been given to the quality of the steel material in the dies, which is the best obtainable.

The double nipple and pipe turning machine shown in Fig. 1, equipped with the die heads just described, has a capacity for work from ½ inch up to 2 inches inclusive.

WALTHAM MULTIPLE SPINDLE DRILLING MACHINE

The accompanying half-tone shows an addition to the line of precision machine tools built by the Waltham Machine Works, Waltham, Mass., which we have illustrated from time to time. This particular tool is a multiple spindle drilling machine, built on the lines of the larger tools used for drilling holes in cylinder flanges, machine frames, etc. The idea here, however, is reduced to the smallest scale on which we have ever seen it used.

The frame of the machine is in two parts; one is a base, carrying the work table, and the other is a stand mounted on the base, carrying the driving mechanism for the spindles. The drive shafts are evenly spaced about a central gear, which is connected with the double driving pulley shown at the top. These gears are enclosed and accurately cut, so that a very high drilling speed is obtained with practically no noise. The lower, or drill spindles are held in interchangeable cast iron blocks, accurately bored to the desired location of the holes. As these blocks can be reversed, it will be seen that the holes may be drilled from either side of the work; or, in the case of clock plates, the upper and lower members may each be drilled from the inner face. By using short drills, holes may be accurately located without the use of a jig, and the ma-

chine can be used for reaming and countersinking holes already drilled or punched. Provision is made for using a jig, however, if desired.

An important feature in the construction of this machine is the extremely close spacing with which the holes may be drilled. This may be less than 0.200 inch center distance. This is accomplished by the use of special ball and pin joints. The joints and all the spindles are of hardened steel, the latter having bronze bearings which can be easily replaced when worn. The connections between the driving and the drill spindles are two or three times as long as is usual in machines of this type, thus making the angle very slight, and materially reducing the wear on the joints.

A Multiple Spindle Drilling Machine, built on a Minute Scale

The table carrying the work is operated either by a hand wheel, or a lever connected to a rack and pinion. An adjustable stop is provided to regulate the depth of drilling. There is also a screw adjustment for setting the vertical position of each spindle separately.

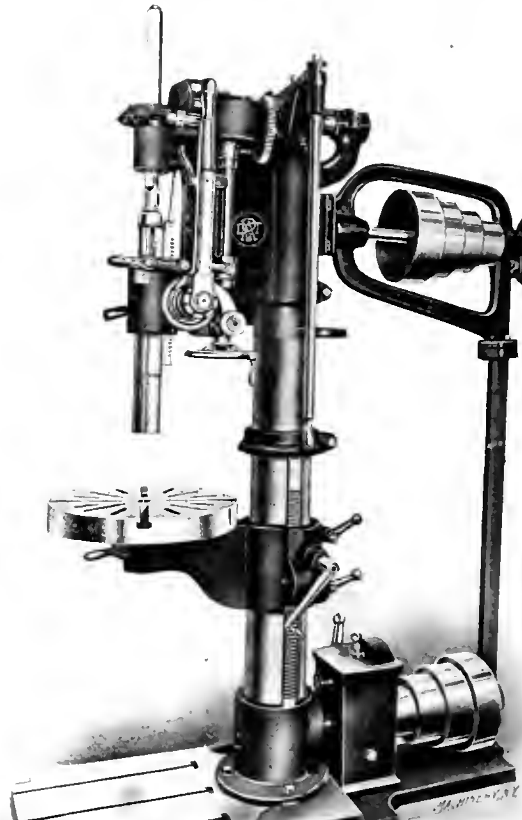
This machine is made in two sizes. The larger, which is particularly intended for clock and similar work, weighs 240 pounds, and is made with any number of spindles up to 14. It will drill to any position inside of a 6-inch circle. The smaller, or watch size, weighs 50 pounds, and can be built with any number of spindles up to 8. It will drill anywhere inside of a 3½-inch circle.

ROBERTSON DRILL & TOOL CO.'S 21-INCH DRILLING AND TAPPING MACHINE

The accompanying illustration shows a 21-inch drilling and tapping machine made by the Robertson Drill & Tool Co., Dept. 5, Buffalo, N. Y. This resembles somewhat in its general lines the 21-inch upright drill illustrated among the new tools in the May issue of MACHINERY. The driving mechanism, however, is entirely different, and the machine is provided, in addition, with a self-contained tapping attachment.

Contrary to the usual construction, the driving cone on the countershaft is placed at the top of the machine, with the driven cone at the base. Four-step cones of large diameter for a 2¾-inch belt are used. The back-gearing is enclosed in the casing shown on the lower cone shaft. The back-gearing may be thrown in and out while the machine is in motion. From this point the power is led to the top of the machine again by miter gearing and a vertical shaft passing through the center of the column. At the upper end it is connected through reversing miter gears with the usual horizontal driving shaft. The long lever which hangs from the top of the column controls the clutch playing between these miter gears, and thus serves to reverse the motion of the spindle, or stop it, as may be required. The clutch provided on the driving pulley of the countershaft is not used in the operation of the machine, being employed only when the workman starts his job or finishes it.

The feed is geared and has 24 changes. It may be operated by a wheel or lever, as well as by power. An automatic stop is provided. The spindle is 1¾ inch in diameter, and is driven by its squared shank, which fits a corresponding hole in the driving gear, as explained for the machine described in the May issue. The gears are all cut from solid metal. All the bevel and miter gears have planed and generated teeth.



Robertson Drill Press with Self-contained Tapping Mechanism

The racks are of steel cut from the solid. All clamps and adjustments are furnished with permanently attached handles.

The height of the machine over all is 77 inches. It occupies a floor space of 18½ by 58 inches. The table is 18 inches in diameter and the machine drills to the center of a 21¾-inch circle. The net weight is 1,450 pounds.

RECENT ADDITIONS TO THE BROWN & SHARPE LINE OF MACHINISTS' TOOLS

The ten accompanying illustrations show the latest additions to the line of machinists' tools made by the Brown & Sharpe Mfg. Co., Providence, R. I. While some of the additions relate principally to improvements in design of older tools, others are radically new in principle. All of them are of interest.

Universal Surface Gage with Fine Adjustment

This firm has been making a universal surface gage for some time. The principal feature of its construction is the fact that the spindle can be swiveled about a horizontal axis

and is so mounted on the base that it can project down past it in a slot provided for the purpose, if desired. The base is provided with a V-groove for use on cylindrical surfaces. For small work the spindle can be removed, and the scriber inserted in a hole provided for it in the clamp.

The new gage preserves all these features, and gives the added advantage of a fine adjustment by means of a knurled screw at the top of the spindle clamp. Turning this brings the spindle and the scriber accurately to the height desired. It has a distinct advantage over other devices intended for the same work, in that the movement is always vertical, no matter what the position of the spindle or scriber. Two gage pins at the rear of the base can be pushed down so as to line the tool up against the edge of a plate, or the side of a T-slot. The scriber may also be used below the base as a depth gage. This tool is made with 9-, 12-, and 18-inch spindles, and with light or heavy base.

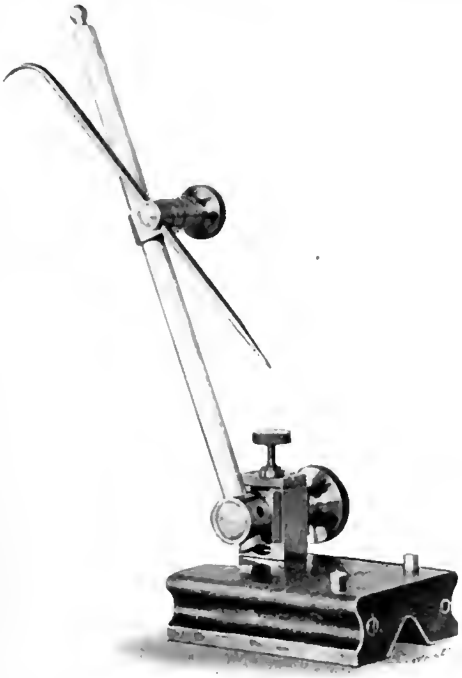


Fig. 1. Surface Gage with Micrometer Adjustment

Standard Caliper Gages

The Brown & Sharpe standard caliper gages have been furnished for many years with internal and external surfaces on the same piece, for all sizes up to 3 inches; larger than that the gages have been made separately for external or internal measurements. To meet the demand for tools for use where measurements of one kind only, either internal or external, are to be taken, separate gages with handles are now furnished for all measurements between ¼ and 3 inches. Furnishing them separately instead of in one piece has a distinct advantage whether both are to be used or not, as it enables one to be employed as a standard gage for testing the other.

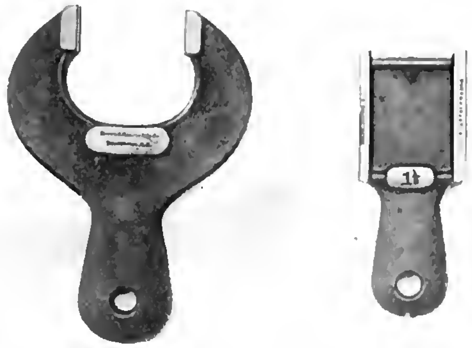

Fig. 2. Standard External and Internal Caliper Gages

A Large Automatic Center Punch

The well-known automatic center punch made by this firm is now furnished for heavy work in a size 11¾ inches long and 1⅜ inch in diameter. This heavy tool has found considerable use in many ways not thought of at the time of the introduction of the smaller size a few years ago. It is employed, for instance, in rolling mills for testing the hardness of metal. The hardness is judged by the size of the impression made, in something in the same way as in the Brinell test. It may be used, as well, for testing the depth of case-hardening, or for laying out heavy work for drilling.

Among the miscellaneous uses which have been found for the automatic center punch may be mentioned its employment by amateurs in making art objects of hammered copper or brass. For this work it has been found much easier to use than the usual punch and hammer, requiring considerably less exertion. It has been recently employed also in the makers' automatic screw machine, where it was desired to punch a square center in the end of a piece of work held in the chuck. It was not found feasible to bring the turret up forcibly enough to make the desired impression. To overcome the difficulty, the striking mechanism of one of these hammers was employed in the turret tool. The latter was brought up with the punch bearing on the work, thus compressing the striking spring of the tool. The spring plunger, being released by this movement, was forced against the head of punch, making the desired impression the same as in the hand-operated tool. The spindle of the screw machine was stopped and held fast for this work.

Tubular Inside Micrometer Gages

These gages are a new design, intended for use in manufacturing operations for measuring inside diameters from 8 to 40 inches. A particular advantage in their construction is the fact that they are of tubing, making them very light and convenient to handle, especially in the longer size. They are used in taking inside measurements as in measuring rings and cylinders and in setting calipers, comparing gages, and in doing other work of a similar nature.

Fig. 3. An Automatic Center Punch of Unusual Size

Fig. 4. Tubular Inside Micrometer Gage

The gage consists of a tube or body, provided with a 1-inch micrometer head at one end, and a fixed measuring point at the other. The measuring points are hardened and ground spherically, thus adapting the gage for measuring parallel or curved surfaces. Provision is made for adjustment to compensate for wear, and a clamp screw is provided for preserving the setting after it has been obtained. A fiber handle prevents the hand from coming into direct contact with the tool, and thus varying its temperature.

Each gage has a movement of 1 inch, and the entire line embraces 32 different sizes, covering the range from 8 to 40 inches.

Universal Indicator

Fig. 5 shows an indicator of new design, of which the distinguishing feature is the fact that it reads movements in any direction—up, down, sidewise or inward. The point which bears against the work is of steel, hardened and ground spherically, thus allowing pressure to be brought upon it from any direction. A scale on the top of the case registers the movement by means of a pointer. This scale is graduated to thousandths of an inch and reads to 0.007 inch either side

of zero. The shank is of hardened steel, and is designed to be held in the tool-post of a lathe. By means of a swivel joint at the end of the shank, the head may be adjusted either above or below the center within a range of 30 degrees on either side.

This tool will be found useful in setting centrally a point or hole in a piece of work to be operated on in a face-plate or chuck. It may be used, also, for testing lathe centers, shafting and other work held between centers, inside and outside diameters of pulleys, cylinders and similar work; and may be employed in testing finished machinery.

Heavy Micrometer Calipers

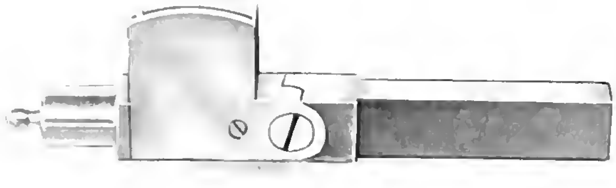

Fig. 5. An Indicator which reads in All Directions

It has always been considered that the careful handling of fine measuring tools is one of the distinguishing marks of a good workman; so the apprentice is always warned not to use a vernier caliper for a monkey-wrench, or a micrometer for a C-clamp. It is not considered good practice, as well, to use the micrometer as a snap gage with the spindle clamped fast. Whatever the case may be for the vernier caliper, the makers of the micrometer shown in Fig. 6 have concluded that there is a legitimate demand for an instrument which can be handled more freely and carelessly than the standard design of micrometer caliper. In consequence, these tools have been made with all parts of much greater weight, stiffness and bearing surface than have been hitherto employed.

Fig. 6. New Design of Heavy Micrometer Caliper

The frame is of heavy I section, of a design which gives exceptional strength and rigidity. The spindle and screw are of larger diameter than usual, giving great stiffness and long life under adverse conditions, owing to the larger bearing surface for the threads. The screw is encased and protected from grit and from injury. Provision is made for adjustment to compensate for wear. The thimble is of unusually large diameter, so that the thousandths graduations are more distinct and easily read.

The clamp ring shown in the engraving securely locks the spindle in any desired position, and it is intended that the tool should be used freely when thus set. This makes it adaptable for use in the grinding room, where there is necessity for taking frequent measurements under these conditions. The construction of the tool is also such as to make it durable under the unfavorable conditions of water, grit, etc., found in this work. Each caliper is provided with a specially designed ratchet stop. It is made in three sizes to measure up to 1 inch, from 1 to 2 inches, and from 2 to 3 inches, respectively.

Hardened Squares with Beveled Edges

In Fig. 7 is shown a hardened steel square with both edges of the blade beveled. This gives practically a line contact with the work under observation, making possible the detection of slight errors, and fitting the tool for use in the tool-room and on all classes of work where the requirements are most exacting.

Besides the provision of the beveled edges, these squares are made with all the care taken with the makers' well-known cast steel try-squares. Every precaution is taken to insure accuracy, the blades being at right angles to the beam. A recess in the beam at the base of the inner edge of the blade is an improvement in the construction which will be appreciated. This is a very desirable feature, as it enables the user to easily remove dust and dirt from the corner of the square and thus obtain accurate results on work having sharp corners. This tool is made in four sizes, of which the smallest has a blade 1½ inch long and a beam 1 9/16 inch long, while the largest has a 6-inch blade and a 4⅜-inch beam.

Fig. 7. Hardened Square with Beveled Edges

Height Gage Attachment for Inside Micrometer

The device shown in Fig. 8 is an attachment which may be used to convert the inside micrometer gage into a convenient height gage. The measuring rod is inserted upwards through the base and clamped securely by turning the knurled nut shown in the engraving. The micrometer is then adjusted and clamped to the upper end of the rod. When thus set, it will be found useful in obtaining the heights of projections on plane surfaces, the location of bushings in jigs, and other measurements on work of a similar character. Its range of measurement is from 2 to 9½ inches or 50 mm. to 230 mm. The V-groove in the base adapts the gage for use on cylindrical work.

Fig. 8. Height Gage Attachment for Inside Micrometer

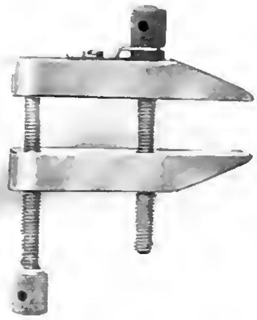

Fig. 9. An Improved Toolmakers' Clamp

Improved Tool-makers' Clamps

The little clamp shown in Fig. 9 is of conventional design, with the exception of one improvement which greatly increases the handiness of the tool. This improvement is the provision of a spring or clip, entering a groove in the head of the inner adjusting screw. Its purpose is to prevent the sliding jaw from dropping when inserting or removing work. It will be found very convenient where a large quantity of pieces of the same size are to be clamped for drilling, as it holds the jaws at the required distance for removing or

inserting each piece, it being necessary to manipulate only the outer screw. These clamps are of steel, case-hardened. They are proportioned throughout to furnish great strength in a light and compact form. The jaws are rounded at the ends to allow clamping under a shoulder or into a recess. The screws are of as fine pitch as is consistent with strength, thus giving great clamping power. The engraving shows the smallest of the line, which ranges from a tool with a maximum opening of the jaws of from $\frac{3}{4}$ inch up to $2\frac{1}{2}$ inches.

Two New Rules

The upper rule shown in Fig. 10 is graduated on one side to 64ths. As may be seen, the reading of these graduations has been greatly simplified by numbering every eighth line, thus: 8, 16, 24, 32, etc. This makes the rule much more convenient and reduces the risk of error from a faulty reading.

Fig. 10. Two New Rules

The lower rule in Fig. 10 is provided with beveled edges similar to those furnished on the ordinary draftsman's instrument. This is intended, however, not only for draftsmen but for tool-makers as well. It will be found useful in laying out fine work, where close measurements are required. Beveling the edges brings the graduations closer to the work, insuring accurate measurements. This style of rule is beveled and graduated on both edges of one side only.

Both of these rules are furnished in a variety of lengths from 1 up to 24 inches.

THE "CISCO" HAND-POWER CRANE

The Cincinnati Iron & Steel Co., Cincinnati, O., is building the remarkably simple and rigid hand-power crane shown herewith. It is intended for general use in machine shops and industrial works of all kinds. It is very easy of action, and the workman requires but one hand in operating it.

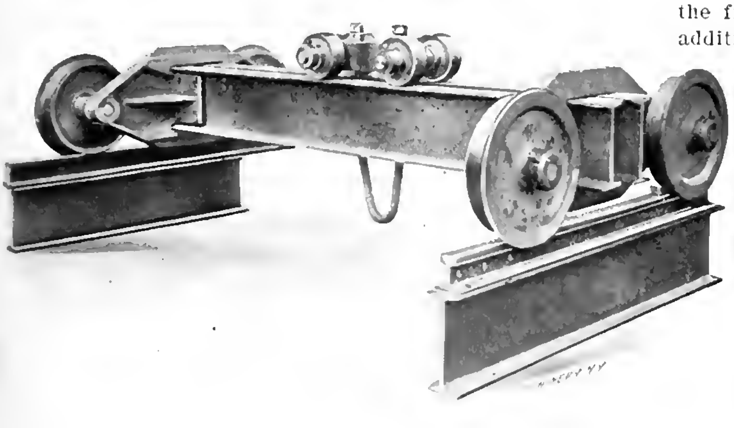

Fig. 1. The "Cisco" Hand-operated Crane

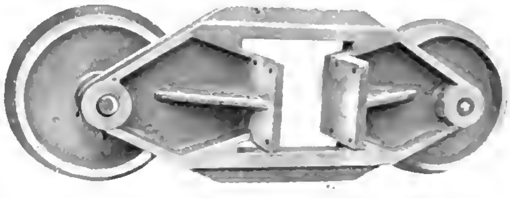

Fig. 2. Detail View of the Truck, showing the Simplicity of the Design

Fig. 1 shows the crane ready for use. The structure is composed of the two end trucks (see also Fig. 2), the cross beams and the trolley. The end trucks are solid castings, with pivots for the wheels, which are mounted in roller bearings. The cross beams overhang on both sides, so that in the case of an overload beyond the capacity of the crane, causing any part of the trucks to break, these beams would drop down onto the crane runway, preventing serious accident. Provision, not visible in the illustrations, is made for keeping the trolley from diverging from the straight line of travel. On the hanging loop of the trolley are placed wheels revolving in a horizontal plane, and supported by collars and set-screws. These bear against the inner faces of the webs of the I beams on each side, thus furnishing a rolling guide.

It will be seen that this crane is so arranged that the purchaser can furnish the I beams himself, if desired, only the end trucks and trolley being shipped from the factory.

TUCKER POSITIVE LOCK COMPRESSION GREASE CUP

The engraving shows a grease cup recently designed by W. M. & C. F. Tucker, of Hartford, Conn. It is of the compression type. The new feature in its design relates to the positive lock against turning under vibration, which makes it particularly adapted to automobiles and other classes of machines that are subject to severe and continued jarring.

The cup itself is not higher above the base than the ordinary grease cup. The locking mechanism is placed on top of the cap in a handy position to operate. To unlock, the small cap is pressed down and turned to the right, when the cap may be screwed down as desired. If left unlocked, it will lock itself after the first quarter turn from vibration or other cause. To remove the cup for refilling, turn the small cap toward the left until it stops, reversing the movement for assembling again. The locking mechanism is covered, so that it is thoroughly protected from dirt and grit of any kind.

A Grease Cup which automatically locks Itself against Vibration

STOEVER 1909 MODEL PIPE MACHINE

The accompanying engravings show the most recent design of the pipe threading and cutting off machine made by the Stoever Foundry & Mfg. Co., Myerstown, Pa. The particular machine here illustrated has a capacity for threading and cutting off pipe from $2\frac{1}{2}$ to 8 inches in diameter, inclusive. The improvements relate to provisions for giving a higher output and making the machine more convenient in operation as well. The style shown is belt driven, though it can be readily changed to use a constant speed motor, as may be seen.

The massive construction of the bed and head-stock has been retained. The spindle, as in the previous models, is provided with heavy three-jawed independent chucks at both the front and back ends, the rear chuck being furnished, in addition, with special grips for use on flanged work. These chucks are made in one piece, with the slots for the slides milled out of the solid. The internal gear drive of the front chuck has also been retained, with few changes in the design.

As may be seen in Fig. 1, all the speed changes of this machine are obtained from quick change gearing. The gear box is oil-tight, giving thorough lubrication to the gears, which are all cut from the solid. A single driving pulley is used. The five changes obtained in the gear box are doubled by the back gearing handle shown at the right of the box, giving ten separate speeds suitable for cutting either iron

or steel piping throughout the whole range of sizes for which the machine is listed. The bore of the spindle is sufficiently large to take extra heavy 8-inch fittings, which is its maximum capacity.

Fig. 2 shows a front view of the slide, with the new design of opening die head in place. This head slides on ways on the front of the stand, thus accommodating itself to eccentricity in the pipe and relieving the machine of the strain produced under these conditions on a rigid head. This naturally results also in far better threads. The adjusting mechanism for opening and closing the chasers and setting them to the desired size is simple and easy of operation. The dies are opened and closed by the lever above the head. This closes with a toggle movement, the three joints being in a straight line as shown, so that there is no possibility of digging into the pipe before the chasers are released. The hand knob for making the adjustments is directly in front of the operator, as is also the dimension scale on the face of the cam ring.

A unique provision of this die head, shown in Fig. 2, is the mounting of the steel front die ring on hinges, so that it may be swung open to facilitate the changing of chasers. This also gives free access to the head for cleaning it of any chips and grit which may have worked their way into the mechanism. If desired the chasers may be removed when the front of the slide is closed, as they can be withdrawn or inserted from the inside of the head, as well as by the means shown in Fig. 2.

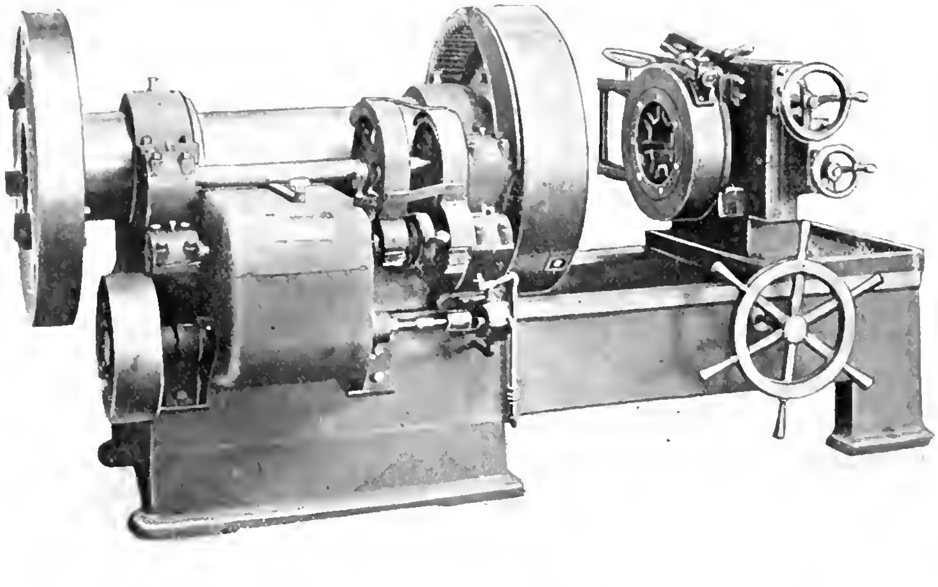

Fig. 1. The Stoever 1909 Model, Geared Drive, Pipe Threading and Cutting-off Machine

The bottom of the slides in which the chasers travel are reinforced with hardened steel plates, thus keeping them true at all times and insuring accurately cut threads. The cam ring is of interchangeable, sectional construction. The cams are of steel, inserted into the ring, so that replacement is possible at a low cost when a cam becomes worn or broken. The chasers are also interchangeable, to the extent that it is possible to replace one without getting a whole set. They are numbered to correspond with the slots in the die ring, and any chaser purchased from the makers at any time may be used with other chasers of the same size, when mounted in its proper slot. This provision is one of the noteworthy improvements in the machine.

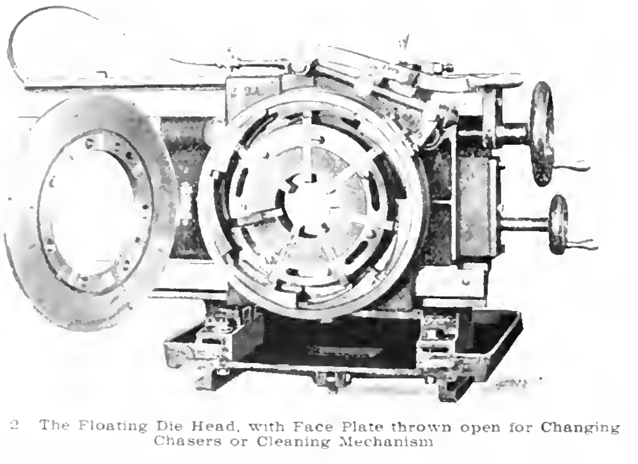

Fig. 2. The Floating Die Head, with Face Plate thrown open for Changing Chasers or Cleaning Mechanism

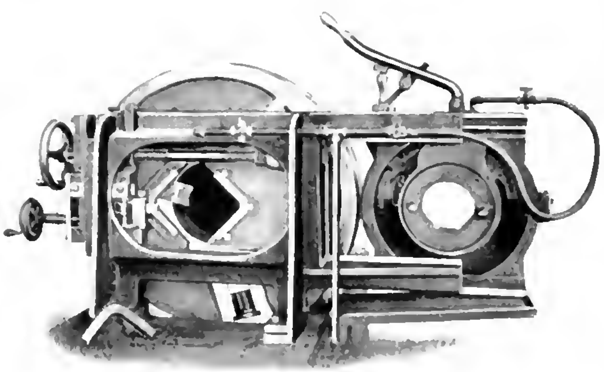

Fig. 3. The Die Head Moved to One Side, to permit Cutting Off Close up to the Chuck, note the Removable Jaws for the Steady Rest

Another feature to which special attention is called is shown in Fig. 3. Here it will be seen the die head is pushed out of the way and clear of the front chuck, allowing the slide to be brought up so close as to make the machine available for 3-inch nipple work. Another improvement, seen in this illustration, relates to the construction of the steady-rest slides. The wearing surfaces of these slides are interchangeable, and may be easily replaced by the operator when necessary, so that it is no longer necessary to await replacements from the factory in case of wear or accident. One of the removable wearing surfaces is shown lying on top of the slide in the engraving.

The oil pump for this machine is of the rotary type, and is fastened to the main driving shaft as shown in Fig. 1, thus insuring a steady and constant flow, irrespective of the diameter being machined. Fig. 3 shows the arrangement of the piping which, by means of the flexible tubing shown, directs the oil to the point of the cutting off tool and to the die head, by connections which adapt themselves to the varying adjustments of the machine.

This machine is one of a complete line, both of standard and automatic types, ranging in capacity from ¼ up to 12 inches.

THE KINKEAD SYSTEM OF ALIGNING SHAFTING

Long experience in the cotton mills of New England had convinced the inventor of the instruments herewith illustrated that the loss of power from friction is a serious item in large establishments, even when unusual pains are taken to keep the shafting in line and well lubricated. He therefore set to work to design instruments which would test the alignment of shafting more rapidly and more accurately than any at that time in use, thus making it possible to keep the transmission of a large plant in good condition at a minimum of expense. The devices herewith illustrated and described were the results of his study on the subject.

The apparatus comprises three instruments—the level shown in Fig. 1, the portable target shown in Fig. 2, and the fixed target shown together with the level and portable target in Fig. 3. The level is a special architect's instrument with an 11-inch telescope, provided with cross hairs and accurate adjustments. The glass magnifies twenty diameters, and is capable of handling an 800-foot line of shafting. The portable target is hung from the shafting by an ingenious jaw clamp,

which is one of the important features of the mechanism This clamp which is operated by the spring and toggle mechanism shown, is so designed that the distance from the shafting to the center of the target is invariable, no matter what the diameter may be. This is very important on a long line, where it may be hung from a 1½-inch shaft at the driven end, and moved to a 12-inch shaft at the driving end without altering the height of the target. The jaws are of cast iron, nickel-plated. The spring which closes the jaws on the shaft is of steel. The target has a fine adjusting screw for vertical movement on the bow by which it is hung, as well as the rapid telescopic adjustment locked by the thumb-screw. The fixed target is mounted on a dead wall or other convenient support at the further end of the line from the level. It is provided with horizontal and vertical adjustments, and carries a lantern so that it may be used at night if desired.

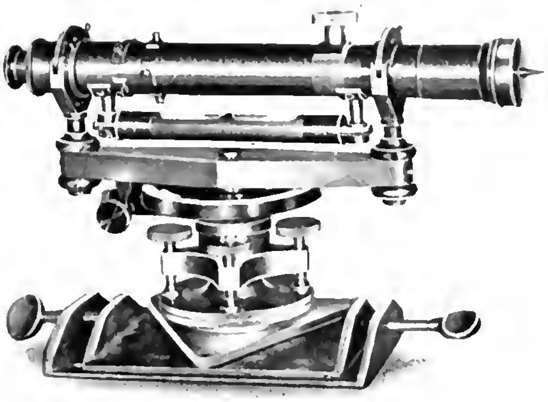

Fig. 1. Special Architect's Level, used for Lining up Shafting

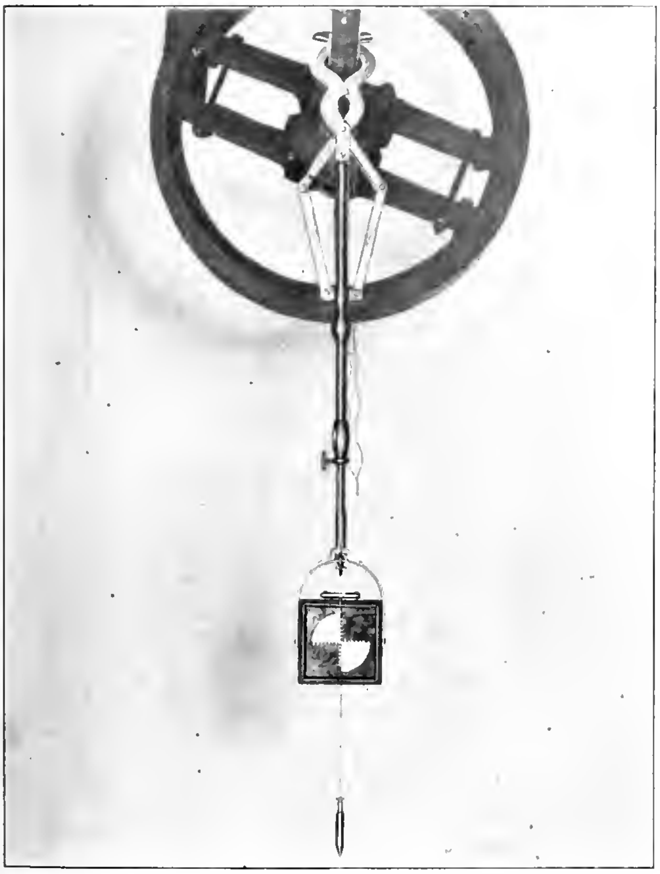

Fig. 2. Portable Target, with Self-adjusting Jaws for Gripping the Shaft

This apparatus is used as follows: First, the portable target is placed on the shaft at the end of the line where the operations are to be begun. The plumb bob is hung from a hook at the base of the clamp as shown in Fig. 2, and the center of the shafting is marked on the floor. At the same time the center line of the target face is lined up with the plumb line, and the spirit level is adjusted, if necessary, to read to zero, the spirit level being relied upon in the future operations to bring the target plumb. The target is then moved a short distance away from this position, and the architect's level is centered over the spot marked on the floor. The telescope is then set to match the vertical center line of the target and the latter is again brought up close to the telescope and adjusted vertically until its center matches the indicating point on the cap shown in place in Fig. 1. The portable target is now removed, and the fixed target is set up on the dead wall or other suitable support at the further end of the line and adjusted in both directions to center with the cross hairs on the level. This target acts as a foresight, and, by comparing the level with it from time to time, it is possible to tell if anything has happened to disturb the adjustment.

In lining up the shafting, a sketch is first made, numbering each hanger, and giving a space to record the levels (whether high or low) and the lateral displacement (whether north or south, or east or west, if the line shaft runs north or south). The portable target is then placed on the shaft at the first hanger and sighted through the level. The edges of the sighting spaces in the target, it will be noticed, are notched to read to eighths of an inch both vertically and horizontally. By reading these on the cross hairs of the level the operator is informed as to the amount of displacement up and down or sideways. The chart record for the No. 3 hanger might read No. 3, ¾ inch high, ¼ inch west.

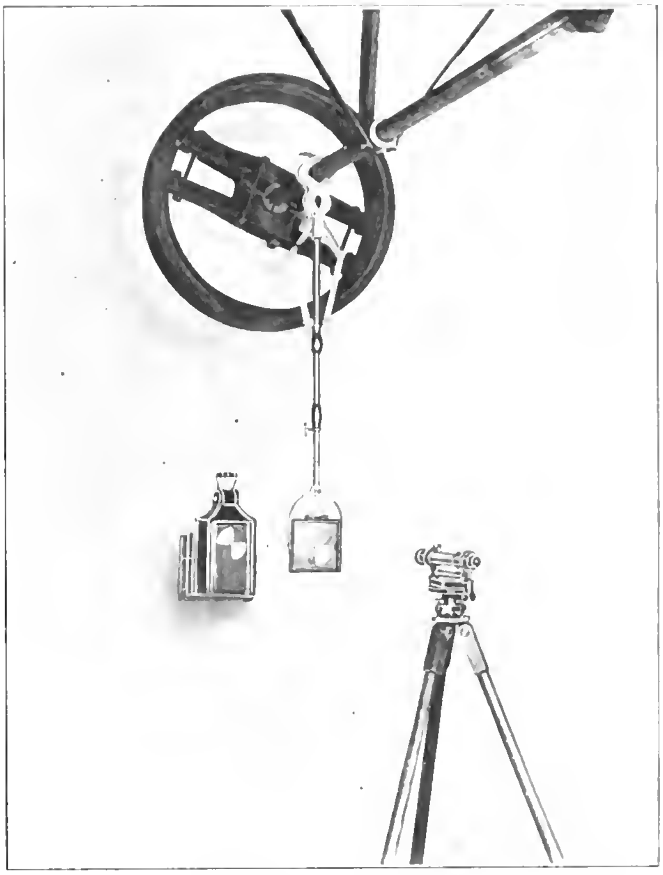

Fig. 3. The Level, Portable Target and Fixed Target, the latter provided with a Lantern for Night Use

After readings for all the hangers in the line have been put down on the chart, the latter is examined to see if any of the hangers are badly out. Sometimes where two or three are way out of line trouble can be avoided by changing these first. It is usually best, however, to adjust the portable target at the furthest hanger and bring that shaft to line and level, and then so on, from hanger to hanger, one man making the adjustments as required by the chart, while the other checks them up as fast as made by sighting through the level at the portable target. If it should be found that there is a decided difference in level from one end to the other of a long line of shafting, it will not be necessary to bring it to the level. It can be graded uniformly from one end to the other by properly adjusting the leveling instrument.

Appropriate variations of this method of operation allow it to be used on shafting running beneath the floor, fastened in wall boxes, or running beneath the bench, as well as when

supported from the ceiling in the usual way For shafting running beneath benches the target is used horizontally. Offset supports are provided for special cases in which obstructions prevent the portable target from hanging vertically. The instruments will also be found useful in setting up counter shafts, in lining shafts parallel with each other or with the main shaft, or in setting shafting at right angles.

It has been the experience of the makers of this apparatus, the Kinkead Mfg. Co., 7 Water St., Boston, Mass., that no line of shafting of the five hundred, more or less, which they have tested has been found in really good condition, even when lined up by millwrights skilled in the ordinary methods of doing this work. The loss of power in shafting is seldom less than thirty per cent or thereabouts. With reasonably good hangers this loss is reduced to fifteen or twenty per cent of the total load. This saving in power can be figured out to a saving in the coal pile for the ordinary plant which will make the use of the equipment decidedly profitable.

The operation of lining up with this apparatus is very rapid. It is possible, for instance, in ordinary work to test and line up 250 feet of shafting in three-quarters of an hour, by using two men. The apparatus does not require experts to handle it, as a little instruction will enable the intelligent millwright to use it as successfully as the engineer. The use of a lantern with the fixed target permits the work to be done as easily, rapidly, and accurately at night as during the day. This apparatus is being used in a large number of mills and factories, using anywhere from 300 to 10,000 feet of shafting.

LODGE & SHIPLEY CRANK-SHAFT LATHE

The accompanying engravings illustrate a set of lathe attachments of unusual interest. They were designed by the Lodge & Shipley Machine Tool Co., Cincinnati, O., for adapting their regular 22-inch patent head lathe to the work of turning the throws of four-cylinder automobile crank-shafts, for manufacturing in large quantities. This attachment is quickly adjusted for the changes in centers required. It affords a strong drive, and supports the crank in such a way that its tendency to spring under heavy cuts is largely overcome, thus permitting a high rate of output for the machine.

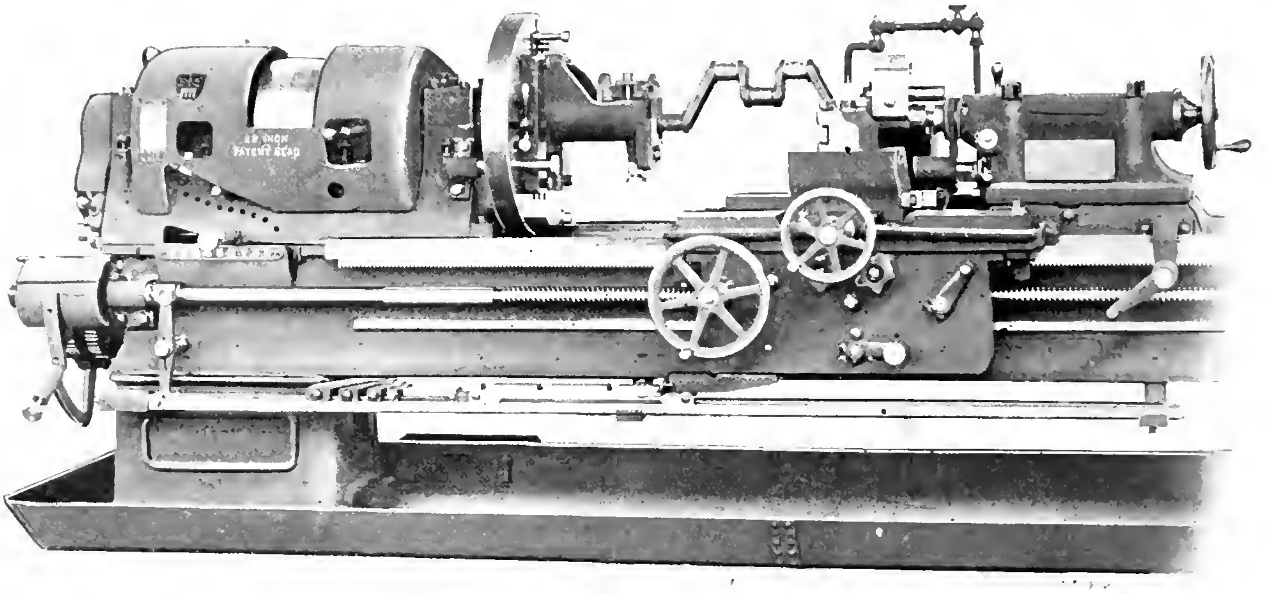

Fig. 1. Lathe, provided with Special Chucks, Tool-posts and Stop Mechanism for Turning Crank-shafts

The special chuck for holding the shaft will first be described. To the face-plate are bolted adjustable ways for guiding the sliding chuck, which is provided with locating holes for a locking bolt for bringing it to the required positions on each side of the center line. This locking bolt with the lever for operating it is plainly seen in Figs. 1 and 2. The chuck is shown in its two positions in these two engravings, Fig. 1 showing it set for machining the outer throws, while Fig. 2 shows it at work on the inner throws.

Fig. 2 shows the shaft as it is first placed in the machine. The crank, whose journals have been previously turned is gripped in a bearing in the chuck, having a hinged cap. It is centered and driven by the sliding jaw, whose forked opening embraces the cheek of the crank. This is most plainly shown in Fig. 3. The tail-stock chuck is a simple block of steel, bored for three bearings. The two end bearings are bronze bushed and tapered, and either of them may be used for either the taper plug bearing in the tail spindle, or for the taper lock bolt, as will be described. The crank itself is held fixed in the central hole of the chuck, by means of a clamp screw plug.

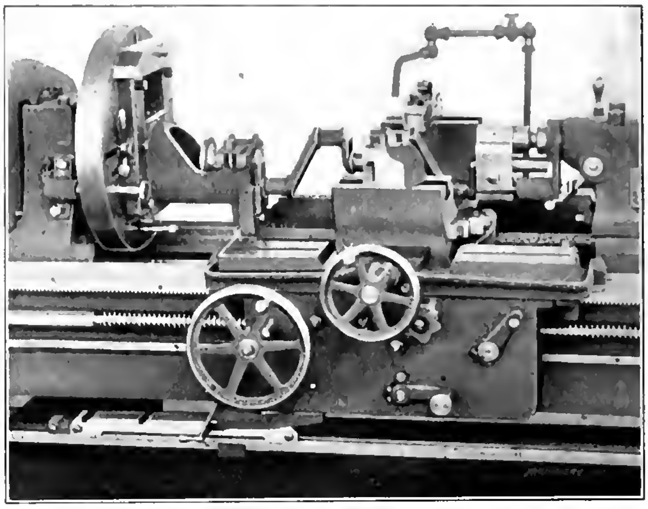

Fig. 2. Locating the Crank-shaft in Position

In setting the work in the proper position in the lathe, the face-plate is first located and held from revolving by means of the pin shown in Figs. 1 and 2, engaging a hole in the lug bolted to the side of the head-stock. The crank-shaft is then clamped in the face-plate chuck as previously described. The tail-stock chuck is placed over the journal at the rear end, and the tail-stock is brought up to the position shown in Fig. 2, with the taper bearing pin in the tail spindle entering the bushed hole provided for it. Bolted to the front face of the tail-stock is a bracket centered accurately by means of a boss encircling the tail-stock spindle. This carries a locating pin which enters the other bearing hole in the chuck, and aligns the chuck at this end with the face-plate drive. When thus aligned, it is clamped by the screw plug arrangement. The locating pin is then withdrawn by the lever shown, leaving the chuck free to revolve on the plug arbor, after withdrawing the locating pin in the face-plate. The arbor and centering pin are made of tool steel, hardened and ground. An adjustable thrust bearing prevents the arbor from seizing in the taper thrust bearing, no matter what the end pressure.

After machining the two inner crank-pins on the center line shown in Fig. 2, the lathe is stopped, the face-plate is again located by the lock bolt in the head-stock and the tail-stock is withdrawn. The locking bolt which holds the spindle to its position on the face-plate ways, is then released and the chuck is raised to the position shown in Fig. 1, where it is located again by the bolt, so that the crank is on the new line of centers. The tail-stock is again brought up, the plug arbor entering the bearing prepared for it in the other end of the tail-stock chuck. After freeing the face-plate, the machine is then ready for turning the other two crank throws.

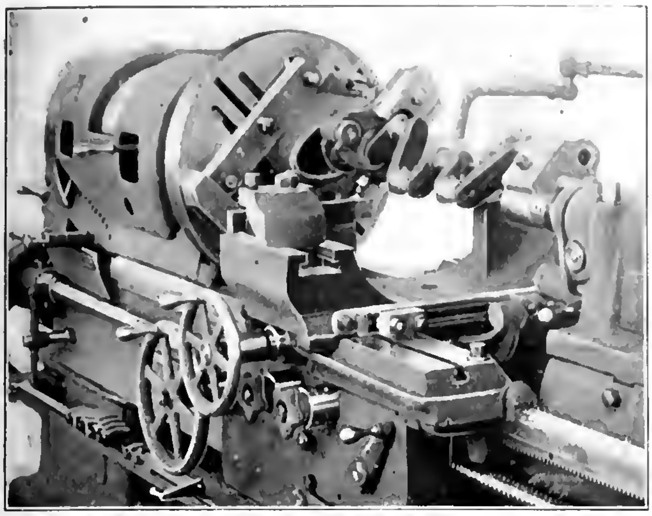

Fig. 3. The Lathe at Work

In addition to the work-holding device, just described, further attachments are provided for holding the proper tools, and for setting them to accurate stops for the various operations. The carriage is most plainly seen in Fig. 3. The front and rear tool blocks are cast in one piece, on a long slide mounted on the bridge of the carriage. This slide has both hand and power movement. The rear tool block carries two cutting tools which are set at the proper distances for fileting out the corner of the blank. The remainder of the stock is turned off with the front tool, leaving the pin ready for finishing on the grinder. The firm support given the tools can be seen in Fig. 3. A vertical rib extends for practically the whole length of the overhang for each tool, supporting it solidly almost out to the cutting point.

Positive stops are provided for both longitudinal and cross movements. The cross-slide stops are shown in Fig. 3, mounted to the side of the cross-slide and abutting against a heavy bracket bolted to the carriage. The construction of the longitudinal stops, most plainly shown in Fig. 1, is of unusual interest. A long bar, with a dove-tail sliding surface on its top, is mounted in bearings extending the whole length of the bed at the front of the machine. This bar, which has a limited longitudinal movement against the pressure of a spring, is connected with a lever at the head-stock end of the lathe as shown, which disengages the clutch connecting the splined lead-screw with the gear box. On the dove-tail of this bar are clamped a series of stops as shown. The long stop with four notches cut in its upper surface is the one used in this operation. These notches are spaced apart the same distance as that between the throws on the crank, thus serving to locate the carriage for the operation on each throw.

As shown in Fig. 1, the apron is provided with a projecting bracket carrying a lever. As the apron is traversed along the bed, this lever drops in the first notch it comes to. The carriage may then be fed along until the bar comes up against its solid stop at the left, when it will be found located in the position desired. By raising the lever the carriage will feed along until the lever drops into the next notch, when the carriage will be stopped for the next throw and so on.

This apparatus serves, however, not only as a positive lock, but for stopping the automatic feed as well. After locking the carriage as described for the operation of feeding down the fillet tools, the latter are moved back out of the way, the carriage is turned back, and the turning tool is brought up to begin its cut. The automatic feed is thrown in and the carriage feeds ahead until the lever drops into the notch as before, when it forces the stop bar to the left and thus throws out the feed clutch at the proper point.

The long stop with the four notches is special for this job. This form of stop motion has been found, however, very useful on regular work and provision has been made for setting it to any desired series of shoulder distances. For such work the special stop is removed and the series of five stops shown at the left are employed. These telescope over each other in such a way that they may be set for any shoulder distance, no matter how short. The carriage will feed until it comes to the first of them, when it will be stopped automatically by the means just described. The tool may then be adjusted to the diameter of the next shoulder, and the stop lever raised again, whereupon, without further adjustment, the carriage will feed until it meets the next of the stops. After again adjusting the tool for the new shoulder, the lever is raised and the feed continues to the next one—and so on. This mechanism gives a usefulness and adaptability to the stop movement of the lathe, closely approximating the more complicated provisions found on turret machinery.

CARROLL-JAMIESON QUICK-CHANGE GEAR ENGINE LATHE

The Carroll-Jamieson Machine Tool Co., Batavia, Ohio, has designed the quick-change gear lathe shown herewith. The gear box gives 32 ratios for turning and threading without changing the gear. This range comprises all standard threads from 3 to 32, including pipe threads. The gear box, which is of very simple construction, will be understood from an examination of Fig. 1. The shifting idler is moved longitudinally by a knob sliding in the slot of the swinging carrier shown above the gear box. The idler is swung toward

Fig. 1. Carroll-Jamieson 14-inch Engine Lathe

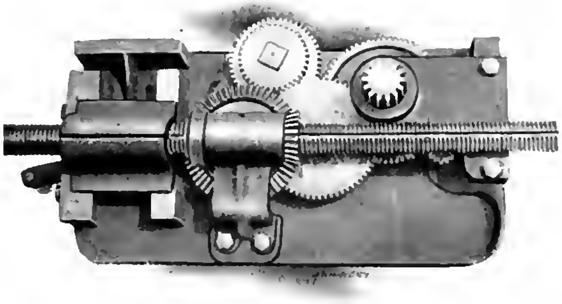

Fig. 2. Detail View of Apron Mechanism

or away from cone of gears to agree with the diameter of the one it is to mesh with, by loosening the clamp handle shown in front of the gear box, and setting the frame to the required position. The changes can be made instantaneously, with one hand on the knob and one on the handle.

The improved construction of the apron is shown in Fig. 2. This is provided with friction drives, and an uncommonly long slide for the nut, provision being made for taking up wear at this point. The rack pinion has an outboard support, as shown. While nominally a 14-inch lathe, this lathe swings 14⅞ inches over the bed.

NEW TOOL-HOLDERS MADE BY THE WESTERN TOOL & MFG. CO.

The Western Tool & Mfg. Co., Springfield, Ohio, has recently added to its line a number of tool-holders of various kinds, of which examples are shown herewith. The first of these (see Fig. 1) is a turret tool-post. It is designed to give the engine lathe some of the advantages of the screw machine and turret lathe for producing duplicate work, and should be found very useful for this service, particularly in shops which do not care to go to the expense of purchasing an expensive turret machine.

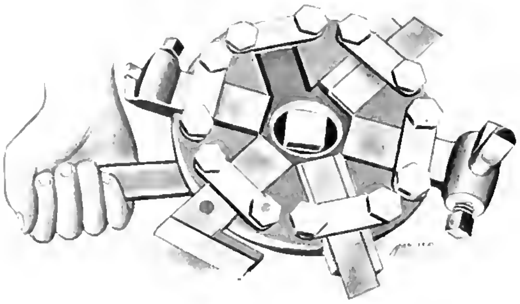

Fig. 1. A Turret Tool-holder for the Engine Lathe

As may be seen, this device is mounted on an angle plate which is clamped to the tool block of the lathe in which it is to be used. The various tools are clamped by the straps and binding bolts shown, into slots in the face of a disk. This disk is mounted on a pivot, provided with a screw adjustment for centering the tools with the center line of the lathe. The clamping handle shown binds the whole structure firmly together when the cut is being taken. To change from one tool to another, it is only necessary to release the binding lever, index the disk to bring the next cutting attachment into action, and tighten it again. The separate clamping of the various tools permits each to be adjusted for the diameter of the cut to be taken.

This turret tool-post is fitted with a set of regular tool-holders furnished by the makers, including turning, threading, side, parting, and boring tools. In ordering, it is necessary to furnish exact measurements of the tool-post slot of the lathe. The attachment is made of steel throughout, carefully hardened. It is furnished in three sizes, of which the smallest takes tool-holders with shanks ⅝ x 1¼-inch, the middle size ¾ x 1½-inch, and the large size ⅞ x 1⅝-inch.

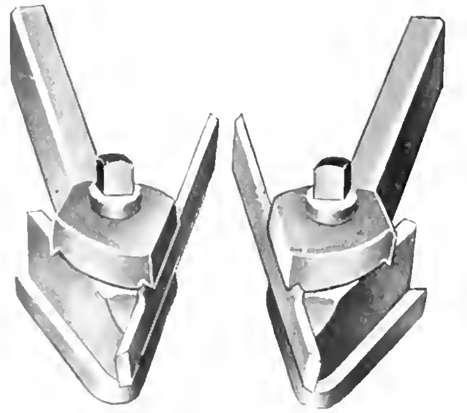

Fig 2. A Side Tool-holder which may be used with either Right or Left-hand Blades

The side tool shown in Fig. 2 is interesting in its provision for cutting either right- or left-hand in the same holder. A dovetail groove for receiving the blade is cut on each side of the body, and the clamp may be revolved to correspond with the side in use. The tool is thus either a right- or left-hand side tool as required. A new turning tool of similar design has also been constructed, giving a choice of a right- or left-hand turning tool in the same holder.

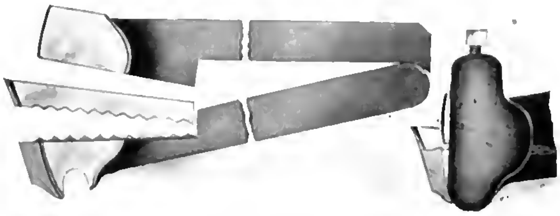

Fig. 3. A Turning Tool for Heavy Work

In Fig. 3 is shown a design of turning tool-holder intended for the heaviest work. The blade, it will be seen, is clamped in a holder which somewhat resembles a pair of tongs in its construction, having a hinge at the rear end. The clamp shown binds the two sides together with the blade between them, at a point near the cutting edge. The bottom of the blade is serrated to match corresponding serrations on the lower jaw of the holder. It is thus impossible for it to slip under the pressure of the heaviest cut.

BAUSH THREE-SPINDLE DRILL PRESS WITH MULTI-SPINDLE ATTACHMENT

The three-spindle drill shown in Fig. 1 is built by the Baush Machine Tool Co., 200 Wason Ave., Springfield, Mass. While designed particularly for use with the multiple spindle attachment shown in Fig. 2, it is well adapted to the general manufacturing work commonly performed on the multiple spindle drills of the sensitive type. It is shown with three spindles, but will be furnished with four or less, as may be required by the purchaser, although the makers have found that the three-spindle machine is the best adapted for the usual run of light drilling.

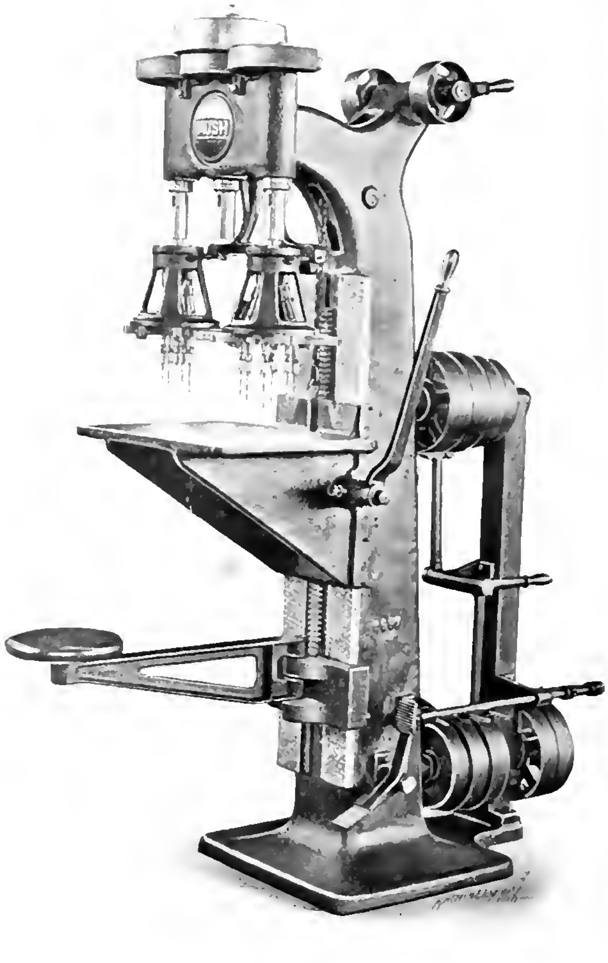

Fig. 1. Baush Three-spindle Drill

The frame is made in one piece, with ways on the face along which the stiffly designed work table is fed and adjusted. This table is counterbalanced and provided with an adjustable hand lever for feeding and an adjustable stop at the depth to be drilled. The total travel of the table is twenty-two inches. A revolving-top seat for the operator is adjustably mounted below the table.

The three-drill spindles are spaced seven inches apart and are provided with No. 3 Morse taper holes. They are connected by gearing and driven by the single vertical driving pulley shown, which is belted over the quarter turn pulleys at the rear to the upper shaft at the back of the machine. The latter is connected with the counter-shaft at the base, cone pulleys giving the machine three speeds, ranging from 272 to 377 revolutions per minute when the counter is speeded up to 320 revolutions per minute. The diameter of the tight pulley for the latter is 10 inches, for a two-inch belt. The quarter turn pulleys are mounted on an eccentric shaft for tightening the belt. The belt capacity is sufficient to drive one-inch drills.

Fig. 2 shows an attachment for the machine which is a multiple spindle drilling machine in itself. It is, in fact, a reproduction on a minute scale of the drilling head of the regular Baush multiple-spindle machine. It was designed to meet a demand for something capable of performing the same work as these large machines, but for much lighter service. As shown in Fig. 1, the attachment is very simply mounted in the drill press, it being only necessary to insert the taper shank in the spindle and hold the device from revolving by catching the steadying rod in slots provided to receive it in a bracket attached to the frame of the machine. The attachment can, of course, be used in any other make of drill press, it being a simple matter to provide means to keep the head from rotating.

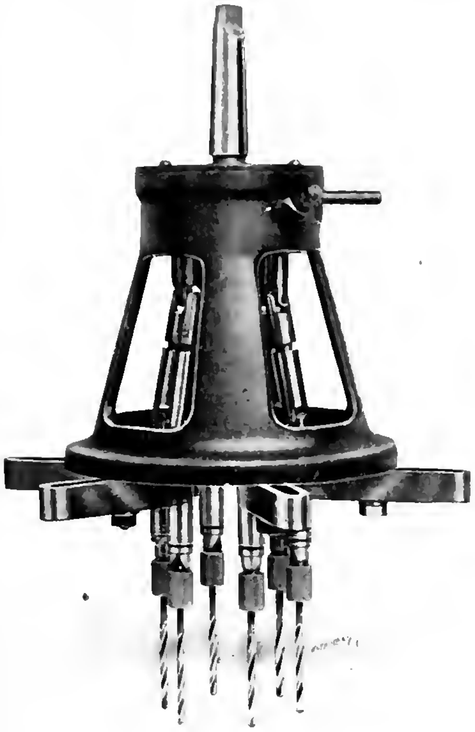

Fig. 2. Small Multiple-spindle Attachment; may be used on Regular Drill Press

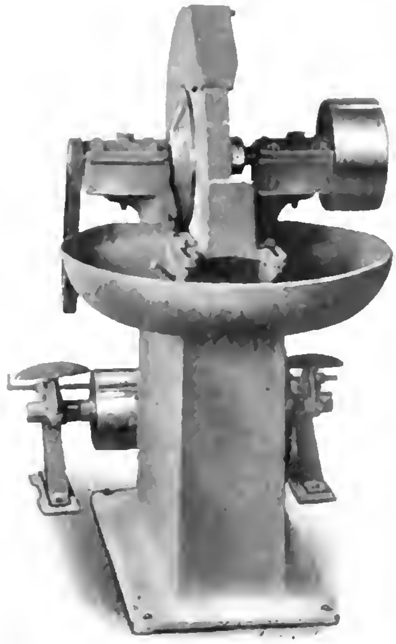
This multiple drill head will be furnished with eight spindles or less, to drill anywhere within a circle of from five to eight inches diameter. The lay-out will be varied when the customer's work demands a special arrangement. The head shown in the engraving drills anywhere within a five-inch circle. It is provided with six spindles, and weighs twenty pounds. The largest drill that can be used is ¼ inch, and the maximum distance between adjacent drills is ¾ inch. The spindles are ⅝ inch in diameter. With the spindle speeds given by the machine the drill speeds are 1,000, 1,200, and 1,400 revolutions per minute respectively. A ball thrust is employed to take the pressure of the cut. A No. 3 Morse taper is provided for the driving spindle. The 5-inch head with six spindles weighs twenty pounds.

STERLING TWENTY-FOUR-INCH SINGLE WHEEL TOOL GRINDER

The Sterling Emery Wheel Mfg. Co., Tiffin, Ohio, has just brought out the wet tool grinder illustrated, which has no pump to get out of order. Water is supplied to the wheel by a special device which acts when the wheel is running. As soon as the machine stops the water drains off the wheel, leaving it dry and in balance. The machine may be used as a dry grinder by disconnecting the belt at the left-hand side operating the device, which floods the wheel with water when in operation.

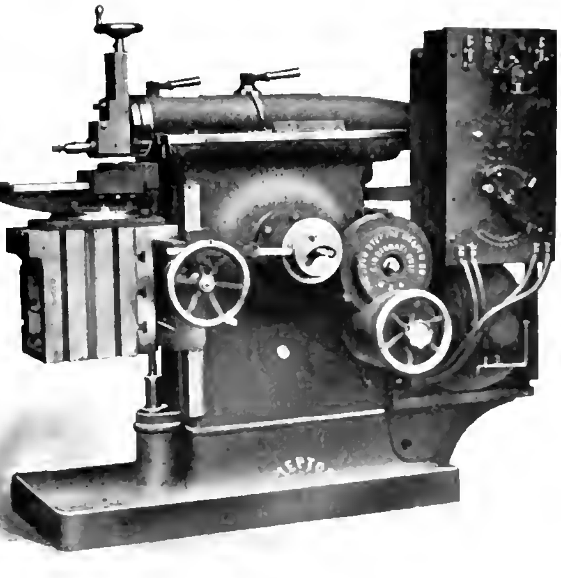


Sterling 24-inch Single-wheel Tool Grinder

Each grinder is equipped with a 24-inch by 2-inch approved grade and grit grinding wheel; the machine can be made to accommodate a wheel three inches thick if desired. The bearings are of the self-oiling type, and the following are the principal dimensions of the machine: Floor space, 30 x 45 inches; height of machine to center of arbor, 37 inches; driving pulley, 4½ x 10 inches; diameter of flanges, 12 inches; weight with counter-shaft and wheel, 900 pounds.

STEPTOE SHAPER WITH COMPACT MOTOR DRIVE

The halftone illustration shows a 16-inch shaper with an unusually compact motor drive built by the John Steptoe Shaper Co., Cincinnati, Ohio, for the United States battleship *Delaware*.



Steptoe 16-inch Shaper with Compact Motor Drive

The principal feature of the drive is the motor stand, which is set on the base of the machine, thus avoiding vibrations when the motor is running, and at the same time placing it as close to the column of the machine as is possible to get it. The arrangement of the motor is such that it takes up no more room than is actually required for the return stroke of the ram. This compact arrangement was necessary on account of the limited space available for its installation in the space assigned to it on the *Delaware*. The

controller is placed on top of the motor so that the operator is not compelled to leave his position to change the speed of the machine The motor is made by the General Electric Co., and has a speed variation from two to one.

Another new feature of the machine is an adjustable feed rod which permits the table to be either raised or lowered by the operator without attention, the feed rod automatically adjusting itself. The device is simple, consisting of a friction box through which the feed rod of flat cold rolled stock passes. The hooks on the end of the friction box pull out the rod or shorten it as the table is raised or lowered. By means of this device the common cause of breakage of the feed mechanism is avoided, i. e., the table feeding to the end of the cross-rail and the nut on the back of the apron striking the cross-rail. The friction element then comes into action, avoiding the destruction or breakage of any part.

* * *

NEW MACHINERY AND TOOLS NOTES

Power Hammer: Fritz A. Schulz, 66 N. Jefferson St., Chicago, Ill. This is a light hammer of the horizontal beam type. It weighs about 500 pounds, and will strike about 300 blows per minute. The front or anvil end of the machine is mounted on a wooden block, while the rear is supported on legs.

"Cresco" Pipe Wrench: Crescent Forging Co., Oakmont, Pa. This wrench is made in 10, 14, 18, 24, and 36 inch sizes, taking pipe from ½ to 3⅛ inch diameter. This wrench is of very simple construction, with the gripping parts made of hardened tool steel. The thread and nut are also hardened. It is light, strong and moderate in price.

Rivet Spinning Machine: Fritz A. Schulz, 66 N. Jefferson St., Chicago, Ill. This machine is arranged for rolling simultaneously the two heads of a through rivet. The work is held between the riveting spindles, which are mounted on a headstock of the lathe type. Suitable provision is made for clamping the work, and for adjusting the distance between the spindle heads.

Lathe Tool Holder: Ready Tool Co., New Haven, Conn. These tool holders are made in a variety of designs adapted for turning, threading, facing, etc. They are made to take stock sizes of either carbon or high-speed steel, so that no forging of any kind is required, except for the threading tool, which has ratchet teeth cut in its rear face. They are made in a variety of designs and sizes.

Quick Acting Vise: Oliver Machinery Co., Grand Rapids, Mich. This vise is intended particularly for wood workers and pattern makers' use. The steel screw is provided with buttress threads, working in a solid bronze nut. The quick action is obtained by lifting the screw to free it from contact with the nut, when the front jaw may be pushed in or out as desired. When raised, it at once drops back into the nut.

Crude Oil Forge: Tate, Jones & Co., Pittsburg, Pa. This is a portable forge intended to solve the difficult problem of the use of coal forges around construction work. The base of the forge furnishes the reservoir for the crude oil which is used as fuel, so that no separate receptacle is required, as when coal or coke is used. It is for this reason a much safer piece of apparatus to use, particularly in exposed and dangerous places.

Wrench With Separate Handles: New Metal Tool Steel Co., 338 Cumberland Ave., Portland, Me. This wrench is of unusual construction in that a separate handle is provided for the adjusting screw, in place of the usual knurled nut. This gives much greater power than can ordinarily be obtained, so that it can be used as a pipe wrench, or to hold round-headed bolts. By a peculiar provision in the jaws, it may be employed for cutting iron wire up to ⅛ inch diameter as well.

Hydraulic Valve: Bowes-Adams Co., Monessen, Pa. This valve is designed to be used under the heaviest hydraulic pressure. By an ingenious form of construction the valve is packed against the escape of the water on bronze valve seats, instead of by cup leather packing as is usual. The continual annoyance and repairing incident to the use of leather packing is thus avoided. It is made in the three-way or four-way type and operates for given service much easier than orthodox designs.

Automatic Grinder for Inserted Tooth Saws: Newton Machine Tool Works, Inc., Philadelphia, Pa. The automatic grinding device for sharpening face mills, described in the department of New Machinery and Tools in the February, 1909, issue of Machinery, has recently been adapted by the builders in the form of a special machine for sharpening saws, the attachment being mounted on a frame, provided with driving mechanism for rotating the saw blade. The same motor is used for driving the emery wheel and the work.

Pneumatic Counter-Shaft: Hannifin Mfg. Co., 88-92 West Jackson Boulevard, Chicago, Ill. This counter-shaft, which provides for two speeds or forward and reverse, is operated by air, controlled by a valve at the side of the machine. The clutch surface inside of the pulley is forced into contact by a pneumatic piston, provided with cup-shaped packing. The connection with the air valve may be made by rubber tubes, or by any other form of piping, and the valve may be placed in any convenient position, considerably removed from the counter-shaft, if required.

Abrasive Metal Cutter: Slack Mfg. Co., Springfield, Vt. Sales office, 15 Madison St., Hartford, Conn. On page 486 of the February, 1909, issue of Machinery, we described a grinding machine having thin disk wheels of alundum or other suitable abrasive, used for cutting off steels bars, piping and similar materials. This wheel is capable of severe service for this work, cutting through high-speed steel with the greatest ease. This business has been purchased by the Slack Mfg. Co. from the Colton Combination Tool Co., who were making it at the time of our previous note.

Quick Acting Monkey Wrench: Leo. M. Barrett, K. of P. Building, Indianapolis, Ind. This wrench, instead of employing a single screw as usual, makes use of a double-ended screw, one threaded right and the other threaded left hand, thus giving twice the movement to a turn of the thumb nut, ordinarily obtained. A lock nut is provided if desired to hold the adjustment permanently, though there is no more tendency for the adjustment to change than with the usual design. The wrench has a malleable hollow one-piece handle with wood grips. It is made in seven sizes, ranging from 6 to 21 inches.

Single-Phase Self-Starting Motor: Bell Electric Motor Co., Garwood, N. J. This motor is designed for single-phase service. It is arranged to start itself automatically as a direct-current motor operating on a single-phase current, the armature being wound for this purpose and provided with a commutator. High starting torque is thus obtained. When the motor has come nearly up to speed, a short-circuit mechanism automatically comes into use. This short circuits the commutator so that the motor, during its regular work, operates on the induction principle. The mechanism is exceedingly simple and, being automatic, it operates of its own accord when the current is turned on again after a stoppage from accident or intention.

Tooth Chamfering Attachment: Long Arm System Co., Cleveland, Ohio. In the March, 1908, issue of Machinery, in the department of New Machinery and Tools, we illustrated and described an attachment for rounding the ends of the teeth of transmission gears. The makers of this attachment have recently re-arranged it to bring the cutter work spindle into a horizontal position instead of vertical as in the older design. This permits the use of a tail-stock if desired, and thus adapts the machine for work on gears located in the centers of shafts. It also permits swiveling the attachment to any desired angle, thus varying the shape of the chamfered tooth. The device is of very simple construction and works automatically until the gear is completed.

* * *

It is stated in the *Engineering Record* of March 20 that a vanadium steel locomotive spring in recent tests was stressed to 115,000 pounds per square inch, 23,600 times before fracture. This would indicate the great superiority of vanadium steel over other steels for purposes of this kind. It is not stated, however, when and where the tests were undertaken

OPERATIONS PERFORMED ON THE "LO-SWING" LATHE

The accompanying illustrations show a number of operations which can, to advantage, be performed on the "Lo-swing" lathe, manufactured by the Fitchburg Machine Works of Fitchburg, Mass., and described in MACHINERY, September, 1907. The feature of the lathe is that it is adapted for rapid turning of small parts, not exceeding 3½ inches in diameter. Such parts as axles, automobile steering knuckles, transmissions and cam shafts can be more economically produced on this machine than in ordinary lathes. The usual cross slide is eliminated and the adjustment of the tools is obtained by a micrometer adjusting screw bearing against the end of the tool which is itself placed in a heavy tool-holder. This construction reduces vibration at the cutting point and permits higher speeds and greater depth of cut.

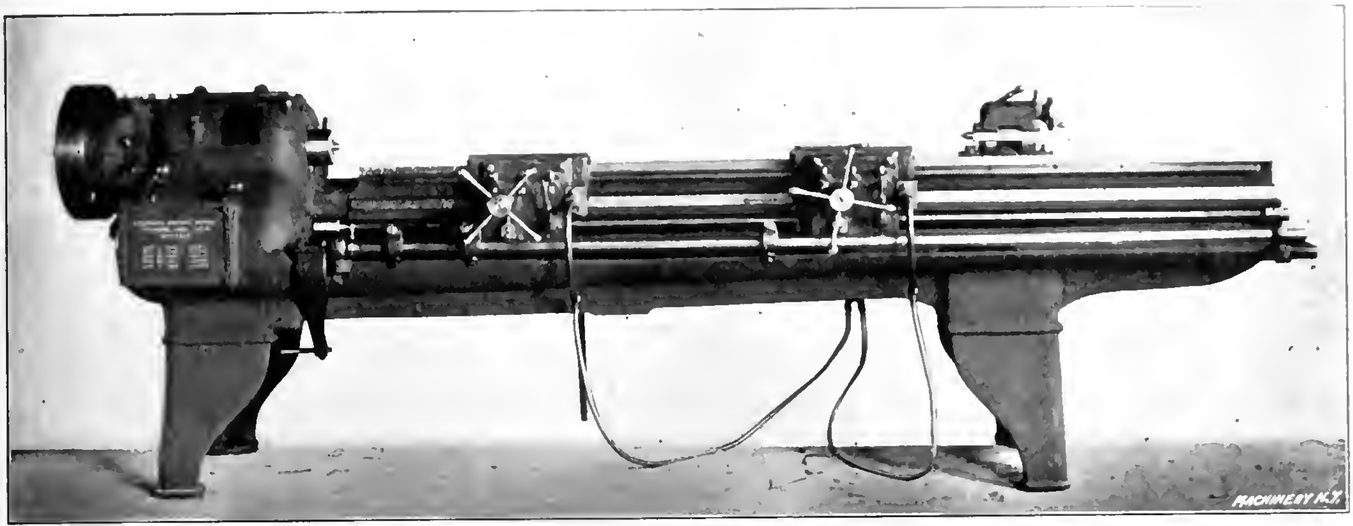


Fig. 1. "Lo-Swing" Lathe with Bed extended to Increase the Capacity of the Machine

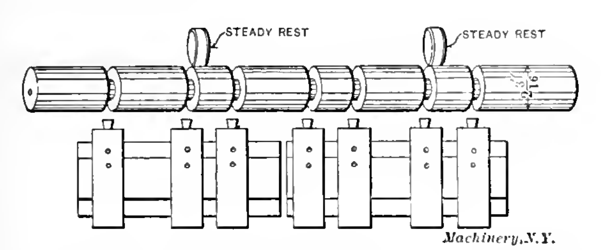

Fig. 2. First Operation in Turning Cam-shafts on the "Lo-Swing" Lathe

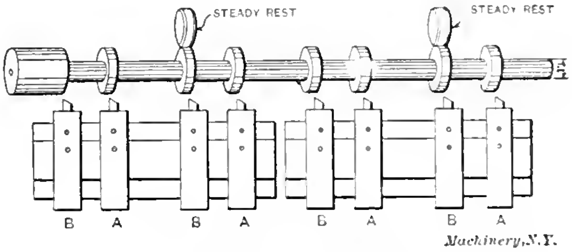

Fig. 3. Second Operation Metal between Cams Removed

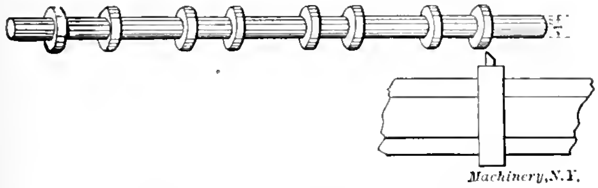

Fig. 4. Third Operation: End Turned Down

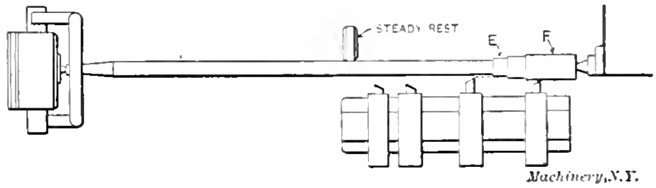

Fig. 5. Second Operation Turning E and F

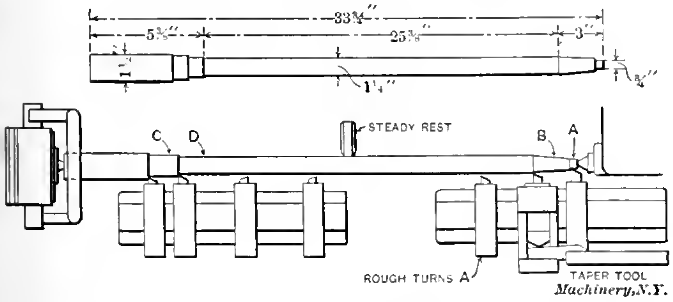

Fig. 6. Shaft to be Turned and First Operation: Turning A, B, C and D

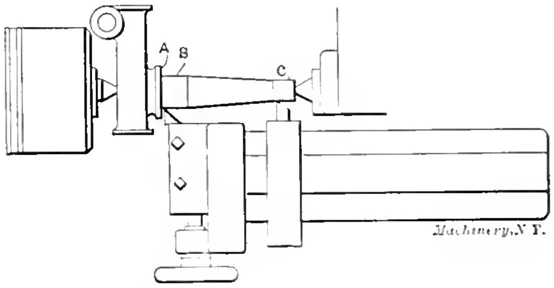

Fig. 7. Turning Steering Knuckle, First Operation Turning A, B and C

The machine as shown in Fig. 1 with its bed extending beyond the rear leg, is provided with two carriages which are so designed that they can pass by the tail-stock. Six tool-holders are provided regularly, and by means of these, a piece having several shoulders can be finished at one travel of the carriage, instead of, as usual, machining one diameter at a time. A stop mechanism is provided to take care of the varying lengths and depths, so that after the lathe is set up for one particular job, no time is lost by the operator in measuring lengths or calipering the work.

An interesting example of a piece which would ordinarily require considerable time for measuring is a cam shaft cut from a solid bar. Fig. 4 shows an 8-throw cam shaft, which is finished by the following method in the "Lo-swing" lathe. The first operation, as shown in Fig. 2, consists of cutting seven grooves with accurately spaced tools, so as to permit the cutting tools for removing the metal between the cams to start. The second operation, as shown in Fig. 3, consists of cutting out the metal between the cams with two travels of the carriages. The tools *A* take the cuts over the longer distance between the cams, and the tools *B* the cuts over the shorter distance. The third operation, as shown in Fig. 4, consists of removing the metal from the end held by the dog in the second operation. By this method, the three separate operations require altogether only one hour.

Another application of the lathe is shown in Figs. 5 and 6, where the operations necessary for turning the driving shaft of an automobile are shown. The finished shaft is shown in the upper part of Fig. 6. The illustrations indicate clearly the method followed, and Fig. 6 also shows how a tapered portion is turned in conjunction with a straight part. This

shaft can be turned in seven minutes on the "Lo-swing" lathe, whereas in an engine lathe it would require about forty minutes to finish the shaft. In the first operation the diameters *C* and *D*, Fig. 6, are turned by the tools in one carriage and the taper *B* and the diameter *A* by the tools in the other carriage. In the second operation, Fig. 5, the diameters *E* and *F* are turned.

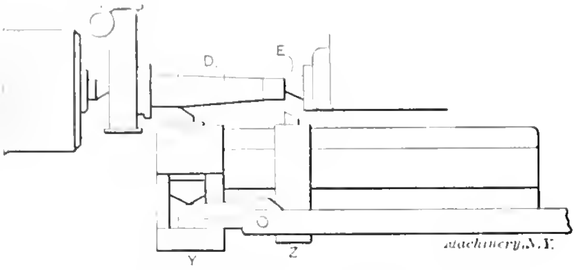

Fig. 8. Turning D with Y and Facing End with Z

Another example of work done to advantage in this machine is that of turning steering knuckles in two operations as shown in Figs. 7 and 8. In the first operation, Fig. 7, *A*, *B* and *C* are turned, and in the second operation, Fig. 8, the tapered part *D* is turned and the end *E* faced.

* * *

POWER REQUIRED FOR TAPPING

A series of experiments has been made by the American Tool Works Co., 300-350 Culvert St., Cincinnati, Ohio, for obtaining the pulling capacity of the friction drive of the radial drills built by the company. These tests, however, are also interesting on account of the fact that they record the power required for driving pipe taps. In the accompanying table are given the results of experiments covering nominal pipe tap sizes from 2 to 8 inches, inclusive. The holes tapped were reamed with standard pipe tap reamers before tapping.

POWER REQUIRED FOR TAPPING

Nominal Size of Pipe Tap, Inches	Revolutions per Minute	Net Horse-power	Thickness of Metal, Inches
2	40	4.24	$1\frac{1}{8}$
$2\frac{1}{2}$	40	5.15	$1\frac{1}{8}$
*$2\frac{1}{2}$	38.5	9.14	$1\frac{1}{8}$
3	40	5.75	$1\frac{1}{8}$
*3	38.5	9.70	$1\frac{1}{8}$
$3\frac{1}{2}$	25.6	7.20	$1\frac{3}{4}$
4	18	6.60	2
5	18	7.70	2
6	17.8	8.80	2
8	14	7.96	$2\frac{1}{2}$

* Tapping steel casting; other tests in cast iron

The horse-power recorded was read off just before the tap was reversed. In the table, however, is given the net horse-power, deductions being made for the power required to run the drill without a load. The material tapped was cast iron, except in two instances, where steel casting was tapped. It will be seen that nearly double the power is required for tapping steel casting.

The results obtained will, of course, vary with the conditions. More power than that indicated in the table will be required if the cast iron is of a harder quality or if the taps are not properly relieved. The taps used in these experiments were of the inserted blade type, the blades being made of high-speed steel.

* * *

NEW APPRENTICE EDUCATIONAL SCHEME

A new idea in cooperative apprentice education has been developed by Mr. B. B. Quillen, of the Cincinnati Planer Co., Cincinnati, Ohio, and a committee of Cincinnati manufacturers consisting of Messrs. Fred. A. Geier of the Cincinnati Milling Machine Co., William Lodge of the Lodge & Shipley Machine Tool Co., James Hobart of the Triumph Electric Co., J. M. Manley of the National Metal Trades Association, Ernest Du Brul of Miller, Du Brul & Peters, and B. B. Quillen of the Cincinnati Planer Co., presented the plan to Superintendent Dyer of the public schools, who received it with much enthusiasm, and presented it to the Board of Education with the recommendation to adopt same. It is expected that the school committee will establish it not later than July 1.

The plan is to send the apprentices to school one-half day each week, the employer paying the apprentice for the time he is in school. The cooperative school course will be continued throughout the term of apprenticeship contract, which in Cincinnati is four years. There are about 500 apprentices working in Cincinnati machine shops, and the manufacturers have agreed to start the course with 150 each week, which would make a class of 15 boys each half day for five days in the week.

The manufacturers feel that the loss of time of the apprentices attending school will be more than made up by their increased efficiency, and that the plan will be the means of securing many more apprentices than has been possible in the past. The course in instruction will be confined to shop mathematics, shop drawing and to other studies that will be of direct benefit to the apprentice in his daily work.

The development of the new plan will be watched with much interest. It is apparent from this move and other developments of similar nature that the need of more education for apprentices in connection with their shop training is generally recognized and the cooperative school courses devised are steps in the direction of rounding out the apprentice training more fully than is possible with the ordinary shop training common in the past. Whether it is practicable to devote only one-half day a week to this plan of educational work remains to be demonstrated.

* * *

NATIONAL MANUFACTURERS' ASSOCIATION CONVENTION

The National Manufacturers' Association held its annual convention in New York, May 17-19, the headquarters being the Waldorf-Astoria Hotel. The program included the following papers: "Mutuality and Fair Exchange in Trade Relations," by Count von Bernsdorff, the German ambassador; "The Iniquity of Anti-Injunction Legislation," by Hon. Charles E. Littlefield; "Legislation Affecting Labor Relations," by James A. Emery, general counsel of the National Council for Industrial Defense; "Law and Reason—Labor's Best Friend," by F. R. Boocock; "The Open Door and Your Opportunity," by S. D. Scudder, of the International Banking Co.; "Industrial Education and Manual Training Schools," by J. C. Monahan, superintendent of the Stuyvesant schools; "Desirable Improvements in Interstate Trade," by Thomas E. Durbin of the Erie City Iron Co.

The meeting was characterized by a bitter attack on Samuel Gompers and other leaders of organized labor in connection with the report of the committee on industrial education. It was claimed that the cause of industrial education was imperiled by the attitude of organized labor and Mr. Anthony Ittner declared that the committee could still be of service to keep the movement free from the dominance of organized labor which has its own special purpose in view and tends to sacrifice the public welfare to the supposed advantage of a class. This attack on organized labor was not unanimously supported and one member of the committeee, Mr. Fred W. Sivyers, of Milwaukee, refused to sign the report on the ground that it contained too many personal opinions.

The powers of the Interstate Commerce Commission over freight rates were declared inadequate, because it gives the commission no authority to deal with a freight rate, no matter how unreasonable, until it has actually been put in force. A considerable period of time must necessarily elapse between the date of complaint and the completion of the investigation. The great variety of rates was alluded to, over 150,000,000 rate items having been filed with the Interstate Commerce Commission between July 1, 1906, and January 15, 1909.

John Kirby, Jr., Dayton, Ohio, was elected president of the association following James Van Cleave of St. Louis, who has served three terms. Mr. Kirby advocates a tariff commission which shall have the power to constantly revise the tariff in the interests of all concerned, rather than having it periodically revised by Congress in a manner detrimental to general business and favorable to certain powerful interests.

THE FALLACY OF THE BOILED SHIRT IDEA

"Look on this picture," said a professor in a school of technology, holding out a colored plate advertising a correspondence school and showing in the center of a group a smooth, well-dressed figure of a man in white collar, tie, immaculate derby hat, and trousers creased to knife-edge. On either side of the dressed figure were men in overalls holding oil cans, sledges, and other implements of the workingman. The inference was that the central figure in the boiled shirt was the directing head of the grouped men in caps and jumpers.

"But what is the truth of this picture?" said the professor. "As a matter of fact, this young fellow in the good clothes to-day is drawing a salary of $1,000 to $1,500 a year and he is holding on to that job with clinched fingers. On each side of him are men who are getting $6 a day and pay for overtime.

The point which the professor out of his experience laid emphasis upon is this old invasion of the boiled shirt into a field of training which makes the boiled shirt ideal especially intolerable. Several years ago this professor was in charge of a graduating class of young men which had shown exceptional average talent and capability. There was sharp demand for such men in the work of construction, and positions had been tendered the school graduates. But almost to a man they declined to enter this active field of construction.

"Every one of them virtually decided against the jumpers in favor of the boiled shirt. They wanted to be consulting engineers," said the professor. "I jumped all over them, but it accomplished nothing. I showed them instances in which some of the biggest establishments in Chicago had been dismissing consulting engineers until hardly one of them was left. They wanted white shirts and creased trousers and rather than take good positions as construction men they went out to look for jobs that would allow of the boiled shirt.

"And the result? Most of them to-day are employed as draftsmen in establishments which pay them only the barest living wages. The average draftsman, pursuing his white shirt ideal, is as little considered as is the counter salesman in the average dry goods store. He is making concession of salary in order to wear good clothes.

"There is no position in the field of technology to-day which has as little promise as that will-o'-the-wisp, 'consulting engineer.' A few years ago, when engineering was far more on an experimental basis, the need of the consulting engineer who had knowledge and judgment and initiative necessarily was urgent. But in these years the conditions have been changing. Standard methods have been evolved from past consultations of engineers who have attained best results. There are fewer and fewer opportunities every year for this man who is bent upon becoming a consultant in engineering.

"On the other hand, methods of construction and the active handicraft of the constructor are more than ever in demand. The builder wants somebody to build, not some one to tell him how to build. He needs the educated man in the jumpers and cap, not the fellow in the creased trousers and the colored tie. Creased trousers in the *ensemble* of an organization are the badge of the non-producer; the cap and jumper mark the producer—the man who is making dividends for the company.

"It has been remarked that the graduate of the European technical schools has a hard time in this country—and so he does. They are theoretical men, universally. They have studied to pass their examinations based upon the text book. They can't compete with the graduate of the American schools, which has carried laboratory work right along with theory. Several years ago a young fellow came over here, well equipped in theory in his particular field. He came to me, and, liking the fellow, I tried to help him. The best I could do, however, was a job for him in an establishment where he got $15 a week. He had something in him, however, and his employers saw it. They hooked him up with another young fellow who knew the practical side of things, and the two worked together in team formation. It was an entirely satisfactory arrangement. The foreigner finally was promoted a step. Still with a practical partner in his wake, he was promoted again and again. And to-day he is general manager of the plant. But virtually he got the position through shedding his boiled shirt."—*Chicago Tribune.*

THE CHAMPNEY PROCESS OF DIE SINKING

CHESTER L. LUCAS*

In this era of interchangeable manufacturing, the progress of press work for making duplicate parts has been so rapid, and so many are interested, that the description of a novel method of making dies for drop-press work may be interesting to those engaged in die making for general production as well as to those in the drop-forging industry.

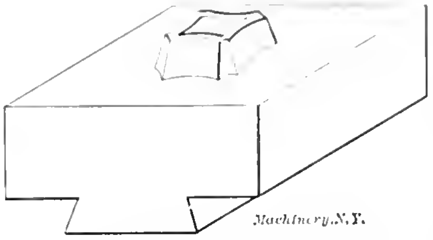

Fig. 1. Casting which forms the Heated Die by being Dropped upon it

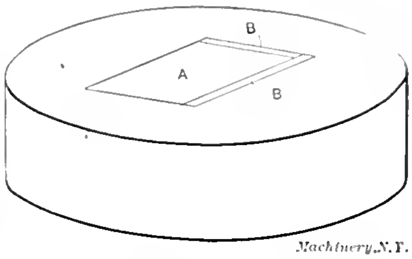

Fig. 2. Ring containing the Die Blank to be formed

Several years ago Mr. George F. Champney (now deceased) was engaged in business in Bridgeport, Conn., under the name of The Patent Steel Die Co., making dies for the forging trade and for the jewelry business, and as far as can be learned he was the originator of the "high drop" method of die sinking. This process was for a long time kept secret, and even to those who had a general idea of it, the details were not very clear. If, for example, a die for striking up a deep hollow-ware bowl was to be made, his plan was to first make a model of plaster of paris. From this model a casting, as shown in Fig. 1, was made of the finest and closest grained iron obtainable, with a large amount of metal left behind the model for strength. The sand was then cleaned from the casting without removing the hard scale, which is an important feature of this process, and it was then keyed to the hammer of the high drop. This high drop was rightly named, for although it was of the usual drop-press design, the ways are eighty feet high, the lower parts of iron and the upper of wood, faced the whole length with steel. The hammer itself is of cast iron and weighs 3,200 pounds. It is about two feet square and three feet long, and is raised by a windlass operated by hand. A pull on the rope attached to the release lever allows the huge weight to drop, and on the ways a latch is fitted to catch the hammer on the rebound, for a double blow is fatal to the die.

To the base of this great drop-press, which was necessarily very heavy, is fitted a cast iron ring (Fig. 2), which is 3 feet in diameter and 10 inches thick. The opening in the center of this ring is square and large enough to take any ordinary size of die blank. After keying the cast iron hub (or type) into the hammer of the drop and raising it to a height judged by the operator to be sufficient, the die blank *A*, which has been heated to a bright red, is placed within the square opening in the ring at the base of the press, and shims *B* placed around it so as to completely fill the space between the blank and the inside edge of the ring. The heavy hammer is then released, driving the hub with its facing of hard scale into the red-hot die blank. As the displaced steel could not go sideways on account of the shims, it had to go upwards and helped to bring the resulting impression up to shape. After being struck, the die was annealed and the scale removed by pickling; then enough was planed from the face to leave the die the proper depth, and by means of scrapers and rifflers the impression was smoothed and finished as in the ordinary methods of die sinking. Next the die was "shanked" to the press in which it was to be used, and after hardening and polishing it was ready for use.

* Address: Saugus Station, Lynn, Mass.

SPRING MEETING OF THE NATIONAL MACHINE TOOL BUILDERS ASSOCIATION

The spring meeting of the National Machine Tool Builders' Association was held at the Plankinton House, Milwaukee, Wis., May 25-26, and was conducted by President Fred L. Eberhardt of Gould & Eberhardt, Newark, N. J., and Secretary P. E. Montanus of the Springfield Machine Tool Co., Springfield, Ohio. Forty-eight of the ninety-one concerns having membership in the association were represented by fifty-three members May 25. Following the regular business of the association, the effect of the proposed tariff on the machine tool industry at home and abroad was discussed, following which was a discussion on the extent to which machine castings should be guaranteed by foundries. This discussion was led by Mr. James N. Heald of the Heald Machine Co., Worcester, Mass., who was followed by William Lodge of the Lodge & Shipley Machine Tool Co., and P. E. Montanus. Mr. Montanus made some observations on manufacturing conditions noticed on his recent European trip, the tenor of which was that American machine tool business in Europe has reached its zenith, and that we may expect more and more strenuous competition abroad as Europeans learn and adopt American manufacturing methods. Murray Shipley of the Lodge & Shipley Machine Tool Co. made an address on "Competition," in which he discussed in some detail the various legal and moral phases of business rivalry.

On Wednesday a paper was presented by Mr. William Forsyth, "Machine Tools for Railroad Shops." In the afternoon the members visited the mammoth plant of the Allis-Chalmers Co. at West Allis, a suburb of Milwaukee. The members of the association as a whole were optimistic, and the consensus of opinion was that the business outlook is good and that the machine tool trade will boom in the Fall.

* * *

At the seventh convention of the International Railway Congress, held in Washington, D. C., in 1905, it was decided to hold the next convention in Switzerland, and it has now been officially announced that the next session will be held in Berne, July 3 to 16, 1910.

* * *

PERSONAL

Lou Hunt, timekeeper of the Fairmount Mining Machinery Co., Fairmount, W. Va., has resigned, and is succeeded by Mr. Gordon Lake.

George E. Marquette, of Kenosha, Wis., has been appointed foreman of the tool-room of the Knox Automobile Co., Springfield, Mass.

George E. Ingalls, assistant manager of the Chapman Valve Mfg. Co.'s shops at Springfield, Mass., has been appointed to a position in the main office at Boston.

U. Anderson, formerly of Fond du Lac, Wis., has been made superintendent of the Prescott Co., Menominee, Mich., following Mr. Loren Prescott, who is vice-president of the company.

Elmer E. Neal, superintendent of the Smith & Wesson Co., Springfield, Mass., revolver manufacturers, has resigned to take a similar position with the Bristol Engineering Co., Bristol, Conn.

James Dillon, of Fond du Lac, Wis., has been made machine foreman of the Prescott Co., Menominee, Mich. Mr. John Roscoe, the old floor foreman is still in place and Mr. Anton Nelson, general foreman, has resigned.

Robert Reed, chief draftsman of the Fairmount Mining Machinery Co., Fairmount, W. Va., has resigned and taken a similar position with Scotdale Foundry & Machine Co., of the same place.

Clement Booth, who for the last four years was in charge of the tool and gage department of the Remington Typewriter Co., Ilion, N. Y., is now with the Standard Roller Bearing Co., Philadelphia, Pa.

W. H. Maxwell, formerly general manager of the Angle Steel Sled Co., Kalamazoo, Mich., has resigned his position to become secretary, treasurer and manager of the Kalamazoo Steel Goods Co.

Carl S. Dow, lately publicity manager of the B. F. Sturtevant Co., and formerly in charge of instruction and textbook departments of the American Correspondence School, has joined the staff of Mr. Walter B. Snow, publicity engineer, 170 Summer St., Boston, Mass.

J. C. Jurgensen, chief engineer of the Hotel St. Regis, New York, has resigned his position to take the chair of engineering plant instruction at Columbia University next fall. A new course has been established for training students in the duties of engineers in charge of power plants.

A committee of five composed of Wilfred Lewis, Hugo Bilgram, Gaetano Lanza, Charles R. Gabriel and E. R. Fellows, was appointed April 13 by the president of the American Society of Mechanical Engineers to investigate involute gearing with a view of recommending standard tooth forms and dimensions.

Milton Thurlow, chief draftsman of the Prescott Co., Menominee, Mich., has resigned, and his position is filled by Mr. Carl Weidling, who was a former employe, before the dull times. Mr. Thurlow has obtained a position with the Berlin Machine Co., Beloit, Wis.

Claude E. Holgate, who for the past ten years has filled the position of assistant to the general manager, and has been in charge of the sales department of Gould & Eberhardt, Newark, N. J., has resigned to take charge of the automobile department of a daily paper in that city.

The author of the series "Design and Construction of Electric Overhead Cranes," now running in MACHINERY, published an article in the April 9 issue of the *Engineer* (London) describing a 150-ton floating crane for the Kawasaki Dockyard Co., Japan, built by Cowans, Sheldon & Co., Ltd., Carlisle, England, which was designed by him.

B. Elshoff, for twelve years assistant superintendent of the Allis-Chalmers-Bullock Co., of Cincinnati, and for the past two years superintendent of the electrical department of the Allis-Chalmers Co., of Milwaukee, recently severed his connection with the last named company. Mr. Elshoff may eventually accept a position with an eastern firm, but for the present will remain in Milwaukee.

Prof. Charles B. Richards, for the past twenty-five years head of the mechanical engineering department of the Sheffield Scientific School, Yale University, will resign his position in June. Prof. Richards was one of the founders of the American Society of Mechanical Engineers in 1881, and is the inventor of the Richards steam engine indicator.

W. A. Garrett, former president of the Sea Board Air Line Railway, and now chief executive officer, will resign his position November 1 to become vice-president of the T. H. Symington Co., Baltimore, Md. Mr. Garrett was at one time superintendent of the middle division of the Wabash R. R., and the news that he is to leave railroad service has caused considerable surprise and regret among his friends.

John J. Harman, graduate of the Mechanical Engineering College of the University of Illinois, has been made a member of the Harman Engineering Co., 120 Fredonia Ave., Peoria, Ill. Mr. Harman has been connected with the Link-Belt Co., Acme Harvester Co., United States Geological Survey, National Tube Co., etc., in various capacities.

Dwight T. Randall, member of the American Society of Mechanical Engineers, late engineer in charge of fuel tests, Technologic Branch, United States Geological Survey, has associated himself with the Arthur D. Little Laboratory of Engineering Chemistry of Boston, in charge of the Department of Fuel Engineering. Mr. Randall, who is a graduate of the University of Illinois, was formerly connected with R. W. Hunt & Co., and Westinghouse, Church, Kerr & Co., and later in charge of the Steam Engineering Laboratory of the University of Illinois, and of Steam and Boiler Tests at the St. Louis Exposition.

OBITUARIES

William Delaven, of Springfield, Mass., inventor of the Triumph voting machine and manager of the Triumph Voting Machine Co., died April 9 aged forty-six years.

Mace Moulton, a well-known consulting engineer of Springfield, Mass., died suddenly at the Ansonia Hotel, New York, April 27, aged fifty-four years.

Benjamin F. Nichols, a prominent manufacturer of Springfield, Mass., died suddenly at the Continental Hotel, New York, April 23, aged sixty years. He organized the B. F. Nichols Belting Co., Holyoke, Mass., and later capitalized the Metallic Drawing Roll Co., of which he was treasurer and manager, until he sold the stock in 1893 in order to form the England Metallic Drawing Roll Co., Manchester, England.

Ralph Scott, a young inventor of electrical appliances and author of several works on electrical engineering, died at his home in Newark, N. J., April 25, aged twenty-six years, following an operation for appendicitis. Mr. Scott was born in Bradford, England, and came to this country with his parents when young. He was the inventor of the Scott arc light and had a remarkable record as an inventor for one so young, over forty patents on various electrical contrivances having been secured by him. Just before his death, he finished at his factory at Newark, N. J., what is believed to be the largest arc light in the world for the Lackawanna Railroad terminal at Hoboken. The light is of 1,500,000 candle-power and the globe is six feet in diameter.

H. T. T. Cedergren died in Stockholm, Sweden, April 13, 1909. Mr. Cedergren was president of Stockholm's Public Telephone Co., which he founded twenty-six years ago and

which he conducted with such remarkable success that his company not only forced the Bell Telephone Co. in Stockholm, which obtained a franchise a few years earlier, out of business, but has also held its own in competition with the Swedish state telephone service. All things considered, the telephone service in Stockholm is equal or better, and the charges very much lower than elsewhere, and this record has been due in a large measure to Mr. Cedergren's exceptional managing ability. He also founded telephone companies in Moscow and Warsaw and took a prominent part in the working out of the plans for the telephone system in Mexico installed by a Swedish telephone company.

THOMAS A. WESTON

Thomas A. Weston, inventor of the differential pulley block, the multiple disk brake, the triplex chain block and other inventions, died in New York, May 3 in the seventy-eighth year of his age.

Mr. Weston, although born in England, was a thorough American, not only in the legal sense but at heart. He came to this country when quite young, and for a time was a clerk in the old hardware house of Pratt & Co., Buffalo, N. Y. He had an inventive mind and a natural aptitude for mechanics. His most widely known invention is the differential block which in later years became recognized as an addition to the so-called "mechanical powers," that is, the elementary means whereby power applied is transformed as to time and distance in its ultimate effect or result. The differential block is an adaption of the old "Chinese windlass," and is a reduction of a mechanical principle to its simplest terms, which enables a man, without other aid to lift one thousand pounds or more, and it holds the load suspended automatically at any point. The invention was patented in Great Britain and the United States, the licensees in Great Britain being Tangye Bros., Ltd., of Birmingham, and in the United States, Yale & Towne Mfg. Co., of Stamford, Conn. The invention was immediately recognized as a most valuable lifting mechanism and soon came into general use.

Mr. Weston's next most notable invention was that of the multiple disk brake, which in various forms has since been widely used in connection with machines of many kinds in which a brake resistance is needed, especially in cranes and hoists. It consists of two series of disks alternately interposed, those of one set being connected at their centers to a spindle, and those of the other set at their peripheries to an external casing. Each unit of longitudinal pressure applied to the series thus produces a frictional resistance between each pair of disks which is multiplied by the number of disks in the series, thereby making a brake mechanism of great compactness and power.

Mr. Weston's third and last important invention is the triplex chain block, manufactured by the Yale & Towne Mfg. Co., which like his original differential pulley block embodies the automatic holding of the load at all points, thereby eliminating all danger, but which in addition possesses a very high mechanical efficiency. The principle of the differential block involved a large waste of power and very low efficiency, averaging from 25 per cent to 30 per cent, whereas the triplex block attains an efficiency of nearly 80 per cent; in other words, for each 100 foot-pounds of power applied it gives back nearly 80 foot-pounds of useful work as against only about 25 foot-pounds in the case of the differential block.

Mr. Weston made numerous minor inventions, and all of the latter part of his life was occupied in the study of mechanical problems. He was a man of culture, refinement and exceptional intelligence, whose contributions to the mechanical world in the relatively minor field above indicated were of great value and importance and will have a permanent place among the notable inventions of the past half century.

* * *

COMING EVENTS

May to November, 1910.—International Exhibition of Railway and Land Transport, Buenos Ayres, Argentine Republic, commemorating the first centennial of the Argentine Independence. The officers of the exhibition are: Alberto Schneidweind, general director of Argentine Railways, president; H. H. Loveday, general manager of Argentine Railways, and Dr. H. H. Traya, local director of Central Argentine Railways, vice-presidents; Juan Pelleschi, commissioner general; Eduardo Schlatter, secretary.

June 1.—Opening of the Alaska-Yukon-Pacific Exposition in Seattle, Washington, which is designed to call the attention of the world to the importance of Seattle as the western gate-way to the United States, and to its rapidly growing commercial importance. The exposition will include many working exhibits, among which are meat packing, watch-making, jewelry, silk-making, rope-making, telephoning, printing, etc.

June 1-5.—International Railway General Foremen's Association convention at Chicago, headquarters Lexington Hotel. E. C. Cook, secretary-treasurer, Royal Insurance Building, Chicago. The program comprises these papers: "Air Brake Equipment," "Coaling of Engines with Mechanical Devices, "How to Obtain the Greatest Despatch in Handling Engines Through Terminals." "Installation of Hot Water Washout and Filling System," "Best Method of getting Work through Shop with Economy and Despatch." "Most Approved Type of Ash-Pan Conforming with Requirements of the Interstate Commerce Commission," "Use of the Oxy-Acetylene Process of Welding Fire-boxes, Locomotive Sheets, Frames, and other Locomotive Work."

June 7-19.—Cleveland Industrial Exposition, under the auspices of the Cleveland Chamber of Commerce, Cleveland, Ohio. It is estimated that 125,000 different articles are manufactured in Cleveland's 3,500 shops, and it is proposed to display to the world at this exposition the wonderful industrial facilities of the city. The products comprise steel ships, heavy machinery, hardware, twist drills, reamers, milling cutters, wire nails, bolts, nuts, vapor stoves, malleable castings, automobiles, paints and oils, etc. William G. Rose, Cleveland, Ohio, secretary.

June 9-11.—Joint convention of the Southern Hardware Jobbers' Association and the American Hardware Manufacturers' Association at Hotel Schenley, Pittsburg, Pa. F. D. Mitchell, 309 Broadway, New York, secretary and treasurer.

June 11.—Meeting of the Internal Combustion Engineers' Association at the Sherman House, corner Clark and Randolph Sts., Chicago, to install officers for the ensuing year which were elected at the May meeting, and for the transaction of other business. Walter A. Sittig, secretary, 61 Ward St., Chicago, Ill.

June 16-18.—Annual convention of Railway Master Mechanics' Association on Young's Million Dollar Pier, Atlantic City, N. J. Joseph W. Taylor, Old Colony Building, Chicago, Ill., secretary.

June 21-23.—Annual convention of the Master Car Builders' Association on Young's Million Dollar Pier, Atlantic City, N. J. Joseph W. Taylor, Old Colony Building, Chicago, Ill., secretary.

June 22-24.—National Gas and Gasoline Engine Trades Association convention, South Bend, Ind. Headquarters, Oliver Hotel. Albert Stritmatter, Cincinnati, Ohio, secretary.

June 24-26.—Seventeenth annual convention of the Society for the Promotion of Engineering Education at Columbia University and Pratt Institute, in New York and Brooklyn. These dates immediately precede those of the meetings of the American Institute of Electrical Engineers, the Society for Testing Materials and the American Society of Civil Engineers, and New York City is very near the geographical center of the meeting places of these three other societies. It will, therefore, be a convenient place of meeting for all who wish to attend the convention of one of the other societies. An unusually attractive program has been arranged, which will include the report of the joint committee of engineering societies on engineering education by Dugald C. Jackson, a report of the committee on technical books for libraries by Arthur H. Ford, a report of the committee on engineering degrees by William F. M. Goss, a report of the committee on entrance requirements by Robert Fletcher, besides contributed articles. In addition a special session will be devoted to the discussion of engineering mathematics by the committee of fifteen appointed at the Chicago meeting of the American Association for the Advancement of Science, which has been requested to prepare a special report for the Society for the Promotion of Engineering Education for its meeting in 1909. Arthur L. Williston, secretary, Pratt Institute, Brooklyn, N. Y.

June 28.—Annual convention of the American Institute of Electrical Engineers at Frontenac, N. Y. Ralph W. Pope, secretary, 29 West 39th St., New York.

June 29.—Annual meeting of the American Society for Testing Materials at Atlantic City, N. J. Edgar Marburg, secretary, University of Pennsylvania, Philadelphia, Pa.

September 25-October 9. Hudson-Fulton celebration of the three-hundredth anniversary of the discovery of the Hudson River by Hendrick Hudson in 1609, and the one hundredth anniversary of the successful application of steam to the navigation of the Hudson River in 1807. The headquarters of the commission are in the Tribune Building, New York City, General Stewart L. Woodford, president, and Mr. Henry W. Sackett, secretary. The commission solicits the loan of collections of machinery, models, books, etc., having a bearing on the history of early steam navigation in the United States.

Oct. 18-22.—Annual convention of American Street and Interurban Railway Association at Denver, Col. Bernard V. Swenson, secretary, 29 West 39th St., New York.

SOCIETIES AND COLLEGES

Upper Iowa University, Fayette, Iowa. Catalogue of the university for the fifty-third year.

University of Illinois, Urbana, Ill. Bulletin No. 14 containing catalogue of the school of railway engineering and administration.

University of Wisconsin, Madison, Wis. Bulletin No. 287, containing announcement of the summer session which begins June 28 and ends August 6.

Museum of Safety and Sanitation, 29 West 39th St., New York. Circular illustrating the proposed museum designed by Whitfield & King, and containing an extract from the article in the March issue of the *Century* by Dr. W. H. Tolman on saving lives by lessening accidents.

Museum of Safety and Sanitation, 29 West 39th St., New York. Monthly bulletin No. 1, entitled Safety, a publication issued by the Museum to promote the installation of safety devices for the protection of workmen in factories, mines, mills, and other places where there is danger from machinery or other hazards.

The Ohio Society of Mechanical, Electrical and Steam Engineers held its nineteenth meeting May 21-22 at Canton, Ohio. The following papers were presented: "Heat Insulation," L. O. Hooge; "The Interpole Motor," Prof. H. B. Dates; "Hot, Soft Water for Steam Boilers," G. H. Gibson; "On the Ethics of the Society Members," H. E. Gahr; "Continuous Melting," R. H. Probert. "Lubrication of Steam Cylinders by Grease," B. Fisher; "Recent Developments in Glower Lamps and their Application to Modern Illumination Practice," A. L. Eustice; "Some Practical Points on Power Plant Piping," Julius Roemer. David Gaehr, secretary, Schofield Building, Cleveland, Ohio.

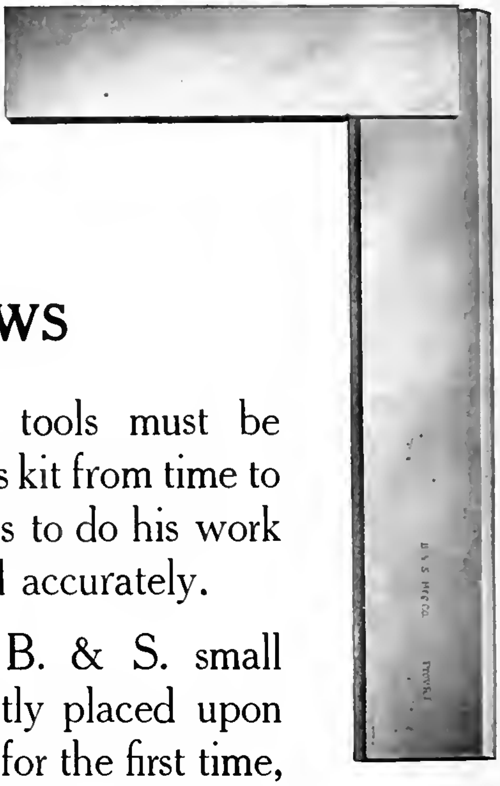
University of Wisconsin, Madison, Wis., announces the ninth session of the Summer School for Artisans, beginning June 28 and continuing six weeks. Courses are open in steam and gas engines, electricity, machine design and mechanical drawing and other subjects. There are no entrance requirements, the purpose of the school being to offer practical instruction through lectures and laboratory work to young men in the trades. Certain advanced engineering courses are offered for those who have the requisite preparation, and a general university summer session is held during the same period. New features of the coming session are courses in public utility testing and accounting. Further information may be obtained from F. E. Turneaure, Dean of the College of Engineering, University of Wisconsin, Madison, Wis.

The Air Brake Association held its sixteenth annual convention at Richmond, Va., May 11-14, at which the following papers were presented: "Pipes and Pipe Fittings for Locomotives and Cars," by J. R. Alexander; "Air Brake Instruction," by Thomas Clegg "Yard Air Brake Test Plants and Air Brake Repairs," by F. Von Bergen; "Higher Braking Power," by J. W. Kiehn; "How Can the Road Foreman of Engines Render the Most Effective Assistance to the Air Brake Service?" by John Talty; "Handling Passenger and Freight Trains with 'ET' Equipment," by H. A. Flynn; "The Engine House Inspection Repairs and Maintenance of Air Brakes," by W. D. Seeley; "The Best Arrangement of Air Pump and Main Reservoir Capacity for 100-Car Train Service," by J. P. Langan. The secretary of the association is F. M. Nellis, 53 State St., Boston, Mass.

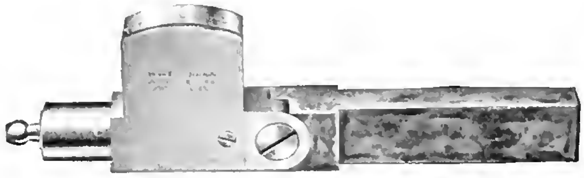
Postal Progress League, 361 Broadway, New York, is an association formed to effect a much-needed change in the United States postal service rates. It advocates a reduction of the general merchandise rates from 16 cents per pound to 8 cents per pound, which is the old rate of 1874; in the rural service, a common tariff on all local mail matter of one cent on parcels up to 1/24 cubic foot (6 x 12 x 24 inches); five cents on larger parcels up to ½ cubic foot (6 x 12 x 12

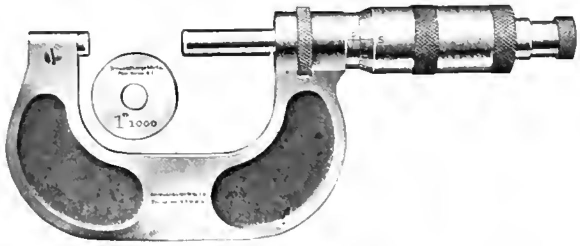
BROWN & SHARPE MFG. CO.

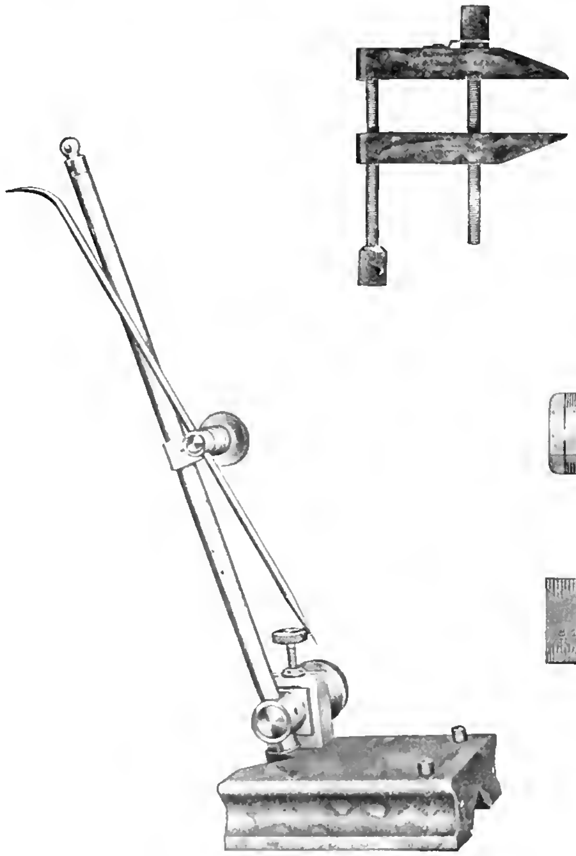
Providence, R. I., U. S. A.



EVERY MACHINIST KNOWS





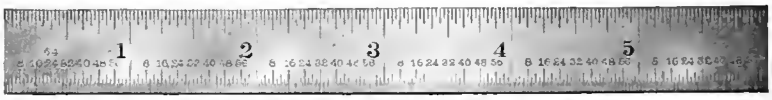


That new tools must be added to his kit from time to time if he is to do his work quickly and accurately.

The new B. & S. small tools, recently placed upon the market for the first time, will constitute a valuable addition to his outfit.

Their **Accuracy, Simplicity** and **Durability** particularly recommend them where tools of the **Highest Quality** only are used.

Many other important features embodied in their design are fully explained in a new folder entitled, *"A Machinist's Kit."* Send for a copy.



1000 VARIETIES.
ONE QUALITY.

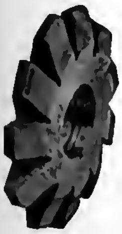
BROWN & SHARPE MFG. CO.

Providence, R. I., U. S. A.

EFFICIENCY AND QUALITY

MARKED CHARACTERISTICS OF

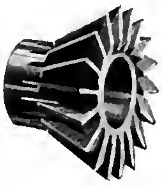
B. & S. CUTTERS

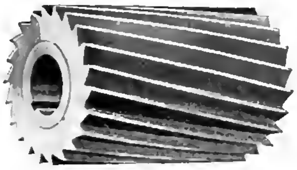


WELL KNOWN TO ALL USERS OF HIGH GRADE TOOLS.

Many years ago we established a custom of thoroughly testing out the qualities of any new design of cutter before placing it upon the market. This rule has always been rigidly adhered to and is the principal factor to which the **Accuracy** and **Uniform Quality** of all B. & S. cutters may be attributed.

The B. & S. Mfg. Co. stamped on a cutter therefore signifies its **Reliability, Accuracy** and **Durability.**





inches), ten cents on still larger parcels up to one cubic foot (6 x 12 x 24 inches). The space rate should be limited to one cubic foot, length six feet, weight twenty-five pounds. The league advocates these rates as effective means of checking the extortions of the express companies, and making the postal service self-supporting by adding millions to its revenues.

American Foundrymen's Association and American Brass Founders' Association held a joint convention at Cincinnati, Ohio, May 18-20. A fine line of foundry machinery and foundry appliances were exhibited. The following papers were presented: "The Manufacture of Brass Ingot; Its Uses and Advantages," by W. M. Corse; "The Use of Waste Heat," by F. W. Reidenbach; "The Patent Situation in the U. S. Respecting Alloys," by C. H. Clamer; "The Cost of Steel Melting in Foundries," by Dr. Bradley Stoughton; "The Side Blow Converter for Steel Castings and Its Operation," by J. S. Whitehouse; "Open Hearth Methods for Steel Castings," by W. M Carr; "Notes on Air Furnace Construction for Malleable Castings," by W H. Kane "The Use of Pulverized Coal for Foundry Purposes," by Richard K Meade; "Machine Molding vs. Hand Molding," by George Muntz; "Pattern Shop Equipment," by A. M. Spencer; "The Heart of the Foundry as Seen by the Foundry Engineer," by D. S. Hawkins; "Cores and Core Making," by F. K. Cheney; "Continuous Melting in the Foundry of the Westinghouse Air Brake Co.," by S. D. Sleeth; "Continuous Melting," by R. H. Probert; "The Permanent Mold," by Edgar A. Custer; "The Practical Value of Chemical Standards for Iron Castings," by Dr. J. J. Porter; "Pyrometry in the Annealing Room," by S. H. Stupakoff; "General Principles of Operation of Industrial Pyrometers," by C. H. Wilson. "Notes on Brass Melting," by Charles T. Bragg; "Melting of Brass Turnings in the Oil Furnace," by E. H McVeen; "Electrolytic Assay of Copper," by George L. Heath; "The Tensile Strength of Zinc-Aluminum Alloys," by W. D. Bancroft; "System of Distributing Waste Losses in Raw Materials to the Cost of the Finished Product," by L. W. Olsen; "A Comprehensive Foundry Production Tally," by C. E. Knoeppel; "Foundry Costs," by B. C. Franklin; "Modern Cupola Practice," by J. C. Knoeppel; "Notes on Steel Scrap in the Cupola," by C. R. McGahey. Richard Moldenke, Watchung, N. J., secretary-treasurer of the American Foundrymen's Association; William Corse, secretary, American Brass Founders' Association.

NEW BOOKS AND PAMPHLETS

Statistics of Railways in the United States for the Year Ending June 30, 1907. 789 pages, 6 x 9 inches. Published by the Interstate Commerce Commission, Washington, D. C.

Test of Reinforced Concrete Beams: Resistance to Web Stresses. By Arthur N. Talbot. 86 pages, 6 x 9 inches Published by the University of Illinois Engineering Experiment Station, Urbana, Ill.

This pamphlet on tests of reinforced concrete is No. 29 of the series 1907-1908. It supplies data on resistance to web stresses which has not been as thoroughly investigated as has tensile resistance of the reinforcement and compressive resistance of the concrete. The pamphlet tabulates the results of a large number of tests.

Tables of the Properties of Steam and Other Vapors. By Cecil H. Peabody. 133 pages, 6 x 9 inches. Published by John Wiley & Sons, New York. Price $1.

This well-known work which was published in 1888 has passed into the 8th edition and has been rewritten and is offered to the public by the author with confidence that the new methods of redetermining the properties of steam are such that the tables may be expected to have permanence. The temperature-entropy table gives the solution both for saturated and for superheated steam. The tables are excellent examples of fine typography.

Results of Purchasing Coal Under Government Specifications. By John Shober Burrows. 44 pages, 6 x 9 inches. Published by the United States Geological Survey, Washington, D. C.

The pamphlet reviews the results of purchasing coal under government specifications, and is accompanied by a paper by Dwight T. Randall on burning the small sizes of anthracite for heat and power purposes. The paper will be found of general interest to power plant managers and others concerned with the economical production of power.

Significance of Drafts in Steam-Boiler Practice. By Walter T. Ray and Henry Kreisinger. 61 pages, 6 x 9 inches. Published by the United States Geological Survey, Washington, D. C.

The experiments thus far made seem to indicate that it is possible to double or treble the capacity of a boiler without making radical changes in the furnaces and boilers. The experiments are of great interest to power plant managers, especially those troubled by insufficient capacity and the apparent necessity of increasing the capacity by adding new equipment.

Internal Combustion Engines. By William M. Hogle. 256 pages, 6 x 9 inches. 106 illustrations and diagrams. Published by the McGraw Publishing Co., New York. Price $3.

The aim of the author in preparing this work was to confine the treatment to the practical and applied phases of the subject, eliminating so far as practical the involved thermodynamic mathematical formulas found in other works on the gas engine. The general scope of the work is indicated by the following chapter headings: The Beau de Rochas Cycle; The Clerk Cycle; The Diesel Motor; Comparison of the Cycles; Practical Operation; Care of Engine (troubles and remedies); Starting Devices; Carbureters, Vaporizers and Injectors; Producers; Fuels and Combustion; Compression; The Indicator Card; The Cylinder; The Fly-Wheel; The Frame; Engine Foundations; The General Dimensions; The Cam Mechanism; The Valves and Ports; Crank-Shaft and Reciprocating Parts; Governing Devices; Ignition; Engine Testing; and Report of Tests.

Automatic Screw Machines and Their Tools. By C. L. Goodrich and F. A. Stanley. 255 pages, 6 x 9 inches. 284 figure numbers. Published by the Hill Publishing Co., New York. Price $2.

The wide development of the automatic screw machine makes an authoritative work on screw machine practice most welcome. The work covers the leading machines, comprising the Pratt & Whitney, Brown & Sharpe, Cleveland, Gridley, Alfred Herbert, Spencer, Acme, Potter & Johnston, and Prentice machines of the single-spindle and multiple-spindle types, illustrating and describing their constructive features. The second section treats of points on setting up and operating, speeds and feeds, spring collets and feed chucks, box tools and other external cutting appliances, drills, counterbores and other internal cutting tools, screw machine taps and dies, forming tools and methods of making them, knurling tools and their applications, why chips cling to screw machine tools, etc. The work is printed on heavy coated paper and the general typographical appearance is excellent.

Harper's Machinery Book for Boys. By Joseph H. Adams. 372 pages, 5½ x 7¾ inches. Illustrated. Published by Harper & Bros., New York. Price, $1.75.

The aim of the work is to instruct boys in the principles of machinery and the use of tools and to impress that knowledge by giving plans by which water wheels of the over-shot, under-shot and Pelton types, steam turbines, steam engines and boilers, windmills and turning lathes, pumps, force pumps, siphons, power transmission by belts, shafts and gearing, motor boats, jig saws, and a large variety of other machines of a simple nature that can be built of wood, and wood and metal in combination with the tools and supplies that are within the reach of enterprising boys having plenty of leisure and pocket money. The scope of the book is indicated by the following chapter headings: Principles of Simple Mechanics; Mechanic's Tools; Power; Power Transmission; Water Power; Wind Power; Steam Power; Electric Power; Hydraulics; Machinery; Metal-Working Machinery; Wood-Working Machinery; Stone and Marble Working Machinery; Concrete Construction and Machinery; Metal Casting and Foundry Work; Forging, Welding and Brazing; Miscellaneous Machines and Apparatus; Automobiles; Motor Boats; The Stationary Gas Engine; Shop Hints; Formulas; Tables, Gages and Measures; A Dictionary of Mechanical Terms. The book is one that will be prized by the average boy of a mechanical bent of mind. Most of the apparatus illustrated no doubt may be constructed from the sketches with fair satisfaction. Some crudity of expression is apparent, particularly in description of gas engines and metal-working tools. The fly-wheel of a gas engine is described as keeping up the motion from working stroke to working stroke "through its stored up centrifugal force." A planer is called a "bed planer," and its platen a "traveler." A knee-type milling machine is a "gear cutter and shaper," and the "bed travels carrying the work back and forth against the tool." The author evidently did not fully understand the principle of action of the milling machine. While slips of this nature are not important, in a sense, it is unfortunate that a book of instruction for the young should contain errors that tend to prejudice those who know against it. The illustrations are free-hand ink sketches and halftones. The latter are made with a coarse screen, the result being that many of the details are lost or obscured. The dictionary of mechanical terms is a valuable feature and well prepared. The book, as a whole, is one that can be commended to those desiring to place a work of this character in the hands of their boys.

CATALOGUES AND CIRCULARS

S. F. Bowser & Co., Ltd., Toronto, Canada. Circular of self-measuring oil pumps for shops, factories, round-houses, garages, etc.

C. W. Hunt Co., 45 Broadway, New York. Catalogue No. 091 of coal and ore handling machinery.

Ingersoll-Rand Co., 11 Broadway, New York. Circular No. 4010 of telescope feed hammer rock drills.

Ingersoll-Rand Co., 11 Broadway, New York. Circular No. 3001 of air and gas compressors.

American Electric Fuse Co., Muskegon, Mich. Catalogue of Allen-Bradley rheostats and electric controlling apparatus.

D. Van Nostrand Co., 25 Murray St., New York. Catalogue of scientific books recently published.

Crocker-Wheeler Co., Ampere, N. J. Bulletin No. 112 of exhaust fans driven by electric motors, direct connected.

Crocker-Wheeler Co., Ampere, N. J. Bulletin No. 113 of large direct current motors for direct connection.

Horace L. Winslow Co., Old Colony Building, Chicago, Ill. Catalogue of Clark blow-off system for locomotives and other steam boilers.

Warren-Webster Co., Camden, N. J. Circular announcement of the 80-page general catalogue of Webster specialties.

Dean Bros. Steam Pump Works, Indianapolis, Ind. Catalogue No. 77 of steam pumps.

Chapman Ball Bearing Co., Boston, Mass. Circular of Chapman ball bearings showing applications to loose pulleys and line-shaft bearings.

Hess-Bright Mfg. Co., Philadelphia, Pa. Sheets Nos. 35 and 36, illustrating worms and worm-wheels mounted with Hess-Bright ball bearings.

Northwestern Expanded Metal Co., Old Colony Building, Chicago, Ill. Booklet of expanded metal manufacture giving valuable data on the strength of reinforced concrete.

E. G. Smith Co., Columbia, Pa. Circular listing "Which Way" levels and Smith beam calipers sold at special prices to clean out stock.

Brown Specialty Machinery Co., Chicago, Ill. Catalogue of the Hammer core machine for making a great variety of cores with rapidity and cheapness.

Baldwin Locomotive Works, Philadelphia, Pa. Record No. 66 on smoke box superheater and feed water heaters, by John W. Converse and Lawford H. Fry, reprinted from the *Railroad Age Gazette.*

Cleveland Twist Drill Co., Cleveland, Ohio. Circular advertising "Peerless" high-speed reamers, "Perfect" double tang sockets, and "Paradox" adjustable reamers.

S. W. Card Mfg. Co., Mansfield, Mass. Booklet entitled "The Passing of the V-Thread" (see Machinery, March, 1909), giving the reasons why the sharp V-thread should be abandoned in favor of the U. S. standard thread and pitches.

Joseph Dixon Crucible Co., Jersey City, N. J. Booklet of graphite products which is a pocket edition of the general catalogue of the products of the company, listing crucibles, flake graphite, machine grease, lubricating graphite, etc.

Shepard Electric Crane & Hoist Co., 50 Church St., New York. Bulletin No. 502 of the Shepard electric hoists which are built in over four hundred types and sizes with a capacity from 500 pounds to 20 tons.

Skinner Chuck Co., New Britain, Conn. Set of four blotter advertising cards illustrating the Skinner planer chuck, combination lathe chuck, 1904 pattern individual lathe chuck, and geared pattern drill chuck.

Hannifin Mfg. Co., Chicago, Ill. Catalogue of Aero chucks, friction chucks, cost-reducing tools, air counter-shafts, gate valve seating machines, etc. This company is the successor of the Manufacturers' Equipment Co.

Nappanee Iron Works, Nappanee, Ind. Circular of the Nappanee portable cylinder boring bar for general work, which is made in three sizes. This boring bar was illustrated and described in the May number of Machinery.

Philadelphia Gear Works, Inc., 1120-1122 Vine St., Philadelphia, Pa. Match scratcher advertising cut gears and card deprecating the policy of waiting until business improves before placing orders for goods.

W. W. Oliver Machine Co., Buffalo, N. Y. Catalogue No. 17 of rolling mills, polishing machines, drop presses, draw benches, drills, foot-power lathes, bench shears, rod cutters, and other light machinery for the working of metal.

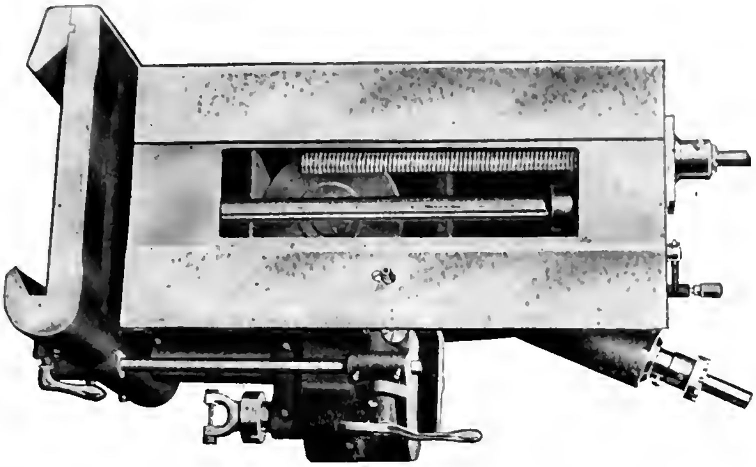
Pneumatic Nut Machinery Co., Inc., 224 High Ave., Cleveland, Ohio. Circular illustrating a nut tapping machine having a turret with six taps and six facing tools and pneumatic feed. The nuts are fed, tapped and removed by a controlled automatic system.

Webster & Perks Tool Co., Springfield, Ohio. Catalogue of grinding and polishing machinery, comprising: Bench grinders, floor grinders, edge grinders, buffing and polishing lathes, etc. The catalogue illustrates automatic oiling devices applied to these grinders for insuring copious supply of lubricant to the bearings.

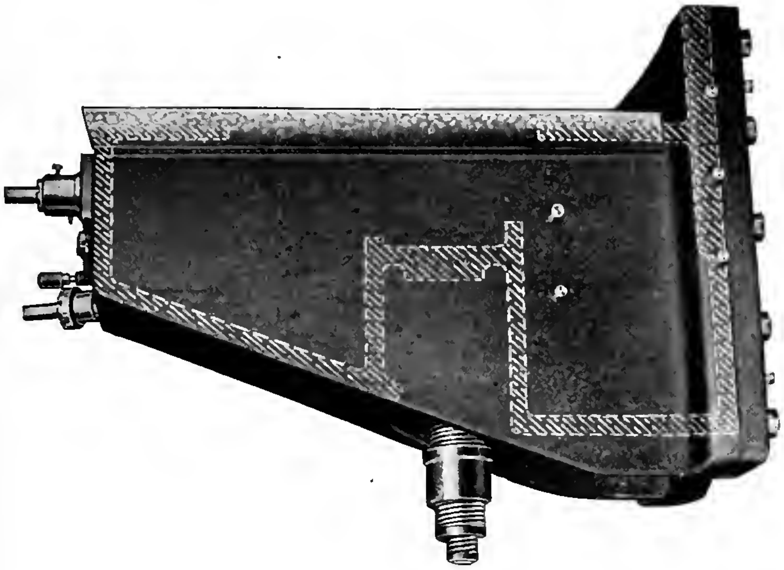
Northwestern Expanded Metal Co., 930-950 Old Colony Building, Chicago, Ill. Booklet of beam and column data compiled by Ernest McCullough, chief engineer of the company. The booklet contains a fund of valuable data on beams and columns, and advertises the expanded metal manufactured by the company.

Webster Tool & Mfg. Co., Springfield, Ohio. Catalogue of tool holders, expanding mandrels, portable stands, surfacing files, turret

Cincinnati



High Power Miller



Rigidity

The knee of a Miller is subjected principally to twisting strains due to the pressure of the cutter against the work, tending to overturn the table and saddle.

Cincinnati High Power Miller Knees are designed to resist these twisting strains. The cuts show the webbing. They are reinforced boxes, and a box will resist twisting better than any other rectangular structure.

Prove this to yourself.

Take a light box, complete with lid fastened down and note its torsional stiffness compared with a box of the same size that has no bottom and only one end made of boards twice as thick.

The complete box will win.

This is the principle on which our machines are designed throughout.

The Cincinnati Milling Machine Company

Cincinnati, Ohio, U. S. A.

EUROPEAN AGENTS—Schuchardt & Schutte, Berlin, Vienna, Stockholm, St. Petersburg, Copenhagen and Budapest. Alfred H. Schutte, Cologne, Brussels, Liege, Milan, Paris, Turin, Barcelona and Bilbao. Chas. Churchill & Co., London, Birmingham, Manchester, Newcastle-on-Tyne and Glasgow.
CANADIAN AGENT—H. W. Petrie, Ltd., Toronto, Montreal and Vancouver.
AUSTRALIAN AGENTS—Thos. McPherson & Son, Melbourne.

[illegible] bench legs, C-clamps, lathe dogs, friction clutches, adjustable shell reamers, grinders, quick-change drill chucks and collets, shapers, engine lathes, etc.

General Electric Co., Schenectady, N. Y. Bulletins Nos. 46 and 59, describing Type I ammeters, voltmeters, and wattmeters for alternating current circuits. The indications of the pointer are rendered "dead beat" and the scale extends through an arc of 300 degrees, and is practically uniform throughout. The instruments are so constructed as to be uninfluenced by stray fields.

Brown & Sharpe Mfg. Co., Providence, R. I. Booklet illustrating features of the original constant speed drive milling machine. This attractive booklet illustrates the Brown & Sharpe constant speed mechanism, the feed works and other details. It concludes with tables of general dimensions of universal milling machines Nos. 2-A, 2-A heavy, 3-A heavy, and 4-A heavy.

Westinghouse Electric & Mfg. Co., Pittsburg, Pa. Circular No. 1502, containing valuable information on alternating current distribution, covering transformers, lightning arresters, insulators, cross arms, etc. The circular contains fifty-two pages of information of value to central station managers and others concerned with the distribution of power by alternating current systems.

S. Obermayer Co., Cincinnati, Ohio. Leaflet endorsing the movement to increase the available daylight hours during the summer, which was initiated in England. The leaflet advocates advancing the standard time in the United States two hours beginning May 1 and continuing until October 1. The two additional hours given in the hot season are the coolest hours of the day and are best for labor and exercise.

Armstrong Bros. Tool Co., 113 N. Francisco Ave., Chicago, Ill. Circular of the Armstrong automatic drill drift for loosening taper tang twist drills in their sockets. This drill drift requires no hammer, the handle acting as a hammer being slidably mounted on the drift and retracted by a coil spring. This tool was formerly made by the Automatic Drill Drift Co., and was illustrated in the July, 1908, number of Machinery.

Niles-Bement-Pond Co., 111 Broadway, New York. *Progress Reporter* No. 19 illustrating the Niles extra heavy driving wheel chucking lathe which has a capacity of eight pairs of driving wheels in ten hours, and the Niles standard driving wheel lathe having a capacity of five to six pairs of driving wheels in ten hours. The catalogue also illustrates the Pond car wheel lathe having a capacity under ordinary conditions of twelve to fourteen pairs of steel-tired car wheels in ten hours.

T. R. Almond Mfg. Co., Ashburnham, Mass. Quotation from the decision of the United States Circuit Court of Eastern District of New York rendered March 27, 1909, in the litigation of Jacobs Mfg. Co. vs. T. R. Almond Mfg. Co., in which it was decided that the use of a chuck wrench carrying a pinion intended to engage teeth cut in the scroll ring of the chuck by the defendant company is not an infringement. The Jacobs patent is declared invalid.

Weston Electrical Instrument Co., Newark, N. J. Post-card advertising Weston electrical instruments in a novel manner. The card ostensibly is that of the "Weston Correspondence Schools," and in a few words tells how expensive and unsatisfactory educational experience with unsatisfactory electric instruments can be avoided by purchasing the Weston instruments in which the customer gets the benefit of the best work that experience and brains have been able to produce.

Browning Engineering Co., Cleveland, Ohio. Bulletins Nos. 31, 34, and 35 illustrating the Browning lifting magnet for handling castings, scrap metals, structural shapes, etc.; the Browning automatic buckets for handling ore, coal, sand and other materials, and the Browning locomotive crane of the revolving type, operated by steam or electricity, designed for general railway work, such as coaling locomotives, light wrecking work, and for use in industrial plants, stone and brick yards, sand and gravel pits, etc.

Ingersoll Milling Machine Co., Rockford, Ill. Catalogue No. 7 of milling machines of the planer type and knee type. The company has had experience for over twenty-two years on this line of milling machines and has been a consistent advocate of the use of the milling machine for machine operations commonly done on the planer. The line is comprehensive, extending from 20 inches to 10 feet, having from one to four or more heads, arranged according to the needs of the customer. The catalogue also lists inserted tooth milling cutters and illustrates a variety of manufacturing work which these machines are doing in various manufacturing plants.

Gronkvist Drill Chuck Co., 18 Morris St., Jersey City, N. J. Circular of the Gronkvist drill chuck, made in five sizes, having a capacity from 1/32 to 3/4 inch inclusive. In this chuck the ordinary sharp steel jaws are replaced by three hardened rolls which engage the drill and hold it by pressure. The greater the resistance, the tighter the drill is held. No wrench is used, and drills may be released, gripped, tightened and centered with the machine running, it being unnecessary to stop the machine to change drills within the limits of the chuck.

Hudson-Fulton Celebration Commission, Tribune Bldg., New York. Booklet giving a brief history of Henry Hudson and Robert Fulton with suggestions designed to aid the holding of general commemorative exercises during the Hudson-Fulton celebration, September 25 to October 9. The booklet contains a list of the members of the commission and the general plan of tne celebration. The commission is raising a fund of $500,000 to cover the expenses, and contributions are solicited.

Wagner Electric Mfg. Co., St. Louis, Mo. Bulletins Nos. 82 and 83 on polyphase motors and single-phase motors. The Wagner single-phase motor is self-starting, working by repulsion at the start and induction when full speed is attained. A centrifugal governor draws the brushes out of contact with the commutator when full speed is attained, and it then operates the same as the ordinary squirrel cage form of motor. The circular illustrates the application of the motor to vacuum pumps, vacuum cleaning machines, deep well pumps, air compressors, elevators, drill presses. The motor requires no starting box, an ordinary two-pole switch being all that is required for starting and stopping.

Kinkead Mfg. Co., 7 Water St., Boston, Mass. Circular illustrating the Kinkead apparatus for aligning and leveling shafting, comprising a special architect's level and fixed and portable targets, also of special design. The portable target is supported by the shafting, having jaws that grip the shafting and hold the target center at the same distance from the center of the shafting even if it varies in diameter. Some surprising results have been obtained by aligning long lines of shafting in factories by the Kinkead method; in one case the friction load was reduced from 73 to 20 per cent. The time required by this apparatus is much reduced as compared with the common method. In some large textile mills in which the power consumption is an important factor in cost, the advent of this apparatus has enabled all the shafting to be gone over once a month and all hangers kept constantly adjusted in perfect alignment.

Gronkvist Drill Chuck Co., 18 Morris St., Jersey City, N. J. Catalogue of the Johansson combination gages. The Johansson gages are made in Sweden, and are doubtless the most accurate production in existence. They have practically absolutely flat surfaces and parallel sides. The steel of these gages is hardened and treated so that molecular changes are eliminated. The catalogue illustrates some of the combinations that can be made with these gages. With a No. 1 set, consisting of 81 blocks, the sizes vary by 0.0001 inch and a gage ten inches long can be built up, which means that the set consists of not less than 100,000 different gage sizes for internal use. By adding the standard plug gage and a holder and the same number of plugs and snap gages are obtainable. The number of combinations thus made possible are not less than 300,000. The gage is warranted accurate within one hundred thousandth part of an inch per inch.

MANUFACTURERS NOTES

Cincinnati Planer Co., Cincinnati, O., recently broke ground for an addition that will double the capacity of its plant at Oakley.

Massey Vise Co., Chicago, Ill., has removed to its new building, 208-210 Michigan St., where improved facilities have been provided for manufacturing the Massey punch, planer and milling machine vises.

Angle Steel Sled Co., Kalamazoo, Mich, manufacturer of steel sleds, chairs, stools, etc., has removed its general office to Otsego, Mich. The manufacturing plant will remain in Kalamazoo. Mr. C. E. Pipp is general manager.

Independent Pneumatic Tool Co. has removed its general officea from the First National Bank Building, Chicago, Ill., to its own new "Thor" building at 1307 Michigan Ave., where larger space and better facilities are provided for taking care of the company's growing business.

National Scale Co., formerly of Beaver Falls, Pa., manufacturera of computing scales, has been reorganized and has moved its equipment from Beaver Falls to Chicopee Falls, Mass. The capitalization of the company is $125,000, $50,000 of which was raised at Chicopee to secure the industry.

Ing. Ercole Vaghi, formerly Vaghi, Accornero & Co., Milan, Italy, has been reorganized with increased capital and a larger number of salesmen to take care of their increasing business. The Niles-Bement-Pond Co. has recently placed the agency for the Pratt & Whitney product with this firm.

Prescott Co., Menominee, Mich., saw-mill builder, under its new management has introduced a comprehensive cost system, and a number of new machine tools have been added to the shop equipment, including a large Niles crank shaper, a 42-inch Niles boring mill, Pawling & Harnischfeger drill, several lathes, etc.

Kalamazoo Steel Goods Co., of which W. H. Maxwell, formerly general manager of the Angle Steel Sled Co., is secretary-treasurer and manager, will manufacture steel furniture, chairs, and stools, and do electrical welding to order, also all kinds of special work in steel shapes.

Screw Cutting Company of America, Philadelphia, Pa., has removed from 150 Berkley St., Wayne Junction, Philadelphia, to its new factory on the corner of 17th St. and Sedgley Ave., near the North Philadelphia station of the Pennsylvania Railroad. The new plant will be in operation about June 1.

William J. Smith Co., New Haven, Conn., has appointed the well-known engineering firm of Vickers, Sons & Maxim, Ltd., 32 Victoria St., London, S. W., England, as sole agents for the sale of the Smith "one-lock" adjustable reamers in Great Britain, France, Germany, Belgium and Austria.

Arthur D. Little, Inc., 93 Broad St., Boston, Mass., announces that the business of the laboratory established in 1886 has been incorporated under the above name in order that the facilities of the laboratory may be further extended. The company is prepared through its large staff of specialists, to undertake any work involving the application of chemistry to industry.

B. C. Ames, Waltham, Mass., has moved into his new reinforced concrete factory, which has two stories and basement. The floors, walls, roof and stairs are all of concrete, the lower floor being supported by concrete pillars in the basement. The two main rooms have a clear floor space about 70 feet long each. The upper floor will be used for the manufacture of fine measuring gages, while the lower floor will be given over to the manufacture of bench lathes and general machine work.

Slack Mfg. Co., Springfield, Vt., is a partnership recently formed with W. W. Slack, president (Gilman & Son, Inc., Springfield, Vt.); H. K. Parkman, secretary (Gilman & Son, Inc., Springfield, Vt.); and G. C. Parker, sales manager (William J. Smith Co., New Haven, Conn.), for the manufacture and sale of an abrasive metal cutter. All the parties will retain their present positions with their respective companies. The sales office of the company will be at 15 Madison St., Hartford, Conn.

Valley City Machine Works, Grand Rapids, Mich., has purchased a plot of land thirty-three feet wide adjoining its factory and will build an addition 42 feet by 66 feet to provide for its increasing business in the manufacture of wood-working and grinding machinery and water motors for washing machines. This motor has been on the market about one year and has made "a hit" with the washing machine manufacturers because of its simple, compact construction and power.

Westinghouse Mfg. Co., Pittsburg, Pa., lately received an order from the City Electric Co., San Francisco, for a 15,000 horse-power Westinghouse-Parsons steam turbine. This will be the most powerful steam turbine west of the Mississippi River, its power capacity being equal to about ten of the largest railway express locomotives. A 5,000 horse-power steam turbine is being built on order for the city of Detroit and another of the same size for the Nichols Copper Co., Laurel Hill, Long Island.

H. Mueller Mfg. Co., Decatur, Ill., has increased its annual payroll $20,000 as a result of increasing wages five per cent. About seventy-five per cent of the 650 employes of the company participate in the increase, which dates back to February 4. Hereafter the date for conferring with employes on the wage question will be May 1, that date being a better time for judging the year's business than is the earlier date. The policy of the company has been to pay its employes according to the volume of the business and profits made. The pay-roll for 1908 was $371,250, and it is expected that for 1909 it will exceed $400,000.

Warner & Swasey Co. has just purchased the unoccupied half of Brown & Sharpe Mfg. Co.'s lot on Washington Boulevard, Chicago, Ill., and will at once erect a building for its Chicago offices with large showrooms for the display of its complete line of high-grade machine tools. The lot has a frontage of seventy-five feet, and the building to be erected thereon will be of the same height and general dimensions as the Brown & Sharpe Mfg. Co.'s building adjoining; it will be ready for occupancy in the Fall. The location is so near the new railroad station that many believe it will in the near future become the machine tool center of Chicago.

Miami Valley Machine Tool Co., Dayton, Ohio, manufacturer of lathes and sensitive drills, and the Dayton Machine & Tool Works, manufacturer of grinding machines, have consolidated under the name Miami Valley Machine Tool Co. Mr. David Wilson, who has been sole owner of the Dayton Machine & Tool Works, and who has had long experience in the building of machine tools, will be actively connected with the new company and will give his attention to the building of the Dayton grinders as well as the Miami Valley lathes and sensitive drills. The consolidation simply means the enlargement of two growing concerns, and the business of each will be conducted under more favorable conditions.

Reeves Pulley Co., Columbus, Ind., has published a booklet entitled "Engineering Manual," which contains the practical and tech-

SOME MACHINERY AND METHODS OF WATCHMAKING

ETHAN VIALL*

IN going through a large watch factory there are many processes to be seen that only a skilled watchmaker could thoroughly understand and appreciate. There are, however, many things that are of intense interest to the average mechanic and which are well worth the time required to see them, but as few mechanics have either the time or opportunity to do so, the writer will proceed to describe some of the things that impressed him the most while going through the big plant of the Illinois Watch Company at Springfield, Ill. Through the kindness of President Bunn and Superintendent Johnson, the following illustrated article is given:

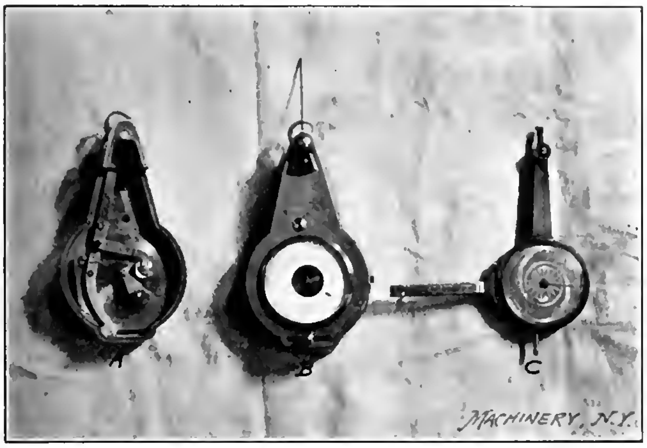

Fig. 1. Caliper Gage and Test Indicator used in Watchmaking, Illinois Watch Company

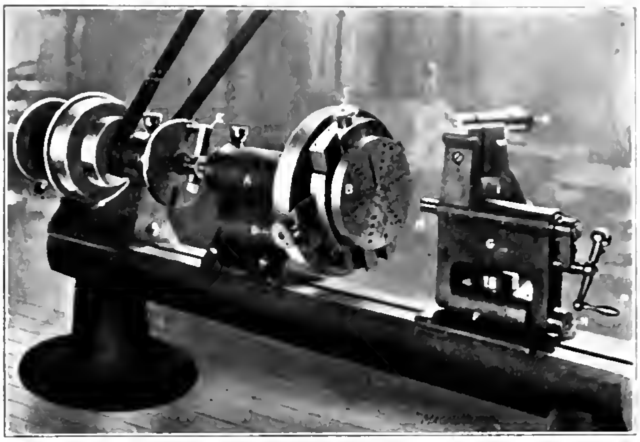

Fig. 2. Dividing Head and Tool Rest used in Laying Out and Boring Master Plates

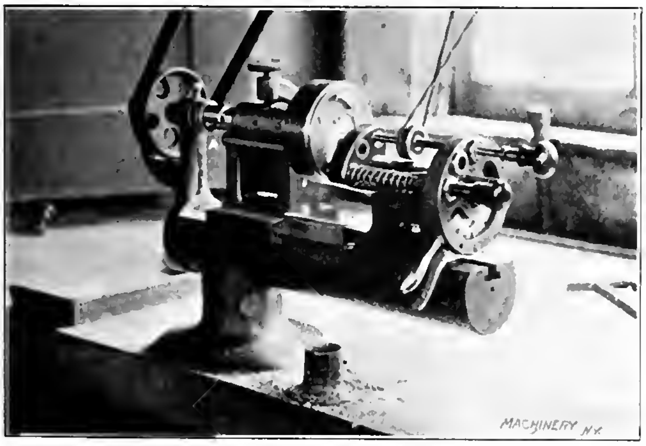

Fig. 3. Bench Lathe equipped with Quill used when Boring Center Holes in Watch Plates

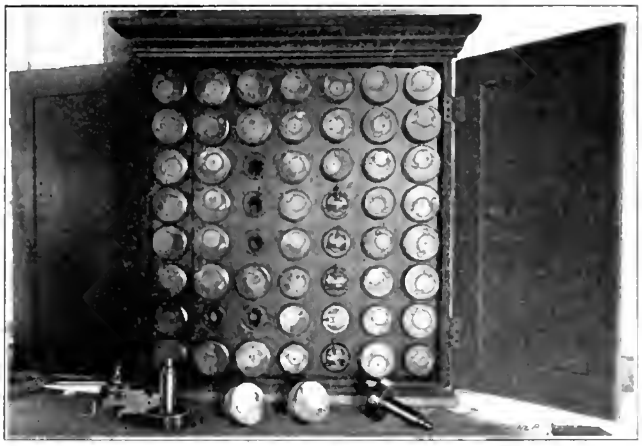

Fig. 4. A Set of Quills used for Boring the Various Holes in Watch Plates

The toolmaking work, as that term is usually understood, is, in this factory, separated into two classes and done in different departments, each in direct charge of a competent foreman of long experience. These departments are known as the machine shop, in charge of G. W. Meredith, and the punch and die department, in charge of C. H. Dockson. There is also a subdivision of the machine shop, known as the cutter making department, in charge of A. R. Mills, under the supervision of Mr. Meredith. In the machine shop proper all of the special machines, jigs, fixtures, master-plates and tools are made that are not included in the work of the punch and die or cutter-making shops. The bulk of the general machine repair work is also done in this department. The punch and die department not only includes the making of punches, dies and sub-presses, but it also includes the actual punch press work, and, consequently, in addition to its special toolroom, it has a complete battery of punch-presses in constant operation. The cutter-making department attends to the making and grinding of all mills, saws, counterbores and tools of that character used in the factory.

All of the fine caliper gages of the type shown at *A* and *B*, Fig. 1, and in detail in Fig. 5, are made in the machine shop. These gages are used in various forms throughout the factory for all the fine measuring required in turning out accurate work in quantities. At *C* this gage is shown in a modified form used for center indicating. Similar fine caliper gages are made and used in other watch factories to some extent. As will be seen from the engravings, the hand of the dial is operated by a small watch-chain or fusee-chain as it is sometimes called, which is wound around the spindle to which the hand is fastened. This spindle has a watch spring coiled around the lower end in such a way as to pull the indicator hand toward zero and keep the chain wound up as far as the caliper jaws will permit.

For laying out, drilling, and boring master plates, the special dividing-head and swing tool-carriage shown in Fig. 2 are used. The dividing head *A* consists of a false face-plate *B*, which is fastened to a cross-slide and which, in turn, is attached at right angles to another cross-slide, the guides of which are solid with the face-plate proper. The whole mechanism is mounted in a bearing of its own and is driven by means of the dog *E*, which engages a slot in the lathe face-plate, as shown. The plate *B* is graduated on its periphery in degrees, and it can be easily turned on its center and clamped at any desired angle. The cross-slides are both fitted with micrometer screws which afford quick and accurate adjust-

---

* Associate Editor of MACHINERY.

ment of the plate in either direction along their line of travel. As can be easily seen, the tool carriage *F* has a part *G* which is hinged at *H* and which may be adjusted out or in by means of the micrometer head *K*, mounted in part *I*, which is solid with the base of the carriage. The center of the tool-holder or spindle *M* in which the boring tool is placed, is exactly half way between the center of the pin *H* and the center of the micrometer head *K*, so that if the micrometer screw is turned outward 0.001 inch the tool is set out just half as much, or 0.0005; in other words, the direct reading of the micrometer indicates the amount that the bored hole will be enlarged on the next cut. The tool is fed into and out of the work by turning the handle *P*.

Formerly all master plates were originally plotted out as shown in Fig. 6, all holes to be bored being figured in two directions from a central point as shown, but the method illustrated in Fig. 7 is now considered much simpler to work from and less liable to error for this class of work. In this plan all holes that are the same distance from the center point are connected by arcs and their distances from a center line marked zero are indicated in degrees. The advantage of this last method to the toolmaker will be at once apparent to anyone who has ever worked out a complicated plate by the first one.

The mounting of the dividing head of the machine shown in Fig. 2, in its own bearing, illustrates the general principle upon which all fixtures used in the factory to hold parts to be bored are made. The usual form of individual bearing, or quill as it is called when used with a separate holder, is shown in Fig. 3. The quill illustrated in this engraving is used to hold a watch-plate while the center hole is bored. The quill holder is in the form of a V-block and clamp, and the quill is

driven from the lathe spindle by a tongue and fork, as shown at A. Each train hole in a watch-plate has a separate quill for centering it while it is being bored out, the plate being located in the jig which holds it, by means of the dial feet holes. There are pins in the face of each quill so located that when they enter the previously drilled dial feet holes, the plate to be drilled is brought into the proper position.

The watch-plates are all first spotted for the drills, then drilled and finally bored as just mentioned. A number of these special quills are shown in Fig. 4, and also in Fig. 29, together with a few split chucks and another form of the fine gages used. Fig. 8 shows another quill fixture which is used in the factory for holding the watch works while uprighting the stem hole.

In Fig. 9 are shown a number of spring chucks and the gages used when making them. These gages or templets have threaded collars in them for the size and length of the thread, bored out collars for sizing the barrel of the chuck and pieces fastened to the side to give the length and also to hold the chuck in place while gaging the bevel.

Fig. 16. Finished Sub-press, Component Parts, and Babbitting Jig

Fig. 10 shows a milling attachment used on a bench lathe for working out slots and irregular places in small jigs, punches and the like. When using this milling attachment the lathe spindle is locked and the spindle of the attachment is driven by a round belt passing over pulley A. Several very interesting attachments for the bench lathe are to be found in the punch and die department, which have been made for the special work done there. Fig. 11 shows a table with a small end mill A in the center, which is used for some classes of die work. The milling cutter is rotated by means of a pair of bevel gears and a shaft connected to the lathe spindle. Fig. 12 shows a filing machine, the table of which can be tilted to a limited extent for the purpose of filing clearance in a hole or for other reasons. The stroke of the file is adjusted by shifting the crank-pin in the slotted plate which is attached to the nose of the lathe spindle. Fig. 13 shows an adjustable plate used when surfacing off small punches or dies with an emery wheel; this plate is extremely handy for many other light grinding jobs.

Fig 17. Thirty-three Thousand Steel Yokes Blanked Out in a Sub-press in Eight Hours

A grinder used for a number of special jobs is shown in Fig. 30. This machine has a revolving work holder with three heads. At A is a head consisting of a long V-block and clamp for holding punches or other round parts while squaring the ends. The engraving shows a sub-press piston being squared up. At B is a face-plate used for holding flat work; the third head is not visible.

Fig. 18. Thirty-five Thousand Brass Center Wheels representing the Work of an Eight-hour Day

Many of the dies made are for such small parts that it would be impossible to make them in one piece and work out the holes, so they are made in sections to facilitate their construction, as shown in Fig. 14. The outside edges of the die parts are slightly beveled and the clamping ring is bored to correspond, so that when the ring is pressed down the die parts are clamped closely and firmly together. Dowel pins in both the die and the ring insure their being replaced correctly if it is necessary to remove them from the sub-press for any reason. A die of this kind is always so divided that a possible fin or ridge on the punching would come at a place where it could be easily removed. Formerly many of the punchings were polished on the edges by hand with diamond dust, but all of this class of work is now run through a series of special burnishing dies, the parts coming out with their edges as smooth and bright as a mirror. Fig. 15 is a swaging

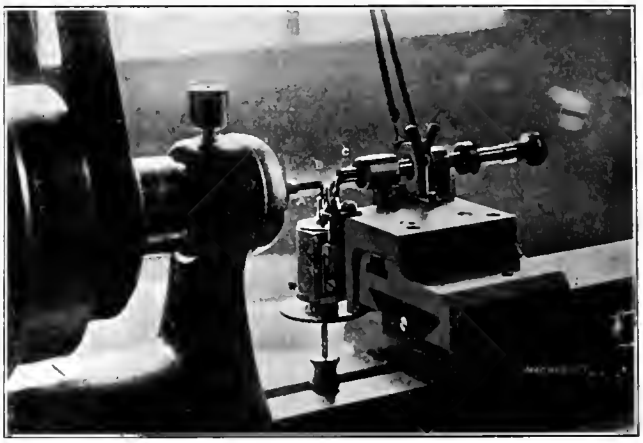

Fig. 19. Milling a Small Counter-bore in a Bench Lathe

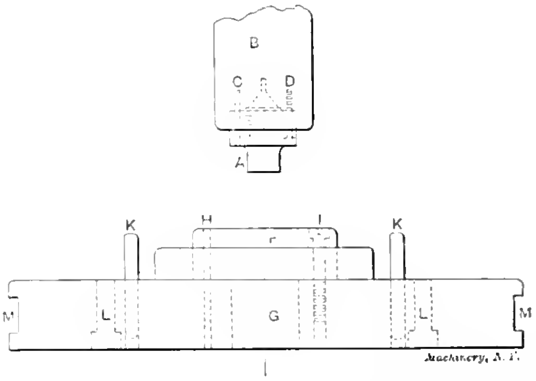

Fig. 20. Method of Fitting Punches and Dies in a Sub-press

punch and die used for rounding the spokes on some of the brass wheels. *A* shows the wheel after the first punching operation and still in the strip from which it was cut, and *B* shows it with the center hole punched. At *C* it is shown just as it comes from the swaging die for the first time. It is next annealed and again placed in the same die coming out as at *D*. The fin or flash is next taken off in a trimming die as at *E*. A completely finished wheel, after it has gone through all the various processes and is ready for the watch, is shown at *F*.

Fig. 21. Grinding the Sides of a Small Saw

The usual method of adjusting the stroke of the ram of a punch-press proved so unsatisfactory that all the presses in this factory have been fitted with a worm gear and worm adjustment, as shown in Fig. 31, in place of the regular gear and pinion-key form. In this way it is impossible for the ram to drop and spoil a die if the key happens to slip while adjusting, as it could originally; besides a more delicate adjustment can be easily made. This method of adjusting is, of course, old and presses could be bought years ago fitted in this way, but where presses of the other style are in use they can often be changed over to advantage as in this case.

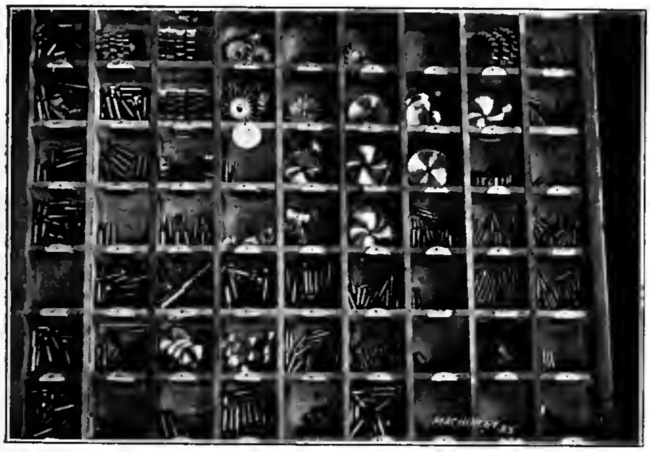

Fig. 22. Drawer Filled with Miscellaneous Tools used in Watch Construction

Making Sub-presses of the Piston Type

As the punchings turned out in this factory are all small, the largest being one ounce in weight and the smallest running 16,000 to the ounce, it is obvious that the separate punch and die system cannot be used, so all punches and dies are mounted in sub-presses of the piston type, of which there are over 800 in use. The making of a sub-press as carried through in Mr. Dockson's department, is quite an interesting process from start to finish. The casting for the upper part or body of the sub-press is first put in a lathe with the rough barrel in the chuck, the bottom faced off and the bottom or base hole bored out, as shown at *A*, Fig. 16. The body is next strapped, barrel outward, onto a face-plate, and centered by a plug which is usually a piece of brass driven into the center hole of the lathe spindle, and then turned to fit the base hole in the casting. The barrel is now turned on the outside and bored taper inside, the outer end or top being the largest. Three or four (usually three) grooves are next cut in the bore as shown at *B*, the piece is then removed from the face-plate when it is ready for the next operation, which is casting the babbitt. In performing this operation, the sub-press body is placed on the special base *C*, which just fits the bored hole in the bottom of the body. The piston *E* is then slipped into place, and is held central with the bore of the barrel by holes in the center of the special base *C* and in the cap *D*, which is next put on. It should be stated here that in actual use the special base *C* fits up into the body so that its top covers the bottom of the bored barrel in order to keep the melted babbitt where it is wanted, the base and body being held tightly together during the casting process, by two C-clamps. In taking the picture, the body was purposely set up as shown in order to give a better view of the positions of the piston and the way it is held. The piston *E* has been previously ground perfectly true from end to end and has had three grooves cut in it lengthwise. It is also well smoked before it is put into the casting jig. The babbitt, which is made up of tin, antimony and a large percentage of copper, is now poured around the piston through the opening *F* in the cap *D*. Just as soon as possible, the whole thing is cooled off in water—the sooner the better. The piston is now pressed out—and this is one of the hardest jobs of the series, for it takes a husky man at each end of an 8-foot lever on a powerful screw press, to start it. After being removed, the piston is carefully lapped with a copper ring-lap and emery, and the grooves are also lapped until the piston can be worked in and out of the barrel with some degree of ease. A collar like the one shown at *G* is next fitted on so as to hold the babbitt firmly in place, for while the taper bore of the barrel prevents the babbitt from going down, it does not keep it from being pulled up. The body and piston are then put into a punch-press and "pumped" at a good rate of speed for some time in order to wear them in, the "spots" on the babbitt being carefully scraped from time to time. When worn in a sufficient amount, the piston is removed and carefully re-centered in a lathe, a bored ring being used to hold it. The piston is again replaced in the barrel, put between centers, and the bottom and bored hole of the body carefully trued up. In this way any untruth that may have crept in is corrected and the outside of the

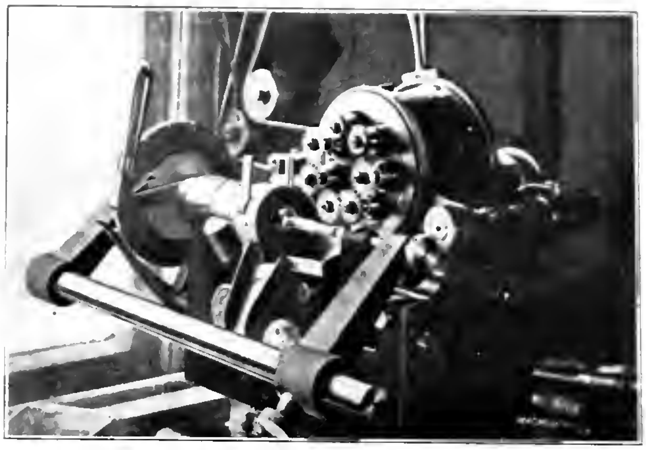

Fig. 23. Machine for Milling Steel Escape Wheels

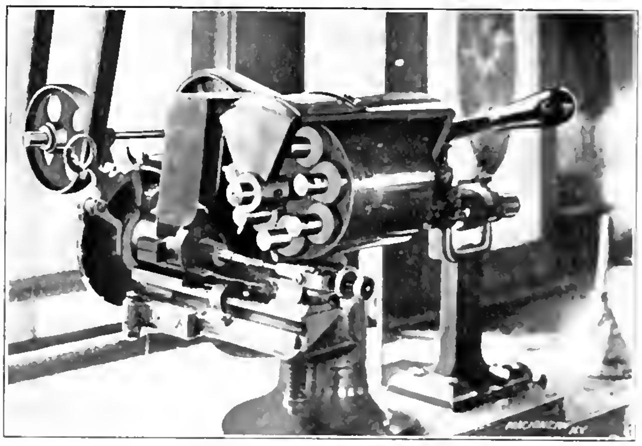

Fig. 24. Machine for Milling Brass Escape Wheels

piston its centers and the bore of the bottom of the body are made absolutely concentric. The base *H* of the sub-press is next fitted, doweled and fastened to the body by two fillister head screws. The bottom of the base is then trued up by taking a light cut over it, using the piston as a mandrel.

The idea of making the bore of the barrel of the sub-press taper, is not simply to keep the babbitt from dropping down, as a shoulder would answer for that; but the main reason is that if the piston becomes loose from wear at any time, the babbitt, which has been left high on top, as shown at *K*, can be forced downward by using a ring and a powerful press, thus taking up the wear. The retaining ring on the top of the barrel is not powerful enough to do this, as it is only intended to keep the babbitt from coming out, as stated.

The way the punches and dies are set into the sub-presses is shown in Fig. 20. In making the piston *B* a recess is bored in the end into which the punch *A* is fitted and fastened by a dowel-pin and screws. The center *E* of the piston is set in far enough so that the punch will not mar or distort it, should it be desired to put the piston between centers. In the lower part of the engraving, *F* is the die, *G* the sub-press base, *H* a dowel in the die, *I* one of the screws used to hold the die in place, *K* dowels that locate the body onto the base, *L* holes for the screws which hold the body and base together, and *M* recesses for the ends of the straps used to strap the sub-press to the bed-plate of the punch press.

Fig. 25. Screw-head Polishing Machine

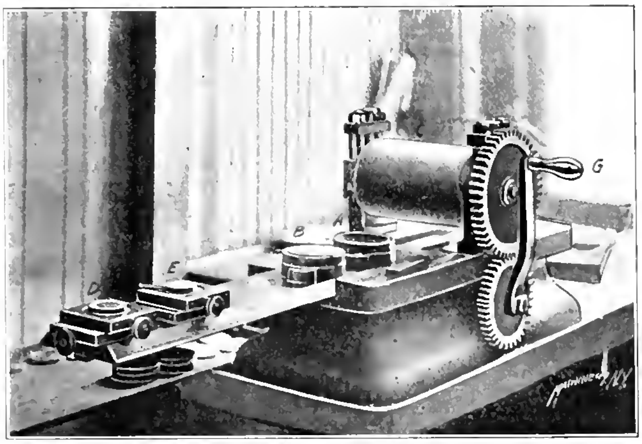

Fig 27. Machine for Figuring Watch Dials

As a general rule, in fitting a punch and die into a sub-press, the master punch is fitted into the piston as explained, and a die blank, the top of which is tinned with solder, is fitted into the base. The punch is then brought down and an impression of the outline made in the solder. The die blank is then removed and drilled out as close to the lines of the impression as it is safe to do, after which the die is slowly and carefully worked out and finished with the master punch as a guide.

Sub-presses of the type just described can be set up in a punch-press in a very short time, and the speed at which work is run through them is marvelous. In Fig. 17 is shown a pile of 33,000, number 18 size steel yokes, which were blanked out in 8 hours, and in Fig. 18 is a pile of 35,000 brass center wheels which were also cut in an 8-hour day. Some of the parts are blanked out at an average speed of over 120 a minute. As a rule it is intended to keep about 65,000 wheels of each kind in stock, ahead of the factory demand.

In the cutter making department the various tools are made in much the same way as in other tool rooms, only the machines used are much smaller. Fig. 19 shows how a small counterbore is milled. The blank, which has been turned up in a lathe, is placed in the upright chuck, as shown at *A*. The flat is milled on one side with the mill *B*, the blank is indexed half a turn and the other flat milled. Cutter *C*, which has teeth on the end only, is then used to mill the clearance on the cutting edges. Small saws are held on an expanding stub mandrel and ground by feeding a cup wheel, set at a slight angle to give clearance, straight in against them, as shown in Fig. 21. Fig. 22 is a drawer full of cutters of all kinds made in this department.

Fig. 26. Machine for Damaskeening the Works

Outside of the toolmaking departments the factory has many interesting tools and devices, only a few of which can find space in this article.

Fig. 23 shows the machine used for cutting the teeth in steel escape wheels, seven cutters being used on each tooth, and Fig. 24 is the machine used on brass escape wheels, fly cutters being used instead of milling cutters as in the previous machine.

Fig. 28. Case in which Finished Watch Parts are Stored

Small screw heads are polished by placing the threaded end in the split chucks of the machine shown in Fig. 25 and then holding a fine stone against the revolving head of the screw. The fancy spotting or birdeye ornamenting of the watch plates is done with the machine shown in Fig. 26.

Fig. 32 shows the profiling machine used for cutting out the irregular recesses in the watch plates.

Minute pinions are fastened to their staffs with the little trip hammer shown in Fig. 33, which rivets over a cup-shaped part of the staff onto the pinion.

A Transferring Machine

The figures and graduations are put on the enameled watch dials in the machine shown in Fig. 27. *A* and *E* are steel plates into which the figures and graduations have been cut;

B and *D* are dial holders and *C* is a rubber roll. Special "paint" is smeared over plates *A* and *E* and then scraped off with a thin steel knife, leaving the engraved places full. Dials are now placed at *B* and *D* and the handle *G* is turned so as to run the table under the roller. As *A* and *E* pass under, paint is left on the rubber from which it is transferred to the dials. For putting special names on dials, the press shown in Fig. 34 is used, though the process is very similar. *A* is the engraved plate, *B* the dial, and *C* a rubber pad. In using this press *A* is painted as before, swung under the rubber pad, and the pad brought down on it, receiving the lettering. It is then lifted, the dial swung under and the paint transferred to it.

All small finished watch parts are stored in glass stoppered bottles arranged in cases, as shown in Fig. 28, and in this way they are kept free from moisture and at the same time are easily accessible.

* * *

A convenient rule-of-thumb for ascertaining approximately the size of engine required to drive a direct-current dynamo is given in *Power*. To find the brake horse-power required, multiply the kilowatts of output by 1.7 for small machines, 1.6 for medium sizes, and 1.5 for dynamos of 500 kilowatts and over.

SOME THOUGHTS ON MACHINE TOOL DESIGN*

FORREST E. CARDULLO†

There is probably no branch of machine design in which greater changes have taken place in recent years than that of the design of machine tools. The greater part of these changes are without doubt due to the work of Mr. Fred W. Taylor, the discoverer of high-speed steel, who has more thoroughly investigated the capabilities and possible performances of metal cutting tools than any other man the world has ever known. The writer had occasion some time ago to study carefully Mr. Taylor's paper "On the Art of Cutting Metals" in the course of his lecture work on machine tool design at Syracuse University. His study of this paper, together with his own experience in machine tool design and operation, has brought the writer to certain conclusions in regard to some points in machine tool design which will be

---

† Professor of mechanical engineering, New Hampshire State College, Durham, N. H.

of interest and value not only to those who may themselves design and build such tools, but also to everyone who has to purchase or use them.

Ratio of Speed Changes

The first point to which the writer would call attention is the necessity of a sufficient number of speed changes. Those who have read Mr. Taylor's paper will remember that he shows that there is a definite relation between the cutting speed and the length of time which a tool will last without regrinding. Should the machine be run at too high a speed, the tool will last but a short time before it will have to be reground. Should it be run at too low a speed, less work, of course, will be done, although the tool will last a comparatively long time. Somewhere there is a golden mean at which the cost of machining plus the cost of tool dressing is a minimum, and theoretically our machine should always be run at that speed. Or course, in handling materials of varying grades of hardness, and, in the case of lathes and boring mills, of varying diameters, this would necessitate a very great number of speed changes. If the number of speed changes be limited, it is apparent that the machine cannot always be working at the point of maximum efficiency. The speed of cutting which gives the maximum efficiency is shown in Mr. Taylor's paper to be that speed which will destroy the tool in from 50 minutes in the case of $\frac{5}{8}$-inch × 1-inch roughing tool, to 1 hour and 50 minutes in the case of a 2-inch × 3-inch roughing tool. These times are of course only approximations and will vary somewhat with the cost of steel and labor and the value of the machine in which the tool is used. If the machine be slowed down from this proper speed, the cost of machining will slowly increase, but if the machine be speeded up above this proper speed, the cost of machining will increase very rapidly. In his paper Mr. Taylor gives a diagram wherein it is shown that if the machine be slowed down so that the duration of the cut is increased from 50 minutes to about 4 hours and 40 minutes, the machine is then working at about 90 per cent of its former efficiency. If the machine be speeded up until the duration of the cut is decreased to about 15 minutes, the machine will again be working at about 90 per cent efficiency. This range of speed is shown by Mr. Taylor's equations to be in the ratio of $\sqrt[8]{15}$ to $\sqrt[8]{280}$ or of 1 to 1.45. Consequently, if we have a machine having several speeds with the constant ratio of 1.45 between the successive speeds, we know that such a machine may always be made to operate within 90 per cent of its maximum efficiency, and that on the average it will operate at more than 95 per cent of its best efficiency.

The following table, which is derived in the manner indicated from the diagram given in Mr. Taylor's paper, shows the speed ratios corresponding to the given average and minimum efficiencies of working:

Ratio	Average Efficiency	Minimum Efficiency
1.1	99.6 + per cent	99.2 per cent
1.2	98.7 + per cent	97.3 per cent
1.3	97.3 + per cent	94.5 per cent
1.4	95.6 + per cent	91.2 per cent
1.5	93.5 + per cent	87.0 per cent
1.6	90.6 + per cent	81.2 per cent
1.7	86.5 + per cent	73.0 per cent

From the table it will appear that even in the case of very costly machines it is of no particular advantage to reduce the ratio between successive speeds unduly. For instance, by doubling the number of speeds and reducing the speed ratio from 1.2 to 1.1, we will increase the average efficiency of the machine only about 1 per cent. It is very doubtful if the accidental variations in shop conditions would not be so great that the gain in practical work would be nothing, since the workman or the speed boss, as the case might be, would be unable to decide which of two or three speeds would be the best. The writer is therefore of the opinion that there is absolutely no practical advantage in reducing the speed ratio below 1.2 and that in the case of machines of ordinary type and cost, a ratio of 1.3 is as small as is advisable. In the case of a speed ratio of 1.3, the machine can always be made to operate at such a speed that the efficiency of working will be above 94.5 per cent and in the average case the efficiency will exceed 97.5 per cent. The 2.5 per cent loss of efficiency so caused is inappreciable as compared with other sources of loss, and it is exceedingly doubtful if the added cost of additional speed changes would not more than compensate for the possible 1 or 2 per cent of gain, entirely aside from the question of whether the extra speed changes would permit this theoretical gain to be realized.

The writer is also of the opinion that a speed ratio of more than 1.5 in the case of expensive machinery operated by highly skilled help, or of 1.7 in the case of cheap machinery operated by comparatively unskilled help is unadvisable. It will be seen that with a speed ratio of 1.5 the average efficiency of working is somewhat greater than 93.5 per cent, making the loss of efficiency in the average case about 6 per cent. It will be seen that when the rent of the tool plus the wages of a mechanic amounts to $4 a day or upward, this 6 per cent of loss means a money loss of $0.25 or more per day, or upward of $75 a year. Of course an increase in the number of speed changes and reduction of ratio would not save all this loss, but assuming that it would save half of it, and further, that the machine is operating only half the time, it is evident that we can afford to spend $150 or $200 for the extra speed changes necessary in order to bring the speed ratio down to 1.3. In the case of ratio of 1.7, the loss is 12 or 13 per cent instead of only 6 per cent, and these figures apply with greatly added force.

We are thus compelled to the conclusion that the useful range of the speed ratio in machine tool work is very narrow, ranging from 1.3 to 1.5 in ordinary cases and that a range of from 1.2 to 1.7 includes the very extremes of rational practice.

Need of Speed Changes being Easily Made

A second point in connection with the matter of the speed changes of machine tools which is of great importance is that these changes should be easily and quickly made so that the operative will have every incentive to use the proper speed. This is a matter of less importance in the case of planers than in the case of lathes and boring mills, since a planer requires a change of speed only when the character of the material which is being cut is changed, while the lathe requires a change when any great change is made in the diameter of the work operated upon.

In this respect a motor-driven tool may have a distinct advantage over a belt-driven tool. The controller furnishes a ready means for varying the speed while the shifting of a belt from pulley to pulley is not always readily accomplished, and most machinists would much rather take two cuts of differing diameters on the back-gear than shift the belt from the small to the large pulley and throw out the back-gear in order to obtain the faster speed from the open belt. This is particularly the case when the cuts are of small duration, so that the shifting would be frequent.

It will be evident to the thoughtful mechanic that it is of great advantage to have the speed-changing mechanism so constructed that the change may be made without stopping the machine. In the case of large machines it will be of great advantage to be able to effect the speed change from the operating station, which for instance in the case of a long lathe will be the carriage. To the writer's mind the particular advantage of these refinements which he suggests, and which will be found embodied in many of the designs of our best tool makers, lies not in the fact that the time required to make the necessary speed changes is shortened, but in the fact that the workman finds it just as easy to run his machine at the proper speed as at an improper one.

Ratio of Feed Changes

A matter of even greater importance than a proper series of easily-made speed changes is a proper series of easily-made feed changes. A change of speed does not mean in general a correspondingly great change in the efficiency of operation of a machine tool, but a change in feed does. Mr. Taylor points out in his paper that in general the best results in quantity of metal removed per hour are obtained when the cross section of the chip is a maximum, even though this entails a comparatively low speed. Therefore it is of importance that the machinist be able to take the heaviest cut which the nature of his work and the power and stiffness of his machine will permit. Just as the best results in the

matter of cutting speeds are obtained when the successive speeds run in geometric ratio, so the best results in the matter of feed adjustment are obtained when the successive feeds run in geometric ratio, unless the number of obtainable feeds is so great that the entire range is closely covered. For instance, a lathe equipped with the following feeds, 0.05, 0.10, 0.15, 0.20, 0.25, is distinctly inferior in productive capacity to a lathe having the same number of feeds arranged geometrically as follows, 0.05, 0.074, 0.111, 0.166, 0.25, wherein each feed is 50 per cent greater than the preceding one.

In general the best work is obtained from a machine tool when the depth of cut is made such that the total depth of metal to be cut away is removed with one or two cuts. Such being the case the depth of cut is practically fixed and not within the control of the operator, leaving the feed and speed as the variables which he must adjust. It is important therefore that the operator be able to take a cut as heavy as the nature of the work or of the tool will permit. Mr. Taylor's paper shows that the speed of cutting is approximately inversely proportional to the square root of the feed. It needs therefore only a very elementary knowledge of mathematics to see that if the feed must be reduced to say 80 per cent of its maximum value, the output of the lathe will be only about 90 per cent of its maximum value. Or in general, if the feed be reduced from its maximum possible value by any given per cent, then the output of the machine will be reduced from its corresponding maximum value by about one-half of that per cent. We may by means of this principle compute the ratio between successive feeds which will give us any required average value for the efficiency of operation of the machine. The values so found are tabulated below:

Efficiency	Ratio	Efficiency	Ratio
98 per cent	1.08	90 per cent	1.66
96 " "	1.18	88 " "	1.92
94 " ".	1.32	86 " "	2.27
92 " "	1.46		

An inspection of the table shows that when the ratio between successive feeds is about 1.1, the average efficiency of operation of the machine may be practically perfect, and that with any considerable increase of this ratio the efficiency drops off. It is the opinion of the writer that the ratio between successive feeds should always be less than 1.3 and that, more especially in the case of expensive machinery, a value of 1.2 or less is preferable.

Convenience of Feed-changing Mechanism More Important than that of Speed Changing

It has already been pointed out that the speed-changing mechanism should be of such a character that the speed changes may be easily and quickly made. In the same way it is of even greater importance that the feed changes may be easily and quickly made. In most small lathes which are now on the market quick-change gears are fitted to the screw-cutting mechanism, which are equally available as quick-change gears for the feed mechanism.[*] In most shops small lathes are not used very much of the time for screw-cutting, and in fact nine lathes out of ten are never used for that purpose, but a quick-change gear mechanism is of much greater importance when used for the purpose of obtaining feed changes than when used for the purpose of obtaining thread changes. In the average case the operator will not have to touch the thread-cutting gear once a week, while it may be advisable to change the feed every five minutes. In the case of large lathes it is advisable to have the feed changes, not in the headstock, but in the apron in order that the workman may be encouraged to use a proper feed whenever possible.

Unlike lathes, planers are generally equipped with ratchet feeds. The successive values of the feed changes in the case of a rachet feed will necessarily run in an arithmetical and not a geometric series, the successive feeds differing by some constant decimal of an inch. So long as the amount by which the successive feeds differ is small, and the range of feeds given by the mechanism is large, a ratchet feed is perfectly satisfactory. Many boring mills are fitted with a feed mechanism driven by a friction wheel of the type generally known as a brush wheel, the driving mechanism consisting of a steel disk of 12 to 16 inches in diameter geared to the table and against the face of which a much smaller wheel edged with leather is pressed. It is obvious that if the steel disk rotate at a constant speed, the speed of the driven wheel and consequently the amount of the feed may be varied by adjusting its position. When it presses the disk near its center it will revolve slowly. When it presses the disk near its edge, it will revolve at comparatively high speed. This feed mechanism has the advantage that it gives an infinite number of feed changes over a wide range, but has the disadvantage that it is not positive in its action, and lacks sufficient power for certain kinds of work. On the whole, the best feed driving mechanism is a nest of gears so arranged that any feed within the entire range may be had by the simple shifting of one or two levers.

Strength of the Feed Mechanism

In that part of his paper discussing the force required to feed the tool of a lathe or boring mill, Mr. Taylor makes the assertion that the feed mechanism should have sufficient strength to "deliver at the nose of the tool a feeding pressure equal to the entire driving pressure of the chip upon the lip surface of the tool." This would lead to the designing of a lathe or boring mill having feed gearing of equal strength with its driving mechanism. In the case of planers and other machines wherein the tool is moved at a time when it is not cutting, these statements do not apply. It is not generally the custom among machine tool builders to design machines having such strong feed works as Mr. Taylor's ideas call for, and the writer sees no reason why such strength is necessary. The amount of force required to traverse a tool in a lathe is not proportional to the width of feed, and while it may be true for fine feeds that in the case of dull tools the traversing pressure may be equal to, or greater than the downward pressure upon the tool, this is not necessarily the case with heavy feeds. As the width of the feed is increased, the downward pressure will increase almost in proportion, while the traversing pressure will increase comparatively little, so that when the lathe is taking the maximum cut which the driving mechanism is capable of handling, the pressure required to feed the tool into the work, even though it be very dull, is much less than the downward pressure. It is the writer's opinion that a feed mechanism designed to have one-half the strength of the driving mechanism is ample for large tools, while for small tools in which of course the feed will be finer, a strength of two-thirds of the driving mechanism might be preferable.

Feed Mechanism should have "Breaking Piece"

The feed mechanism should be provided with a breaking piece whose strength will be less than that of the rest of the mechanism and which may be cheaply and easily replaced. The office of this piece is to prevent the breaking of the more costly and less easily replaced parts of the mechanism, exactly as the fuse in an electric circuit prevents the destruction of any other part of the circuit. Two forms of breaking piece sometimes used for such service are, first, a soft steel pin, driven through a shaft and hub of harder steel, which shears off when the strain becomes too great; and second, a short section of shaft turned down at its center, which twists off under similar circumstances. A breaking piece must be of such a character that it will not spoil any of the rest of the mechanism when it breaks, and should not cost more than a few cents, and should be as easily removed and replaced as a common change gear.

It must not be imagined that a feed gearing designed to have one-half the strength of the driving gear will not be strong enough to meet Mr. Taylor's requirements in all likely cases. If a tool be designed to take a maximum cut of ¾ inch by ⅛ inch, it is not likely that much of its work will be done with such a heavy cut. If both driving and feed gearing be designed with a proper factor of safety, there is ample margin of strength for all usual conditions, while a breaking piece is the best provision against extraordinary stresses.

Pressure on Lip Surface of Tool and its Relation to Design

The pressure upon the lip surface of the tool is required in order that the designer may know, first, the strength required of the driving mechanism and frame of a machine; second,

the power required by the machine; and third, the strength required for the feed mechanism. The two materials upon which the vast majority of machine tools are called to operate are cast iron and steel. Taking first the case of cast iron, we find from Mr. Taylor's paper that the pressure upon the lip surface of the tool varies from 75,000 to 150,000 pounds per square inch of chip section in the case of soft iron, and from 120,000 to 225,000 pounds in the case of hard cast iron. The finer the feed, the greater the pressure per square inch upon the lip surface of the tool. Thus with an ⅛-inch depth of cut and 1/64-inch feed, the pressure on the tool is about 289 pounds, or 146,000 pounds per square inch. With the same depth of cut and ⅛-inch feed, the pressure on the tool is 1,358 pounds, or only about 86,900 pounds per square inch of chip section. Both these figures are given for soft cast iron. Mr. Taylor gives formulas for the total pressure of the work upon the lip surface of the tool, but the following table will be found more convenient for obtaining the required values, although the figures given are of course only approximations:

Feed, Inches	Pressure per Square Inch	
	Soft Cast Iron	Hard Cast Iron
1/64	140,000	220,000
1/32	120,000	190,000
1/16	100,000	160,000
1/8	85,000	135,000

In the case of soft and medium steels we find that the pressure in pounds per square inch of chip section runs from 250,000 to 300,000 pounds, being greater in the case of the finer feeds. In the case of special steels which combine high tensile strength and great elongation, it is probable that these figures would be very much exceeded. The amount of the feed and depth of cut will depend on the kind of work which is to be machined. In the case of small castings 3/16 inch is an ample allowance for depth of cut and ⅛ inch would be much more usual. In the case of very large and heavy castings the depth of cut required might run up ½ inch, and in the case of large "meaty" forgings, it may be even greater than this at some places. In those cases where the area of chip section is not fixed by the work, as in the case of stocky forgings and castings, the greatest width of feed is limited by the strength of the machine itself, which in turn is limited only by the length of the purchaser's purse. I presume it would be possible to build a boring mill or a planer capable of taking a cut an inch deep with an inch feed if anyone wished to pay for such a machine, but whether it could do the average line of work as economically as a machine taking ⅜-inch cut with ⅛-inch width feed is another matter. While there is no settled rule either for the maximum depth of cut or width of feed for any particular type of machine, the matter of the size of tool used is generally definitely known. In the case of forged roughing tools the maximum chip section will be from 2 to 3 per cent of the area of the section of the tool shank. For instance, the heaviest cut which a tool forged from 1-inch by 1½-inch stock will be called upon to take will be ¼ inch by ⅛ inch, or perhaps a trifle greater. In the case of tools ground from bar stock and held in tool-holders, the section of the chip may run up as high as 5 per cent of the section of the bar. Knowing the size of tool for which the tool-holders are designed, we may proportion our machine accordingly.

A matter which has great effect not only upon the quantity of work which a machine is capable of doing, but also upon its accuracy and length of useful life, is its stiffness. While it is true that if we know the maximum pressure upon the lip-surface of the tool we may design a machine for strength and have one which will probably never break in service, yet it is often better to add many times the quantity of metal which mere strength would call for, in order to have a machine with the maximum of stiffness. Stiffness in machine tool design has to do with two points, the first being the actual deflection of the metal of which it is composed under the stresses which come upon it in operation. The second is the play which invariably exists at all joints, more especially the slides of compound rests in lathes, and of saddles in boring mills and planers. The best remedy for actual deflection of metal is to use plenty of it, and to distribute it in such a way as to realize from it its maximum strength. The writer has found that an excellent method of designing such machine parts as require great stiffness is by comparison with existing tools whose operation is satisfactory. Let us assume for instance that we are to design the cross-rail of a planer. The rail is to be 8 feet between the housings and the overhang of the tool below the center of the rail is to be 30 inches. The cut is to be, let us say, ½ inch deep by ⅛ inch feed. Let us assume further that we have at our disposal a 4-foot planer, the overhang of whose cutting tool is 15 inches, and which will take in a satisfactory manner a cut ¼ inch deep by 1/16 inch feed. We now have sufficient data to satisfactorily design a cross-rail for the larger planer. If we assume that the deflection of the tool produced in the two cases should be identical in order to have the work equally satisfactory, we will find that the pressure upon the tool of the larger planer will be 4 times that upon the tool of the smaller; that both the bending and the twisting moments set up in the cross-rail will be 8 times as large, and that the distance over which these moments will operate to produce a deflection will be twice as great. Therefore, if the two rails had the same cross-section, the deflection of the tool of the larger machine would be 16 times that of the tool of the smaller. The stiffness of two bodies of similar section varies directly as the 4th power of the ratio of their homologous dimensions. Therefore, if we make the section of the rail of the larger machine similar in form to that of the rail of the smaller machine, each dimension twice as great as the corresponding dimension of the smaller rail, it will be 16 times as stiff and the deflections in the two cases will be identical. In case the rail of the smaller machine were not of the best form to resist the stresses which it must sustain, the form might be changed, the designer using his best judgment as to what effect such change might have upon its stiffness.

Cause of Vibration

Excessive vibration in machine tools is frequently due to the fact that the pressure upon the lip surface of the tool is not uniform and that the rapid but regular variations in this pressure coincide with the natural period of vibration of some part of the machine. Machines should be built so that the natural period of vibration of every part is very much higher than the period of these rhythmic variations in pressure. The fact that a machine tool of a certain design operated satisfactorily and without appreciable chattering with the old-fashioned carbon steels is no reason that it should operate equally well with high-speed steel since these variations will come very much more rapidly when high-speed steel is used. In order to make the natural period of a machine tool part higher, it is necessary that it be made compact and stocky. In other words, stiffness makes for a high vibration period. Hence, the advent of high-speed steel necessities the redesigning of many tools which were satisfactory with carbon steels. It is necessary that they be given increased weight and stockiness to prevent chattering, although their strength was already amply sufficient to provide for the cut which it is desired to take.

In designing for stiffness, it is, of course, essential that the number of joints between the work and the tool shall be a minimum; that these joints shall be so designed, if possible that wear shall not disturb the alignment of the mechanism; that they shall be provided with means for adjusting them when they become worn; that they shall be designed to wear uniformly; or, if this is not possible, they shall be so designed that they will wear very slowly. While we might dwell at length upon this matter of the design of joints and bearing surfaces, so much has been written upon it that a very few words may well suffice.

Importance of Protected Bearings

Joints and bearings in which the rubbing speed is high, naturally wear out the most quickly. If a bearing is copiously oiled, and dust and grit absolutely excluded from it, its life will be indefinite. The best form of oiling device for costly machine tools is probably a system of forced circulation, operated by a small pump, served from an amply-closed reservoir into which clean oil is returned by capillary drainage. The flooding of the bearings with clean oil will pre-

vent the entrance of grit, and absolutely prevent wear, by the prevention of metallic contact. Many bearings, particularly sliding bearings, cannot, of course, be treated in this manner, but fortunately such bearings have invariably a low speed of rubbing. Such bearings will be more durable if they are carefully scraped and fitted. They should, when possible, be so located that grit and chips will not fall upon them, or else be covered with sliding or telescoping sheet metal shields, for the same purpose. The great object to be sought is the prevention of grit on the wearing surfaces, and any scheme or appliance which accomplishes this purpose will help produce a tool which will be longer lived and more satisfactory in operation.

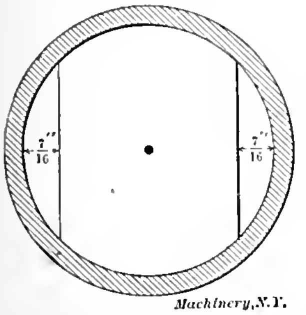
BADLY CHOKED EXHAUST PIPE

The illustration shows a cross-section of a badly choked exhaust pipe that was removed from an old steam engine that had been in service many years. The incident was described in the April number of *The Locomotive* as follows:

"A certain tannery in New England was fitted out, many years ago, with a small slide-valve engine, which was operated at a pressure of 70 or 80 pounds per square inch, and which proved to be adequate, until quite recently, to the wants of the plant. We do not recall the dimensions of the engine, except that the exhaust pipe was three inches in diameter, internally; nor do we know the exact date when the engine was installed. Inquiry elicited the fact, however, that no repairs had been made upon it within thirty-five years; and hence the state of affairs that we are about to describe had existed for that period, at least.



Cross-section of Exhaust Pipe Choked by Lathe False Center

"A short time ago the owners of the plant decided to throw out the old engine, and replace it with one of the Corliss type, capable of furnishing more power. Upon taking the old engine down it was discovered that the exhaust pipe was almost completely closed by means of a piece of cast iron, of the general appearance indicated by the lines shown in the accompanying sketch. On each side of the cast iron piece there was a segment-shaped space, 7/16 inch wide at its widest part; and the entire exhaust of the engine had to pass through these two openings for thirty-five years or more.

"Mechanics of the older school will see at once how the thing came about; but for the benefit of the youngsters it may be well to explain. In former years it was customary to thread all steam piping except the very smallest, by turning the threads upon it in a lathe. In order to secure the pipe properly in the lathe, it was necessary to provide a center-piece which would fit inside the end of the pipe, and in which a hole could be made, to receive the tail-center of the lathe. The center-piece was of course supposed to be removed, after the completion of the thread; but in the case now before us, this detail of the operation was forgotten, or at all events omitted, and the pipe was put in place, center-piece and all.

"The editor could use up a lot of space in trying to estimate the waste of coal that this forgotten center-piece has caused, and in comparing this loss with the cost of a good indicator; but he isn't going to. No indicator was ever applied to the engine; and we are not going to show the owners of the plant how big a mistake that omission was."

The annual prize of $5,000 instituted by King Leopold of Belgium in 1874, will, for the year 1911, be awarded for the best work in French, Flemish, English, German, Italian, Spanish or Portuguese on "The progress of aerial navigation, and the most effective means for its encouragement." The works submitted for competition must reach the Belgian Minister for Science and Art before March 1, 1911.

KNURLS AND KNURLING OPERATIONS—2

DOUGLAS T. HAMILTON*

In this second installment, which treats of speeds of knurling, number of revolutions, camming, etc., reference is made to Figs. 1, 6, 10, 11 and 12 and Table I, which appeared in the June number.

Speeds and Feeds for Knurling

When the knurl has been designed, the next thing to consider, before laying out the cams, is the speed and feed for knurling. This is a subject upon which very little has ever been published. As a general rule, a knurl can be worked at the same speed as the circular form and cut-off tools. It is good practice to feed the knurl gradually to the center of the work, starting to feed where the knurl touches the work as is shown by the distance *c* in Fig. 12, and then to pass off the center of the work with a quick rise on the cam. The knurl should also dwell for a certain number of revolutions, depending on its pitch, and the nature of the material being worked upon. Some advocate the knurl being brought into position on the center of the work on the quick rise of the cam, and then being allowed to dwell for a certain number of revolutions; but the writer has found that this does not work satisfactorily, and cannot be depended upon. It might work when using a knurl which has a very fine pitch, on large stock, but under general conditions it will be found that gradually feeding the knurl to the center of the work will work better.

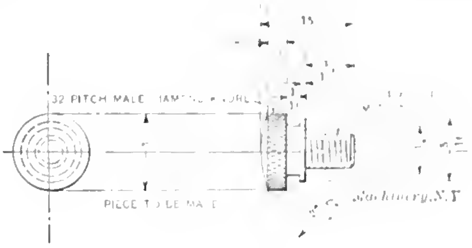

Fig. 13. Thumb-screw to be knurled

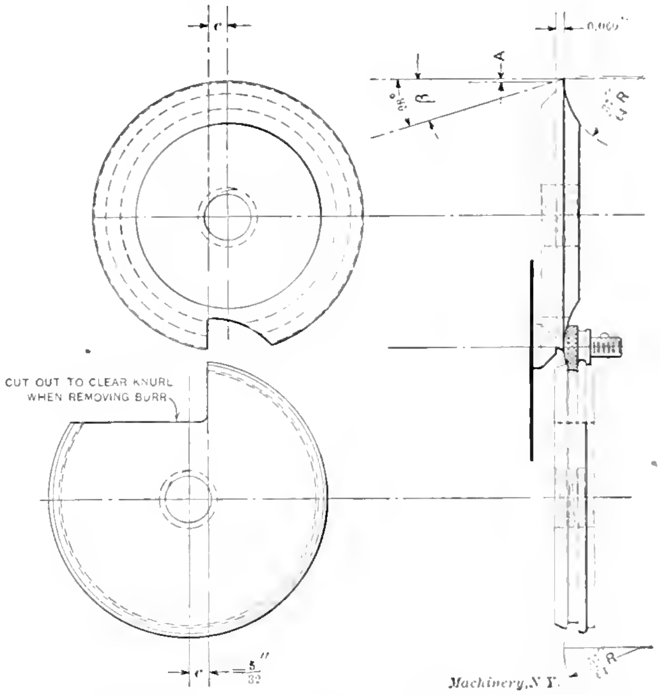

Fig. 14. Circular Forming and Cut-off Tools for Making Thumb-screw, Fig. 13

The feed required for a knurl is governed by the nature of the material being knurled, the diameter of the material, and the width and pitch of the knurl.

The surest and most practical way to find the feed required for a knurl on a certain kind of material is by experimenting. The writer has collected the results of different experiments and compiled them in Table II. This table covers practically all the different materials specified in this article, as the angle of the teeth in the knurls varies in accordance with the hardness of the material on which the knurl is used. In

---

* Address: Northern Electric and Mfg. Co., Montreal, Canada.

that case the feeds given in the table will be practically the same for all the materials previously specified. These feeds are only applicable when knurling from the cross-slide.

Under these conditions the depth of the tooth and the feed per revolution will govern the number of revolutions required to knurl. If in Fig. 12, R is the radius of the stock, d is the depth of the tooth, c is the distance the knurl travels at a given feed per revolution, and h equals $R-d$, then $c=\sqrt{R^2-(R-d)^2}$.

TABLE II. FEEDS FOR KNURLING

Let $R=0.125$ inch and $d=0.0164$ inch; then $h=0.1086$ inch. Therefore $c=\sqrt{0.125^2-0.1086^2}=0.062$ inch = rise required.

Revolutions Required to Knurl

Assume that it is required to find the number of revolutions to knurl a piece of gun screw iron, 1/4 inch in diameter, with a knurl 1/8 inch wide of 36 pitch. The included angle of the tooth for gun screw iron is 80 degrees. The circular pitch is 0.0277, and, referring to Table I, the depth of the tooth is 0.0164; the distance c, as worked out in the previous example, is 0.062 inch. Then, referring to Table II, the feed per revolution for a knurl 1/8 inch wide, knurling on 1/4-inch stock, is 0.0016 inch per revolution. Therefore, total

$$\text{revolutions required} = \frac{0.062}{0.0016} = 38.7 \text{ or, approximately, } 39$$

revolutions. In some cases the feeds given in Table II can be increased 50 per cent and still give good results.

Example of Knurling Operation

Let us now assume an example of a knurling operation on the No. 0 Brown & Sharpe automatic screw machine, and find the principal dimensions of the cam for performing same. A thumb-screw, as is shown at Fig. 13, is to be knurled with a 32-pitch knurl, 1/8 inch wide, using a cross-slide knurl-holder as shown in Fig. 1.

Total Rise on Cam

It is required to find the total rise on the cam to complete the knurling, and also to cut the finished piece from the bar. The total rise can be found by means of the following formulas, derived by the aid of the diagram in Fig. 15. This shows the knurl in position on the center of the work, and the circular cut-off tool is also shown in its relative position to the work and the knurl.

Let T = total rise on the cam,
N = rise required to knurl,
S = radius of stock to be cut off,
A = distance of bevel on cut-off tool as given in Table III,
C = total rise required to cut-off $S+0.010$ inch (to approach) $+\,0.005$ inch (to pass center of stock) $+\,A$,
E = distance from center of circular tool to edge as shown, when tool is cut down below the center,
a = radius of knurl to outside diameter,
b = radius of stock minus depth of tooth in knurl,
c = distance from cutting face to center of circular tool,
$h=a+b+c$,
X = distance from center of cut-off tool to center of knurl, when it is in position on the center of the stock,
R = radius of stock,
r = radius of knurl,
R_1 = radius of cut-off tool,
R_2 = radius of knurl holder shown in Fig. 1,
F = distance between the knurling and cut-off operations. Then

$$E=\sqrt{R_1^2-c^2};\ X=\sqrt{R_2^2-h^2};\ N=\sqrt{R^2-(R-d)^2}$$

(See Fig. 12).

$$F=X-(S+E),\quad T=N+F+C,$$

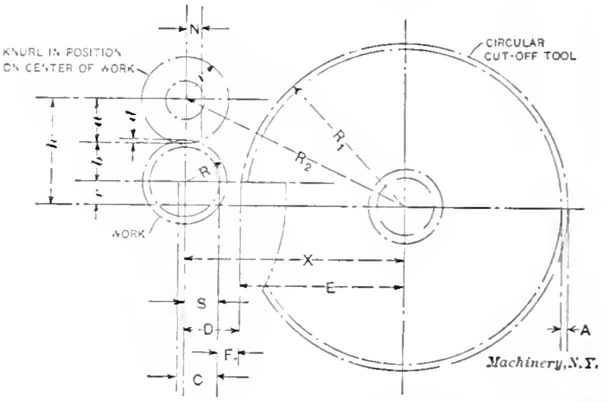

Fig. 15. Diagram for Finding Total Rise of Cam for Knurling Operation

For example, let it be required to design a set of cams to make the thumb screw shown in Fig. 13, the material being 3/8-inch round brass rod, and on which is cut a 32-pitch knurl. For the knurling operation we will use a cross-slide knurl-

Fig. 16. Cams used for Making Thumb-screw in Fig. 13

holder, as shown in Fig. 1. R is 0.1875 inch, r is 0.375 inch, R_1 is 1.125 inch, R_2 is 1.625 inch; d is 0.0156 inch, angle on cut-off tool is 23 degrees, and the width of the cut-off tool is 0.060 inch; then, referring to Table III, A is 0.0254 inch. The cut down below the center on the circular tool e is 5/32 inch. Then, $a = 0.375$; $b = 0.1875 - 0.0156 = 0.1719$; $c = 0.1562$; $h = 0.7031$.

$$P = \sqrt{(1.125^2 - 0.1562^2)} = 1.114,$$

$$V = \sqrt{(1.625^2 - 0.7031^2)} = 1.465,$$

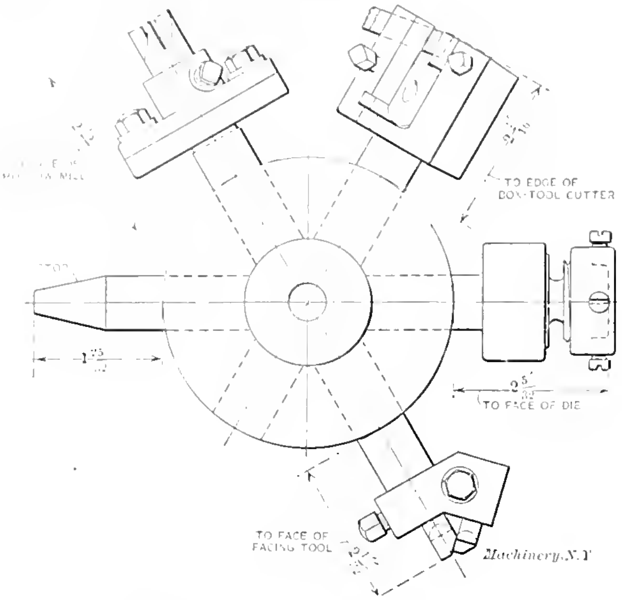

Fig. 17. Arrangement of Tools in the Turret

$$N = \sqrt{0.1875^2 - (0.1875 - 0.0156)^2} = 0.075,$$

$S = 0.1562$ inch, which is the radius of the shoulder left by the circular form-tool.

$C = 0.1562 + 0.010 + 0.005 + 0.0254 = 0.1966,$

$F = 1.465 - (0.1562 + 1.114) = 0.1948,$

$T = 0.075 + 0.1948 + 0.1966 = 0.4664$ inch, which is the total rise required on the cam, for the knurling and the cut-off operations.

Having determined the total rise required on the cam, we will consider briefly the other operations. The order of the various operations is given in the accompanying layout chart, and the position and type of tools used in the turret are shown in Fig. 17. As all the various operations are shown plainly on the chart very little explanation will be required.

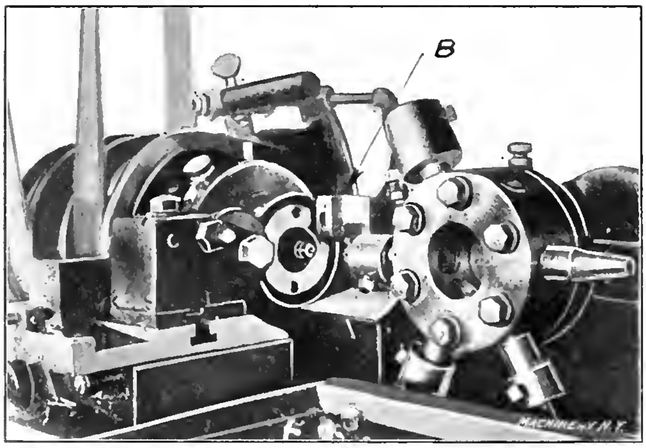

Fig. 18. Machine set up and ready for Making Thumb-nuts

Before starting to design the cams, the drawings of the tools suitable for performing the various operations are collected, using standard tools as much as possible. Then, after selecting the various tools, a lay-out of the circular form and cut-off tools, as shown at Fig. 14, is made. After having drawn the circular tools, and also laid out the turret operations as shown in Fig. 17, the order of the various operations is considered. Referring to the plan of operations shown in the chart, the work proceeds in the following order: Feed stock to stop and chuck, revolve turret, and rough turn with the hollow mill shown in Fig. 17; while the hollow mill is turning down the work, the circular form tool is brought in and forms the head; the form tool retreats so that it will clear the face of the hollow mill; then the turret is revolved and the finishing box-tool shown in Fig. 17 turns down the portion which is to be threaded. Now the turret is revolved and the die-holder is brought into position, and the work is threaded. By referring to Fig. 16, it will be seen that the highest portion of the lobe for the die is cut down equal to two threads, or 0.0554; this allows the die holder to draw out, and the spindle reverses on the tension of the spring (when a draw die-holder is used), which makes the die work easier, and does not crowd it on the work. After the die comes off the work, clearance is allowed between the knurling tool and the die holder, which should be ample so that the tools will not come in contact with each other. Then the knurl travels onto the work, and dwells for 0.01 of the circumference (which in this case is equal to 4.2 revolutions of the spindle), when on the center of the work. It is then forced off the work by the rise shown in Fig. 16, on the back cam. The circular form tool is now brought in again and removes the burr thrown up by the knurl; the form tool is cut away to clear the knurl. Finally, the back cross-slide travels in, and the circular cut-off tool shown in Fig. 14 starts to cut off the piece, but while the piece is being cut off, the pointing tool shown in Fig. 17 is brought in and removes the burr that has been thrown up by the die on the end of the screw; the piece is then severed from the bar, and clearance is allowed to let the cut-off tool return before the stock is fed out again.

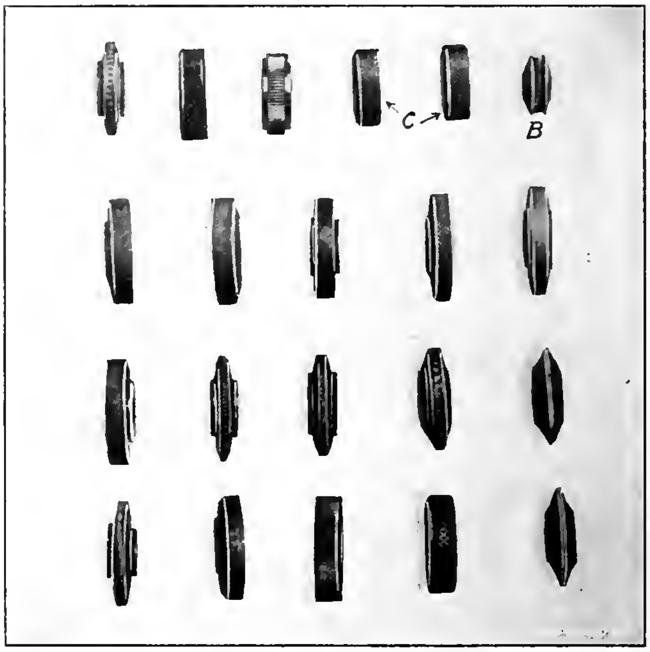

Fig. 19. A Collection of Knurls of Different Types

Cutting the Cams

After the blanks have been spaced off, they are roughed out by drilling a series of holes about 1/8 or 3/16 inch away from the finishing line or by punching, which is performed on an ordinary punch-press. Then the cam is put onto a circular milling attachment. A vertical milling attachment is used in connection with the circular attachment, and a mill of the required diameter, which depends on the size of the roll on the automatic screw machine, is used for cutting the cam. The circular attachment is graduated in degrees and minutes, and it is, therefore, necessary to find the number of minutes in the number of hundredths on the lobe of the cam to be milled.

The surface of the cam is divided into one hundred equal parts, and since there are 360 degrees in a circle, one-hundredth equals 3.6 degrees, or 3.6 × 60 = 216 minutes.

To find the number of minutes which is equal to 0.001 inch rise, divide the total number of minutes contained in the lobe by the total number of thousandths rise. When cutting the cam, the platen of the milling machine is moved till the cutter comes in contact with the edge or face of the cam; then the cutter is fed in 0.001 inch, and the circular attachment is turned the required number of minutes, which is equal to

0.001 inch rise. The milling operation is continued in this way until the lobe is completed. Milling the cam in this manner leaves a series of little steps, or rises, which can be removed with a file, and in this way a true surface is obtained.

In the half tone, Fig. 18, are shown, in position, the tools used in making a knurled thumb nut. The cross-slide knurling tool illustrated in Fig. 1 is shown at *B* in position on the back cross-slide. In Fig. 19 is shown a variety of knurls; at *B* is shown a concave knurl made by the method illustrated in Fig. 6, and at *C* is shown a pair of knurls which will produce a diamond knurl as shown in Fig. 11, when they are used in the knurl-holder shown in Fig. 10.

* * *

DESIGN AND CONSTRUCTION OF ELECTRIC OVERHEAD CRANES—7

END CARRIAGES

R. B. BROWN

In order to calculate the strength of the end carriages, it is only necessary to find the maximum wheel pressure occurring when the crab and load are at the extreme end of the span. Take, for example, a 25-ton crane with a 5-ton crab,

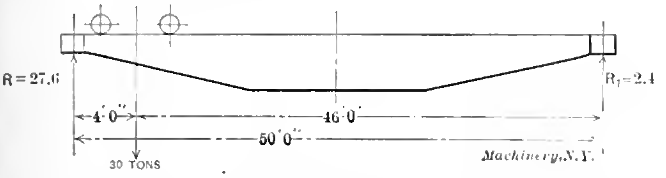

Fig. 44. Diagram for Calculating Wheel Preseure on End Carriages

where the minimum distance from center of load to center of track is 4 feet, as shown in Fig. 44.

The maximum reaction *R* from the traveling load will be $\frac{46 \times 30}{50} = 27.6$ tons, or 13.8 tons per wheel. Added to this is the wheel pressure due to the weight of girders, end carriages, etc., which is practically divided over the four wheels, and in the present case would be about 14 tons, or 3½ tons per wheel, making the total maximum wheel pressure $13.8 + 3.5 = 17.3$ tons.

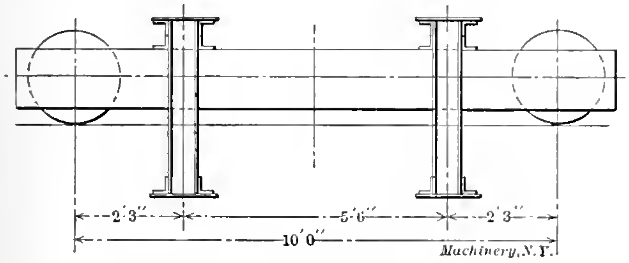

Fig. 45. Arrangement of End Carriegee of Crane shown in Outline in Fig. 44

It is also necessary to know the center distances of the main girders and of the traveling wheels. The former distance is decided by the requirements of the crab, which depend to a large extent on the height of lift, and consequent amount of rope which has to be coiled on the barrel. There is no economy in cramping this dimension, and it is always a convenience to be able to take a moderately long lift without altering the standard patterns. The centers of the traveling wheels should not be less than 1/5 of the span, for electric travelers, particularly those traveling at high speeds, this proportion having been found the most suitable to resist cross twisting.

In the example just given above, the end carriage would be arranged as shown in Fig. 45. It will readily be seen that the maximum bending moment occurs at the center of the main girders, where it is equal to the wheel pressure multiplied by the distance from the center of the traveling wheel to the center of the girders $= 17.3 \times 27 = 467.1$ inch-tons; stressing the material up to 5½ tons per square inch, giving a maximum factor of safety of 5, the modulus required would be $\frac{467.1}{5.5} = 85$.

Rolled steel channels can be used for cranes up to about 30 tons when reinforced with flange plates. When channels are not convenient, plate and angle sections are adopted, consisting of web plates and angles. Some makers substitute bracing for the webs between the girders, but it is doubtful whether any economy is effected by so doing.

The method of attaching the main girders is a detail of some importance, the various systems commonly in use being shown in Fig. 46. Type A forms a very neat connection and is particularly suited for cranes up to about 15 tons. The rail and top flange plate should be run across the top of the carriage as shown, and a substantial gusset ought to be fixed to the lower flange to stiffen the joint. The two sides of the end carriage are tied together by heavy diaphragms, as shown, and this arrangement to some extent ensures the outer member of the carriage taking some of the weight. The tendency for the inner members to take the full load is, however, one reason why this construction is often avoided for heavy cranes, in favor of the method shown as type B, which is the strongest and most satisfactory form for fixing the girders. It will generally be found in this design that the shallowest construction that can be employed at the ends of the girder is sufficiently strong to carry the whole load, even if it were concentrated at the extreme end of the girder, and this fact alone ensures both members of the end carriages getting an equal load, and at the same time does not encroach too much on the head room, for which reason the construction shown in type C is seldom adopted. The attachment illustrated in type D is strong and inexpensive, but occasionally has the fault of limiting the end travel of the crab.

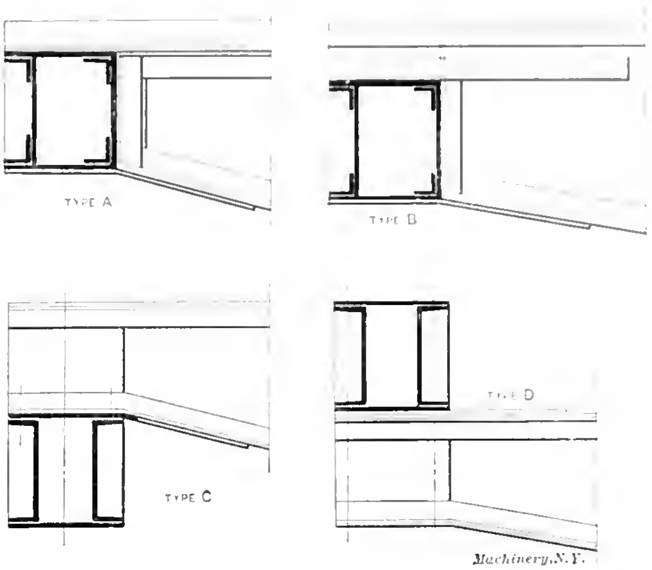

Fig. 46. Varioue Methode in Use for Attaching the Main Girders to the End Carriages

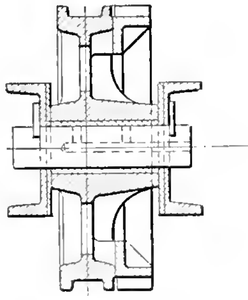

Fig. 47. Traveling Wheel with Bushing running Loose on Pin fixed to the Framing

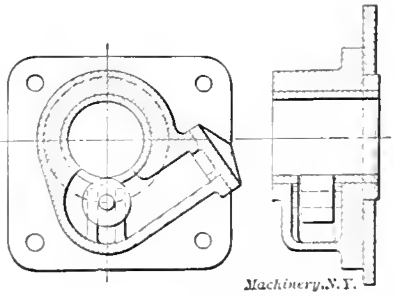

Fig. 48 Self-lubricating Axle Boxes for Crane Traveling Wheels

Wheels, Axles and Bearings

The most convenient sizes of traveling wheels taken from practice seem to be

18 inches diameter for cranes up to 4 tons.
21 inches diameter for cranes up to 7 tons.
24 inches diameter for cranes up to 25 tons.
30 inches diameter for cranes up to 25 tons and above.

The 18- and 21-inch wheels should be made of cast steel, in order to withstand the wear on the tread. The 24-inch wheels are sometimes made of cast steel also, but general practice inclines to steel-tired wheels for this and larger sizes.

The strains due to shrinking both in the tire and center appear to be very great, and it is for this reason that the centers are made heavy to avoid cracking. A very convenient position for the driving spur is to bolt it directly to the traveling wheel, and is a better arrangement than casting it on the center. Some makers key the wheel onto the axle, outside the carriage, so that it can be easily removed; this arrangement, however, rather interferes with a neat connection for the platform at the ends. When the spur is attached directly to the wheel, allowance should be made for the consequent unequal loading on the sides of the end carriages.

Some makers bush the traveling wheels and run them loose on pins fixed to the framing, as shown in Fig. 47. This method allows the wheels to be easily withdrawn for repairs, and simplifies the lubrication, which, however, should consist of grease instead of oil, owing to the fact that the latter is apt to run out when the bushes have worn slightly oval.

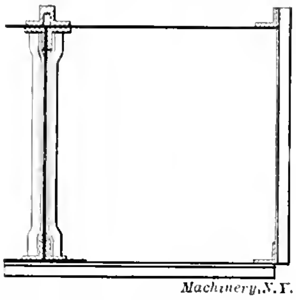

Fig. 49. Section of Girder suitable for Light Cranes of Long Spans

The diameter of the axles must be sufficient to resist bending from a distributed load, and at the same time have enough bearing area to keep the pressure below 1,000 pounds per square inch. Large cranes, and, in the case of some makers, all cranes are fitted with self-lubricating axle boxes, of the type shown in Fig. 48. The roller shown in this illustration is of cork, with a hardwood spindle. The slot in the casting requires to be well made, or occasionally the roller may become jammed and ineffective.

Platforms, Brackets and Traveling Gear

The design and arrangement of the platforms and brackets either improves or detracts from the appearance of a crane, to a considerable extent. A variety of opinions seems to exist on the question of platforms, and while one engineer requires platforms on both sides of a one-ton traveler, another may be satisfied with one platform for a 25-ton crane. In the case of light high-speed travelers, it has been found both convenient and economical to have only a small platform over the cage, to stand on when examining and oiling the crab, the longitudinal shaft and axles being oiled from below, or from a platform fixed to the shop end wall.

If, however, a platform must be fixed to cranes having light lattice or single web plate girders with over forty feet span, it will be found that the section necessary to carry the load itself, is seldom sufficient to withstand the torsional stress due to the platform without deflecting laterally. The best means of overcoming this difficulty, which practically applies to all sizes of cranes with single web girders, is to attach a light subsidiary lattice girder to the main girder by horizontal bracing, as shown in Fig. 17 (April issue). The section employed can be very light. The diagonals, or tension bars are formed of light angles in preference to flat bars, to ensure rigidity and freedom from vibration; since they are strong enough to take compression, they obviate the necessity of counterbracing the central bays.

A section of a special girder is shown in Fig. 49. This has been found eminently suitable for light cranes of long span, traveling at a high speed. In this design it will be seen that the top flange is really a chequer-plate platform, one side being riveted to the web and the other to the lattice bracing, forming the front, the lower side also being braced. The increased width of the top flange gives a lateral stiffness sufficient to withstand the most severe strains.

The various forms of platform brackets in use are shown in Fig. 50. The advantage of each type of bracket is a matter of opinion, but it is generally considered, however, that type A is the simplest and best for plate girders, and more in accordance with the type of bracket which is employed to carry the traveling motor. Type B is formed of flat bars about 3 × ¾ inch and makes a very suitable bracket for box lattice girders, where it can be bolted onto the vertical members of the structure.

Timber is generally employed as a platform, on account of its lightness and cheapness; it also gives the best foothold. When cranes are working in the presence of fire, ¼-inch steel chequer plates are generally used in place of timber, and carried on steel brackets in the same manner.

A type of platform much employed on the European continent is made up of perforated steel screen plates, usually about 3/16 inch thick, which possess the advantage of lightness and good appearance, while the cost is only very slightly in advance of rolled chequered plates. This type is, however, most suitable for those cranes having lattice braced platform girders, which give the close support a plate of this description requires.

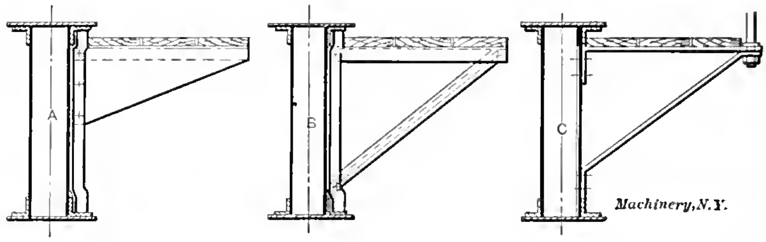

Fig. 50. Types of Platform Brackets

The traveling motor ought, theoretically, to be placed in the center of the drive. Cranes up to 50 feet span are, however, sometimes driven with the motor fixed at one end, but since it adds very little to the cost, it is best practice to place the motor in the center for all cranes over 30 feet span.

Whenever possible, the gearing ought to be confined to two reductions, and in order to do this, the motor should not be speeded above 600 revolutions per minute. Ordinary plummer blocks form a suitable type of bearing for the cross shaft. The bearings are usually placed on about 10-foot centers.

When using flanged couplings for this shaft in conjunction with timber platforms, there is always the disadvantage of either using somewhat high plummer blocks, or cutting the platform away to clear the flange, and this difficulty can best be avoided by using ordinary split muff couplings.

* * *

In 1898 there were not more than 200 automobiles made and put into use in the United States. In 1909 the total number of automobiles made and sold in the United States will approximate 82,000. The effect of the development of the automobile on the reduction of weight of prime movers may be appreciated when it is considered that less than thirty years ago prime movers weighed as much as 800 or 1,000 pounds per horsepower developed, and that the modern automobile engine has been reduced in weight to well under ten pounds per horsepower developed, and has shown its great reliability by running for days without stopping. The average horsepower of the automobiles produced in 1909 is about twenty, the 82,000 machines making an aggregate of 1,640,000 horsepower. At the beginning of this year there were in use in the United States over 184,000 automobiles, aggregating close to 4,000,000 horsepower.

Assembling a Three-throw Built-up Crank-shaft.

NOTE.—The method of machining the various parts of a built-up crank-shaft was described in the Shop Operation Sheet accompanying the March issue. The following relates to laying out and setting the various parts in correct relation with one another, and shrinking them together.

1. Place section *B* (see view of the assembled shaft), which has been fitted to webs 2 and 3, in V-blocks, which should rest on an accurate surface plate. Locate the exact center c in end 2 of the shaft, and with a surface gage scribe the line *a* (See Fig. 1). Transfer this line with the surface gage to a point 3 on the other end of the shaft.

NOTE.—As there are to be three cranks in the shaft, the angle between the center lines of each will be 120 degrees. If then lines are located at points 2, 3, 4 and 5, 120 degrees apart, the cranks will be correctly set when their center lines coincide with the 120-degree points.

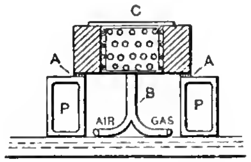
2. Set a protractor *P* to an angle of 60 degrees, and scribe the line *b*. The angle between the two lines on the end of the shaft will evidently be 120 degrees. Rotate the shaft (still keeping the surface gage at the same height) until line *b* coincides with the gage pointer and is parallel with the surface plate, as shown in Fig. 2; then scribe the line 2 which will be 120 degrees from 3.

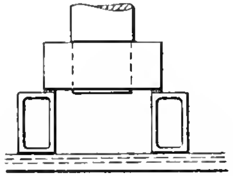
3. Place section *C* in the V-blocks, locate a center in end 5, scribe a line *d* with the surface gage, and transfer this line to point 4. With the protractor lay off the 120-degree line *e*; then turn the shaft until line *e* is parallel with the surface plate as shown in Fig. 4, and, without moving the gage pointer, locate line 5.

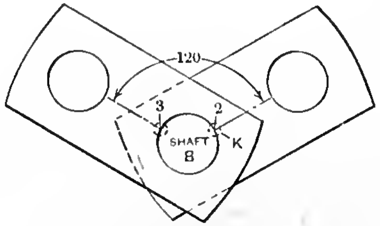
4. Fit lead center piece into the shaft and crank-pin holes of each web, locate the exact centers, and then scribe lines through these centers on the outer sides of the webs, excepting numbers 1 and 6, which do not need to be laid out.

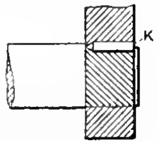
SHOP OPERATION SHEET NO. 104.

W. Burns. MACHINERY, July, 1909.









Machinery,N.Y.

Assembling a Three-throw Built-up Crank-shaft.

1. Place webs 1 and 6 (see the illustration on the preceding sheet) on parallels *P*, which may rest on any suitable table. That side of each web which was previously laid out, should be up.

2. Insert a Bunsen burner *B* in the hole to which the shaft was fitted, and connect the gas and air pipes. Any form of gas or oil burner may be used which will supply sufficient heat. Considerable time may be saved by using two burners and heating two webs at the same time. A cover plate *C* should be placed over the hole, and small strips *A* of asbestos or some other non-conductor between the webs and parallels to prevent the escape of heat.

3. After the burner is started, set a pair of inside calipers to the shaft diameter, and occasionally test the hole in the web to ascertain when it has expanded sufficiently to allow the shaft to enter.

4. Suspend the shaft over the web in a vertical position by any convenient crane, and arrange the latter so that the shaft can be lowered quickly.

5. When the hole has expanded enough to admit the shaft, remove the burner, quickly wipe out the hole; then lower the shaft into place. When the web cools, if proper allowance was made for the fit, the parts will be shrunk tightly together.

6. When webs 1 and 6 are finished, heat web number 3 and insert shaft *B*, setting it so that the center line of the web and line 3 coincide. Web 2 is next heated and shrunk on to section *B*, the two webs being set at an angle of 120 degrees, as shown in the illustration. The webs 4 and 5 are then shrunk to section *C* in the same manner.

7. To prevent the cranks from shifting, cylindrical keys *K* are fitted in all the webs as shown. These keys are made of mild steel and are driven in place by a heavy ram. Small grooves *G* are cut in on either side to permit the escape of oil and air.

SHOP OPERATION SHEET NO. 105.

W. Burns MACHINERY, July, 1909.

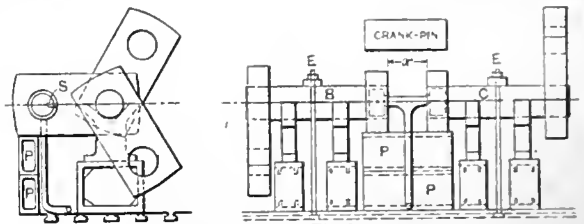


Fig. 1

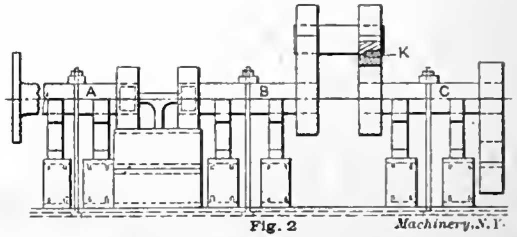

Fig. 2

Machinery,N.Y.

Assembling a Three-throw Built-up Crank-shaft.

NOTE.—The webs are assumed to be properly shrunk and keyed to each shaft section, those attached to section *B* and *C* being set 120 degrees apart. The diameters of each rough-turned section are also assumed to be the same.

1. Secure a set of four duplicate V-blocks, and mount these upon four parallels which are also duplicates and high enough to permit the webs of the cranks to clear the surface plate, as shown in the illustration.

2. Place sections *B* and *C* (see also illustration of Operation Sheet No. 103) in the V-blocks with the ends of webs 3 and 4 resting upon parallels *P*. Make provision for clamping each shaft section to the V-blocks as shown, and set the two sections approximately in line and about the correct distance apart.

NOTE.—The shaft and crank-pin holes for each crank were bored with the webs bolted together, thus bringing the holes at right angles to the inner faces and the same distance apart.

3. Ascertain the distance *x* that the webs should be apart, and, if possible, secure two parallels having widths equal to this dimension. Place one parallel between the webs at each end and clamp the latter together. Adjust the webs until a straight-edge placed through the crank-pin holes as at *S* indicates that they are in line.

4. Tighten the clamps *E*, and remove the parallel blocks from between the webs. Insert a double Bunsen burner in the crank-pin holes, as shown, and heat the webs until the crank-pin, which is a straight cylindrical piece, will enter. When the webs have been cooled, arrange section *A* on additional parallels and V-blocks as shown in Fig. 2; set the webs, and shrink in the pin as explained in the foregoing. In a similar manner finish the third crank.

NOTE.—Locking pins *K* are screwed into the webs and crank-pins to keep the latter from creeping out in case they should become loose.

V.—FORMULAS FOR STRENGTH OF FLAT PLATES

Author and Reference'	Formula as Given by Author	Safe Load at Center of Plate $W=$	Unit Stress in Extreme Fiber of Material $f=$	Thickness of Plate in Inches $t=$

PACKING MACHINERY FOR EXPORT

In this the second article on packing machinery for export (see MACHINERY, February, 1909) we illustrate the packages employed by a number of machine tool builders, which have been especially photographed for MACHINERY. We feel that the subject still is an important one, notwithstanding the depression in export trade of machinery. Even though European countries buy less and less of our machines proportionally as years go by, there is no reason for our manufacturers to neglect foreign business. With proper encouragement a machine tool trade can be worked up in other countries besides Europe. South America is a very promising field for future sales. It is a land practically untouched by American manufacturers, and now is the time when we should be doing the initial work to build up a trade that should grow with years and become as important in time as the European trade. As being of particular significance now, we quote from a book entitled "Aids to Shippers," published by Oelrichs & Co., New York:

"Commerce flows along the lines of least resistance, and those manufacturers, merchants, farmers and miners will be most successful in extending their markets, who deliver their goods to the purchaser wherever wanted. Nothing has contributed so much to the material wealth of the entire world as the tremendous strides made in transportation facilities during the last century, and transportation has become the most valuable commodity of the present day, as in nearly every instance the cost of carrying an article to its ultimate destination determines the question of its sale. Too much stress cannot be laid upon the care that should be exercised in packing merchandise exactly in compliance with the wishes of purchasers, no matter how trivial they may seem. If, for instance, a buyer should instruct a shipper to arrange his package in such a way that a certain weight or size be not exceeded, it is no doubt that the goods are to be carried on mule back or similar conveyance to the interior. A request especially from South American countries will frequently be made that but one kind of goods be placed in each package, and this also should be strictly carried out. Failure to observe this rule results in heavy fines by customs authorities, as the laws of the respective countries demand that each kind of goods imported therein must be packed in a separate package, and forbids the packing of different kinds of merchandise in one receptacle."

The packing of a milling machine for export as practiced by the Kempsmith Mfg. Co., Milwaukee, Wis., is illustrated in Figs. 1 and 2. At one time this company exported 50 per cent of its product, and its export trade now averages about 30 per cent, so that of necessity it has developed methods of packing which reduce complaint from defective shipping to a minimum. In the past five years it has received only one complaint of trouble resulting from packing.

The milling machine to a certain extent is self-contained and therefore lends itself very well to a compact substantial package, and this condition is improved for export by partial dismantling. The table is removed and placed in a low place in the case, and the knee is run down to a low position on the column. The counter-shaft is packed at the rear of the machine with the pulleys at the bottom, as shown in Fig. 1. The loose parts are carefully packed with a liberal amount of excelsior in a box within the main case. This illustration also shows the method of framing and bracing. The lumber used is white pine, as this timber does not split and is in other respects better for the purpose than hemlock or other woods. The machine is securely bolted to 6 x 8 inch skids, and the frame is of 2 x 4 inch material. The corner posts are further supported by intermediate cross and upright posts, and the top framing is placed against the overhanging arm so as to support the machine in case it is turned over on its side.

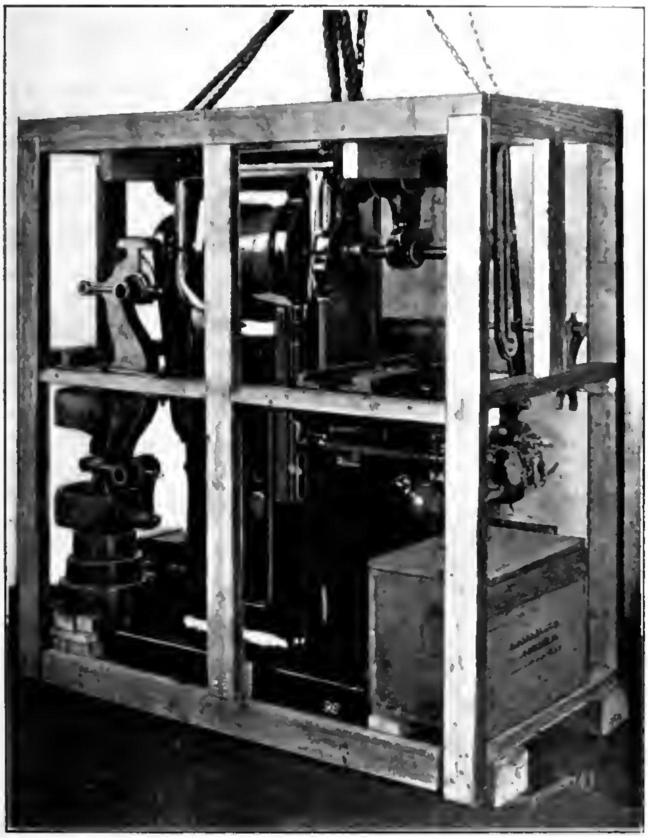

Fig. 1. Kempsmith Knee-type Milling Machine in Framework of Export Packing-case

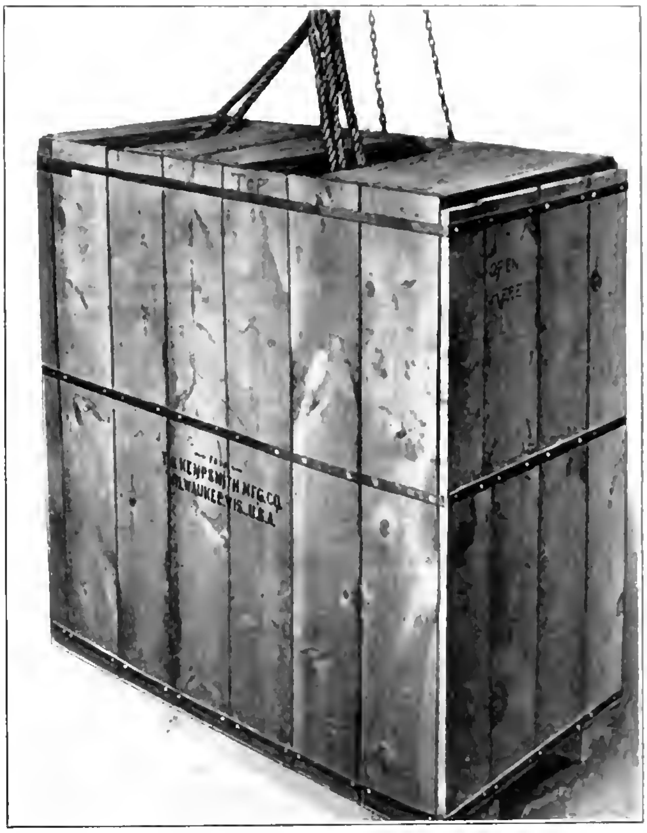

Fig. 2. View of Packing-case for Kempsmith Knee-type Milling Machine, showing Opening at Top for Handling

The sheathing is $1\frac{1}{4}$ inch lumber nailed vertically, as shown in Fig. 2. Three strips of 1/16 inch x 1 inch band iron are passed around the bottom, top and middle of the completed case. Two of the top boards of the case are screwed instead of nailed, this being done for convenience in removing them and thus providing an opening for inserting ropes or other tackle appliances for handling the machine. This feature is known to customers abroad, and facilitates the handling of the machine. An end board shown in the same illustration is provided, which is likewise screwed, with notice to the custom officials that the same is the proper place to open the case for inspection.

All finished surfaces of the machine are thoroughly slushed over both externally and internally to protect them from dampness. It is not safe to leave a finished surface on the interior of the machine, as the damp salt air can work just

[illegible] to parts on the interior as to those on the ex- [illegible] not protected. For the overhanging arm and upper [illegible] surfaces a special brand of slush is used which [illegible] seen after application. The reason for this is that [illegible] parts are subject to exposure in handling both in shipping and receiving at the other end. The hardened slush is not easily rubbed off by the use of ropes, etc., in handling, and therefore protects these parts from exposure and rust, even though subjected to considerable wear. This hardened slush is easily removed with benzine.

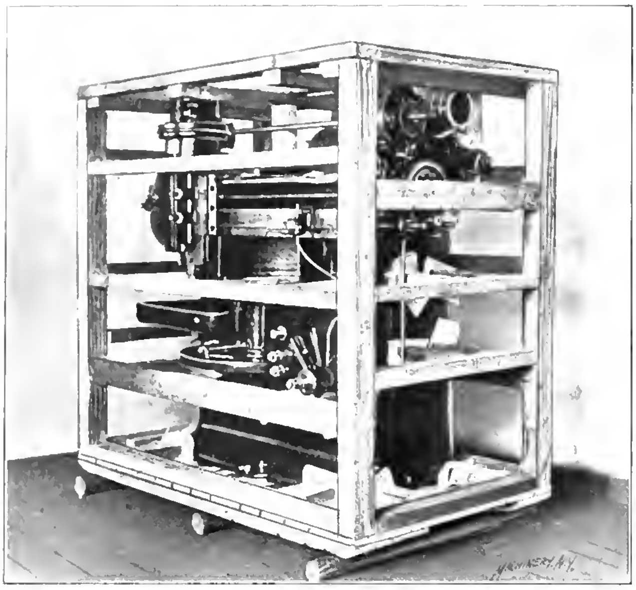

Fig. 3. Framework of Foreign Export Package for Fellows Gear Shaper

Figs. 3 and 4 illustrate the framing and exterior of the package used by the Fellows Gear Shaper Co., Springfield, Vt., for protecting gear shapers. The gear shaper, like the milling machine, is largely self-contained, and does not offer serious difficulties in the matter of substantial packing, and very little dismantling is necessary. The frame work is well braced with about 4 x 6 inch stuff and 2 x 4 inch pieces between. Substantial skids are provided, and the sheathing is nailed vertically, as illustrated in Fig. 4.

The package illustrated in Fig. 5 is a remarkable example of compact packing of a tool, which to the ordinary observer would seem quite incapable of being put in such close compass. This package is the one employed by the W. F. & John Barnes Co., Rockford, Ill., for its upright drills. The machine, which is a 25-inch drill, is packed into a case measuring 76 x 49 x 12½ inches, the gross weight of which is about 1,300 pounds. The company has lost only one of its drills thus packed for export. It will be observed that the base is removed as well as the table and packed alongside of the frame with the cones, feed gearing, etc. Other parts are packed in the interstices so that the amount of waste space is reduced to a minimum. This can be judged from the fact that the cubic contents is only about 27 cubic feet and the weight is 1,300 pounds, or 48 pounds per cubic foot. The case is built up of lumber 1¼ inch thick.

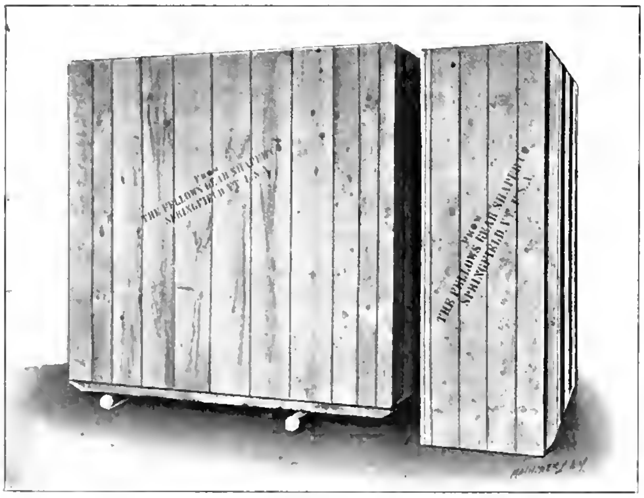

Fig. 4. The Same Case shown in Fig. 3, Boarded up

The Cincinnati Machine Tool Co. employs a very strong framework for its upright drills, covering same with six- or eight-inch wide flooring nailed about six inches apart. The company has found this style of open package satisfactory. It enables the freight handlers to see what they are handling, and if a breakage occurs between Cincinnati and New York it saves shipping the broken machine all the way to Europe. Practically no breakages are reported, but notwithstanding the satisfactory experience, the foreign dealers request closed boxes, and now the company is packing in the same way as before and closing the cases tight.

The Ingersoll Milling Machine Co., Rockford, Ill., builders of heavy milling machines of the planer type, dismantle the machines for their export trade and pack the parts in boxes made of 2 x 6 inch dressed and matched lumber, making the boxes perfectly tight.

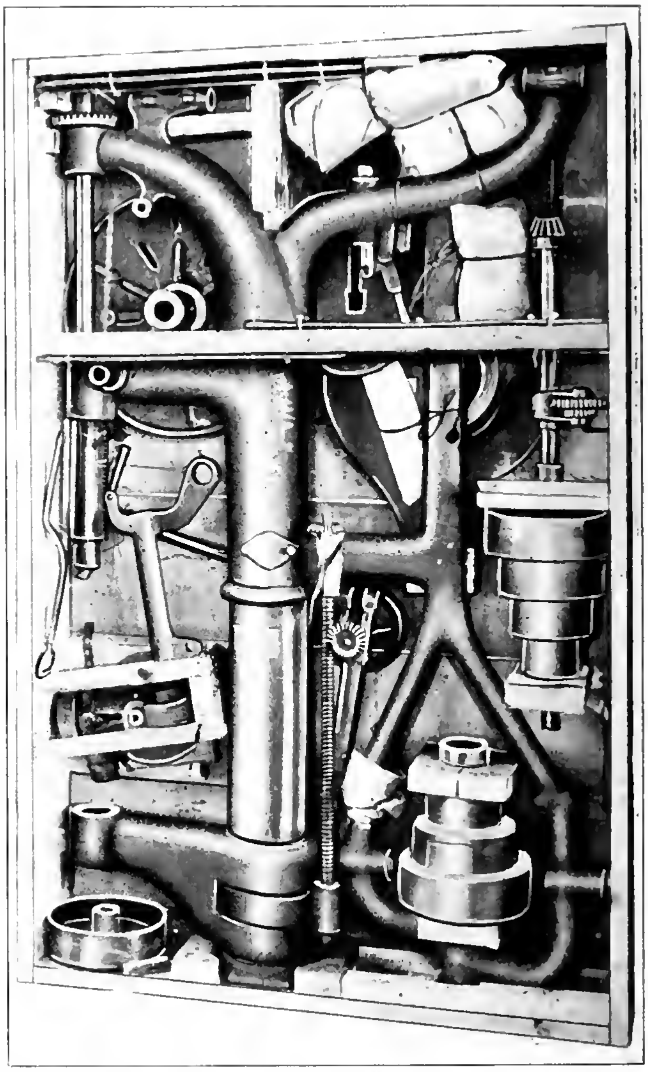

Fig. 5. Twenty-five-inch Upright Barnes Drill packed for Foreign Shipment. Note the Compact Arrangement of Parts and Little Waste Space

The Rockford Drilling Machine Co., Rockford, Ill., dismantle all its machines shipped abroad and pack in substantial boxes, bracing the large parts thoroughly. This method has the objection of requiring the foreign customer to reassemble the machine, and where this is done by users, trouble sometimes arises through improper assembling. The advantage from the point of the manufacturer lies in that the machines do not occupy so much cubic space as otherwise, and therefore the freight rates are lower.

Fig. 6 illustrates the package employed by the Edwin Harrington, Son & Co., Inc., Philadelphia, Pa., for their long lathes. The machine in the package is the 28- and 48-inch extension lathe, ordinarily used as a lathe of 28-inch swing. In packing this machine the head- and tail-stock are put in one box, while the carriage and small parts are packed in

other boxes. The lead screw is left in place on the side of the bed, and boxed in. The illustration shows the bed upside-down. This package only partially protects the machine, the bottom being open and the frame work being held together by strong cross-ties. The upper part of the bed or finished surface is protected from dampness by boarding. In conclusion we quote again from "Aids to Shippers" on the importance of marking packages:

"It is an established fact that the marking of packages plays a considerably more important part in export shipping than most American manufacturers and export merchants are willing to credit. As an instance, we desire to call attention to the fact that several South American countries require that all marks on the packages must be stencilled, brush or other kind of marking being prohibited by law. Some countries, on the other hand, demand that the distinguishing marks and numbers, etc., be placed on the four sides of each package. Again, some demand that the net and gross weight in kilos appear on each case, together with a number, which latter must correspond with the number of the same case given in the consular documents. It is needless to observe that where the laws of the different countries demand such markings, failure to comply with the regulation always results in fines, delays and many other petty annoyances at destination, the fines, in many instances, exceeding the value of the goods considerably. In all instances every case must be distinctly marked with the port of destination in full, this requirement emanating from the steamship companies and being covered by the term 'Port Mark.'"

Fig. 6. Extension-bed Harrington Lathe packed for Export

* * *

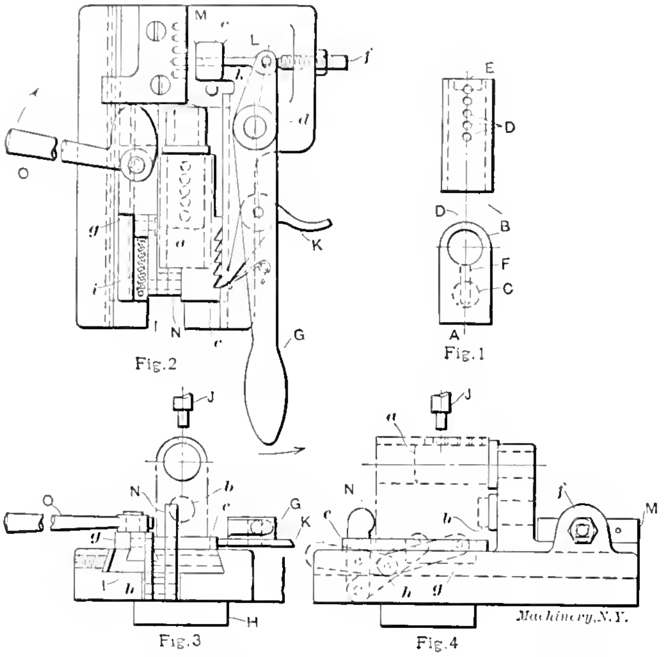
The gas pressure in the powder chamber of the Springfield rifle, model 1903, for the latest pattern cartridge, is about 49,000 pounds per square inch. What this means may be inferred from the following abbreviated directions for cleaning the arm, contained in the pamphlet issued for the instruction of army officers: "Use the cleaning rod and small patches of canton flannel and clean the bore thoroughly with patches soaked in a saturated solution of soda and water. Then thoroughly dry the bore and remove the soda solution by the use of dry patches and finally oil the bore with patches soaked in cosmic oil. Twenty-four hours after the first cleaning, the bore should be again cleaned as described above, as it has been found that the powder gases are probably *forced into the texture of the steel*, and will, if the second cleaning is not resorted to, cause rusting no matter how thoroughly the bore may have been cleaned at first."

A RIVETING FIXTURE

The accompanying engraving illustrates a fixture which was designed for use in a pneumatic riveter. The work is shown in the two views in Fig. 1, and consists of an oblong casting with a half-round top, having a hole *B* extending through it and a hole *C* in one end. The five small holes *D* were drilled in the center of the casting and about two-thirds of the way through. The side *A* is finished and the holes *B* and *C* are a gage distance from this surface. The face *E* is also finished square with *A*. In the finished piece small springs were placed in the lower portion marked *F* of the holes *D*, and it was necessary that the outer part of the holes *D* should be plugged in order to have a continuous ring of metal around the top part. Small brass disks were inserted in these holes and expanded by the riveter sufficiently to tightly fill the hole. Fig. 2 shows a top view of the fixture; Fig. 3, an end view, and Fig. 4, a side view with lever *G* removed.

The fixture consists of a cast iron base, planed off on the bottom, having a round boss *H* which fits into the bed of the riveter. The base is dovetailed, as shown, for the slide *I*, from which a lug projects upward and carries the studs *a* and *b* on which the work is placed. These studs fit the two holes *B* and *C* of the work, and have shoulders against which the side *E* of the work stops. The bottom *A* of the work rests on the hardened tool steel plate *c*. Fig. 4 shows the work in position so that the hammer *J* of the riveter, in descending, will expand the disk in the second hole in the work; when this is done, the slide *I*, carrying the work, is moved along so that the third hole will be in line with the hammer of the riveter, and so on, for the other holes. The stock left between the holes in the work, after drilling, is so small that it is very necessary that the hammer be exactly in line with the hole containing the disk to be expanded, for, if in riveting the hammer strikes the solid part of the casting, it will crack it. For this reason, it is necessary that the slide should be fed forward an exact amount each time, and that it should be properly indexed in this position. This is accomplished by the lever *G*, which is pivoted to the base of the fixture at *d*. The pawl *K* is pivoted to the lever *G*, and meshes into the rack which is cut in the plate *c* fastened to the slide *I*. To the outer end of the lever *G*, is connected the index pin *L* which has a bearing in the boss *e* on the base of the fixture. The plate *M* is fastened to the slide *I*, which car

ries the work, and has five small holes in its side, spaced the same as the holes *D* in the work, and so located that when the index pin *L* is in any one of them, the corresponding hole in the work is in line with the hammer *J* of the riveter. The screw *f* is adjusted so that when the end of the lever *G* stops against it, the pawl *K* will have moved the slide *I* such an amount that the hammer *J* will be directly in line with the hole in the work. This position is shown in Fig. 2. When the lever *G* is thrown in the direction of the arrow, the index pin enters the hole in the plate *M* on the slide, thus locating it accurately in this position. When the lever *G* moves to the end of its throw in the direction of the arrow, the pawl passes almost to the point of the next tooth. In feeding the slide forward for the next hole in the work, the lever must swing in the opposite direction a sufficient amount to move the pawl *K* from the point to the bottom of the tooth in rack *c*, before starting the slide forward; this movement is sufficient to withdraw the index pin *L* from the hole in the plate *M*, thus making sure that the index pin is withdrawn before the slide is caused to move. The mechanism to clamp the work in position, consists of a small slide *g*, dovetailed into the main slide *I*. The clamp *N*, pressing against the work, is pivoted at the center to the slide *I*, and joining the lower end of this clamp and one end of the small slide *g* is the connection *h*. The cam *O* is mounted on the slide *g*, and its face works against the surface of the plate *M*, which is fastened to the slide *I*. Fig. 2 shows the small slide *g* forced forward by the action of the cam *O* against the plate *M* which causes the clamp *N* to be pressed against the work as shown by the full lines of Fig. 4. The dotted lines show the position of clamp *N* when the cam is released. The coil spring *i* forces the slide *g* backward at this time.



Figs. 1 to 4. Fixture for Holding the Work shown in Fig. 1, and Accurately Indexing it when Riveting Disks in Holes D

The operation of the fixture is as follows: The work is placed upon the studs and the cam *O* is swung in the direction of the arrow, thus clamping the work in position. The riveter is started and the disk in the first hole expanded. The riveter is then stopped, and the lever *G*, which at this time is to the right of its movement with the index pin *L* in the first hole of plate *M*, is swung to the left until the end brings up against the stop-screw *f*. This movement withdraws the index pin *L*, and feeds the slide *I* forward by means of the pawl *K* working in the rack *c* on this slide. The lever *G* is then thrown to the right, and the index pin *L* passes into the second hole of plate *M*. The riveter is again started and the disk in the second hole is expanded. These movements are repeated until the disks in the five holes have been expanded. The cam *O* is then released, thus throwing the clamp *N* down and allowing the work to be removed. The operator, having his right hand on the lever *G*, presses against the end of the pawl *K* with his finger, thus throwing it out of engagement with the rack *c*, and, at the same time, throwing lever *G* in a direction opposite to that of the arrow until it brings up against the stop-screw *f*, thus withdrawing the index pin *L* from the hole in the plate *M*. Another casting is picked up with the left hand, and pushed onto the studs *a* and *b*, and, at the same time, the slide *I* is moved back against the stop-pin *k* which is so located that the first hole in the work is in line with the hammer *J* of the riveter. The end of the pawl *K* is now released, and the spring shown forces it into mesh with rack *c*. The lever *G* is swung in the direction of the arrow, thus causing the index pin to pass into the first hole in the plate *M*. The cam *O* is moved in the direction of the arrow, thus clamping the work in position, and the train of operations repeated.

In operation, the fixture proved to be very rapid and accurate, and gave satisfaction.

TEACHING HORSE SENSE

In a communication to the *Engineering News*, George H. Follows, Professor of Machine Design at the School of Applied Science, Carnegie Technical School, Pittsburg, Pa., expresses some ideas regarding the teaching of "horse sense" in technical schools, which are of interest to all who have given any thought to the question, and which suggest the lines along which further improvement may be made. One fault with technical instruction as usually imparted is that no "sense of values" is developed. The technical graduate, as well as the college graduate in general, has but a dim recognition of essentials and non-essentials at the time when he leaves his Alma Mater. He does not know things of prime importance from those of secondary value. He has usually an exaggerated idea of the value of his college training, and of the knowledge that he has assimilated during his years at a technical school. When engaging in practical work, he is likely not to be able to distinguish a big thing from a little thing and at first accomplishes little, because he uses up his time and energies with an unprofitable struggle with trivial matters; in other words, he lacks good "horse sense."

While it is not possible to teach "horse sense" in the abstract, it is possible to develop a sense of judgment in the student provided the instructor himself possesses the qualities necessary for imparting such instruction. This instruction of common sense can be made effective by introducing a course that does not deal exclusively with theoretical considerations but deals with engineering as it actually appears in commercial life. The students should be taught that mechanical drawing is only a means to an end and by no means the end itself. In fact, they ought to be taught that engineering itself is only a means to an end, and that unless mankind is enabled to live happier and better lives as a result of industrial and engineering progress, the object to which the engineer devotes his energies fails of its purpose. They should be given an idea of the organization of engineering concerns and be made to understand that when they first enter practical life, they will be likely to occupy very subordinate positions. Of course, with this instruction in shop organization also follows general instruction in shop management and shop systems, and efforts should be made to impress on the student the true difference between system and "red tape," that is, in other words, the difference between essentials and non-essentials. Last but not least, the student who enters practical life from a technical school needs to be given an idea of the conditions and requirements of the human element in the industries and an understanding of the fundamental principles of economics as they apply to the cooperative work of society. It is evident that it is difficult to obtain competent instructors for this kind of instruction, because experience alone would equip a man to teach successfully along these lines; but undoubtedly students who had had ideas of this kind imparted during their years at school would enter practical work with a truer conception of the conditions of life than the majority of technical and other college graduates now have.

The three-hundredth anniversary of the landing of the Pilgrims at Plymouth, Mass., will be celebrated by a world's exposition in Boston in 1920.

BORING MACHINE PRACTICE IN THE SHOPS OF THE LANDIS TOOL CO.

Anyone who has occasion (for business or other reasons) to visit any considerable number of machine shops in the course of the year, soon learns to grade these shops in his mind with respect to the interest of the work carried on, and the progressiveness and openmindedness of those responsible for the administration of the plant. There are many shops where the mechanic knows beforehand that a visit will be unprofitable, so far as mechanical inspiration is concerned. There are other shops which he has set down on his mental chart as oases in the desert, where he may expect to make refreshing discoveries in shop practice, and to come in contact with alert, intelligent workmen and shop managers. In any such classification the Landis Tool Co., of Waynesboro, Pa., must stand well toward the top. The writer found enough of interest there on a recent visit to the plant to fill many pages of MACHINERY. Much of the material collected is not of a startling or revolutionary nature, but it shows ability in the devising of manufacturing methods, and should therefore be interesting to others engaged in similar work. This material will be published as a series of short articles, each dealing with a separate subject.

One of the things that a live mechanic is always trying to do is (to quote Emerson) "to make two blades of grass grow where one grew before"—in other words, to take two or more cuts where but one was taken before. In pursuance of this idea, various standard machines have been developed into multiple spindle and multiple tool designs. We thus have the multiple spindle drill, the multiple spindle screw machine, the lathe with several carriages and tool rests, and numerous other developments of the same character. It has remained for this firm, however, to devise a multiple spindle boring machine. This was accomplished, as shown in Figs. 1 and 2, without making any change in the ordinary single spindle boring machine other than to provide it with suitable boring bars and driving heads for taking multiple cuts.

Fig. 1 shows a Lucas boring machine, rigged for machining holes in the gear-driven head-stock of the Landis grinding machine. These holes are being bored in a jig built in accordance with the now well-established principle of guiding the boring bars in bushings, so that they are independent of the alignment of the machine spindle. A base is provided for the jig having clamping surfaces identical with those of the work-table on the finished grinder. At each end of this base is clamped a bracket, having bushing holes accurately spaced to the dimensions desired for the holes in the finished headstock. The head-stock casting is clamped on the base between these standards by the same means and in the same way that it will be clamped in the finished machine. When a jig made in this way is accurately constructed and properly used, assurance is given that the holes bored in the work will be in proper alignment and proper position irrespective of the accuracy and alignment of the boring machine.

The particular feature of interest in this operation is, of course, the multiple spindle drive, which permits the boring of all three holes simultaneously. This is a very simple contrivance, as may be seen. It consists merely of a casing having three spindles spaced to agree with the holes to be bored in the work, all connected by means of suitable enclosed gearing. The central spindle is lined up with the spindle of the machine and is connected to it with a flexible coupling which permits the bars to guide themselves in their bushings without reference to the spindle. As the main spindle of the machine is fed forward, it presses against the multiple boring head and feeds the three bars simultaneously through the cut, so that three chips are taken where but one was taken before.

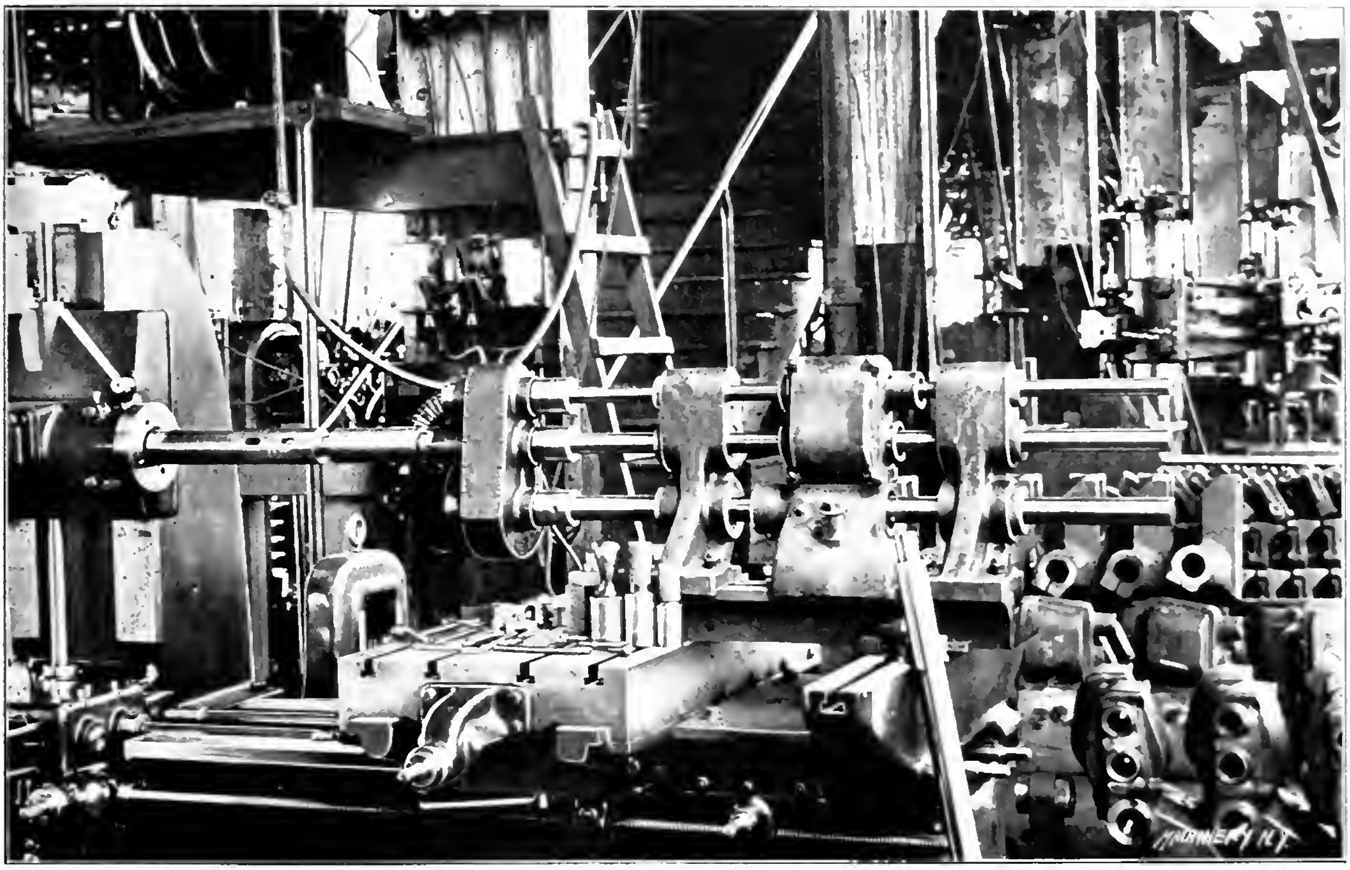

Fig. 1. Lucas Boring Machine with Special Head for Driving Three Bars

A somewhat different arrangement for doing similar work is shown in Fig. 2, where the tail-stocks are being bored for the dead center spindle. Here it is not a case of boring two or more holes in the same casting, but of boring two castings simultaneously. A double base-plate is provided, having ways on each side identical with those provided on the work-table of the grinder. To these ways, as in the previous case, are bolted brackets carrying guiding jig bushings, between which are clamped the tail-stock castings to be bored.

A construction for the boring head different from that in the previous case is required on account of the fact that two spindles instead of three are used. Where three spindles are employed and the drive is led direct to the middle one, the thrust of the cut is approximately balanced, so that there is no tendency to throw the boring bars and the head out of line; but where two spindles are used, one of them driven direct

[illegible] connected by gearing, the thrust of the cut for the cutter is out of line with the spindle of the machine which furnishes the pressure for feeding. There is thus a tendency to twist the boring head around and cramp the bars. In the [illegible] shown this difficulty is avoided by mounting the boring head on ways, machined on an extension of the base plate on which the work is mounted. These ways serve to keep the boring head lined up properly with the boring bars, even under heavy eccentric pressure from the cut. The feeding of the main spindle of the boring machine moves the head along the ways on the base-plate, and thus feeds the boring bars through the work.

The pair of tool heads shown on the platen of the machine in Fig. 2 are of considerable interest. They are of the split variety, making it possible to mount them on the bar without dismantling the setting or removing the bars or the bushings. The construction is more plainly shown in Fig. 3, which illustrates the head shown at the right-hand corner of the platen in Fig. 2. The body of this tool is composed of two members, *A* and *B*, bored to fit the bar and pivoted to connecting link *C*. The side opposite the link is machined with tapered lips as shown, to receive the binding clamp *D*. This is drawn down over the lips by a screw *E*, fitting in a hole tapped into the split between *A* and *B*, being formed half in one member and half in the other. The combination of the screw and wedge action, it will be readily seen, gives a tremendous grip on the boring bar. The screw *E*, of course, fits into its hole loosely when *A* and *B* are tightened on the bar, so that it is not held by the clamping action. To give further assurance of a positive drive, the cross pin *F* is provided in the bar; this drives the head by means of notches fitted to receive it, as shown.

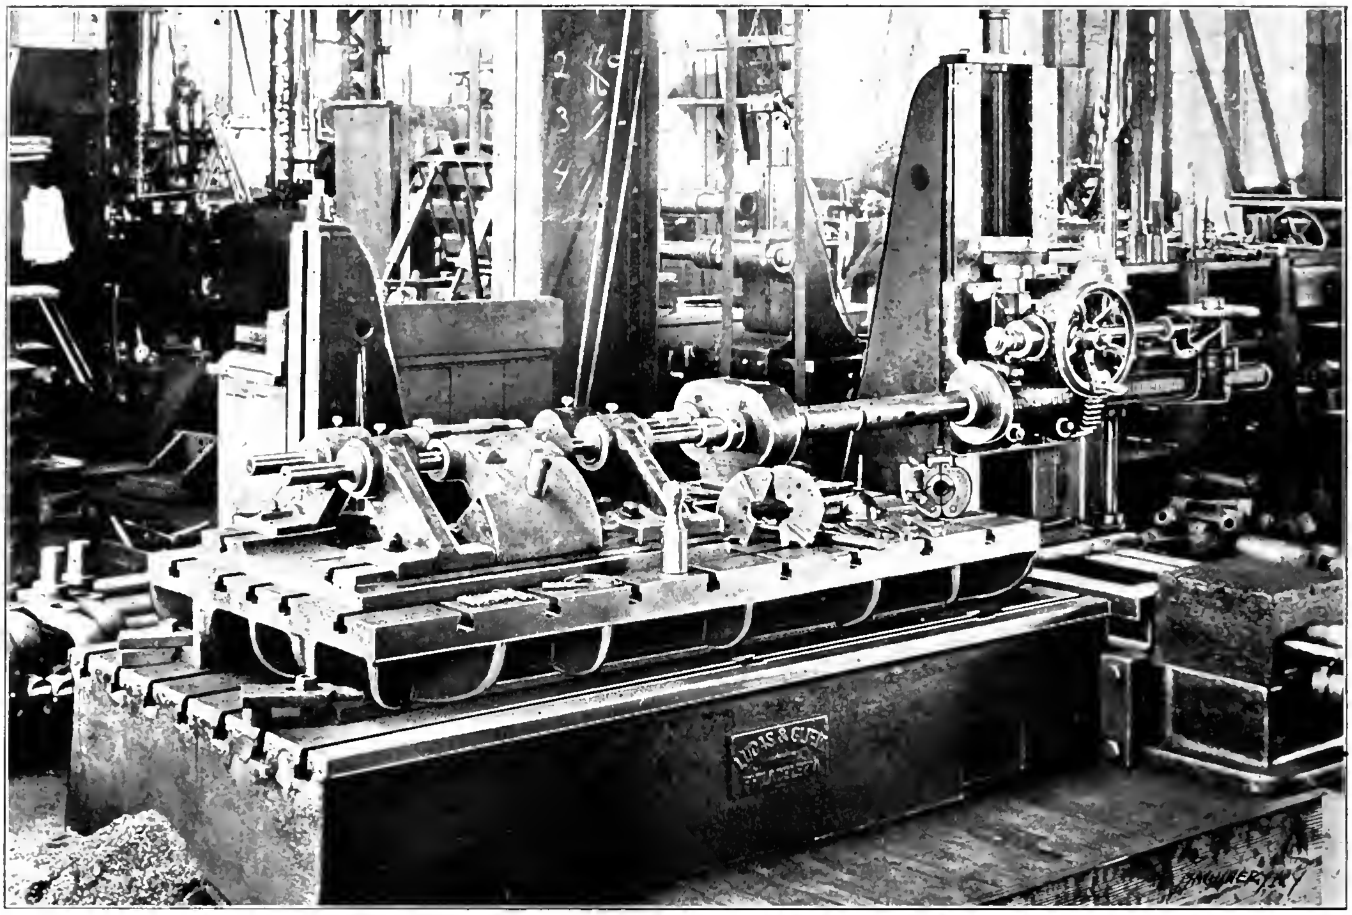

Fig. 2. Boring Two Pieces at once with a Double-spindle Head Guided by Ways on Fixture

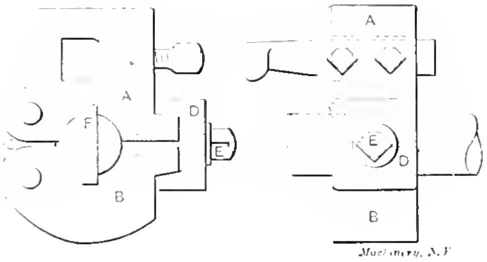

Fig. 3. A Simple and Convenient Split Boring-head

The tool head shown in Fig. 3 is intended for turning the outside of the foot-stock spindle boss. The turning tool used is shown in place at the right of the engraving. Another head of identical construction, but provided with facing cutters, is also shown on the platen of the machine in Fig. 2. This is used for finishing the ends of the bosses on the work.

This combination of double spindle boring attachment, and quickly changed, solidly held tools, makes the operation of machining these castings a very expeditious and accurate one.

* * *

A press report from Dysart, Iowa, states that Nathan Wilson has invented a process for welding copper and steel. He exhibited a hammer which is composed of a copper head and steel face, and he claims that his process of welding is the first in history to prove successful. This is an obvious error. The welding of copper to other metals is a process that has been developed both in Europe and America. By this process, not only can steel be faced with copper, but also with aluminum and other metals that do not weld under ordinary conditions. At the present time the Westinghouse Machine Co. is using steam turbine buckets composed of a steel core and a copper jacket so intimately united that a piece can be drawn in a drawing die and reduced to whatever size and shape required. The metal is received by the Westinghouse Machine Co. in rods and bars and is drawn to shape in ordinary drawbenches. The copper and steel draw uniformly, the relative thickness of the two metals remaining practically the same even with great reduction of cross section area.

* * *

A press message was recently sent by the *New York Times* to the *Chicago Tribune* by means of wireless telegraphy from New York to Chicago. The difficulties involved in sending the message, owing to interference of currents, showed that wireless telegraphy in its present state is not a serious competitor of ordinary wire telegraphy for transmission of messages over land.

A REMARKABLE PROPELLER SHAFT REPAIR

F. E. S.

Did you ever work in a tool-room with one of those chaps who knows it all, who always will take the opposite side of any subject simply to argue, who always can cite without hesitation something that he has seen and done that makes the topic under discussion look like "thirty cents," who is never wrong, who will argue until cornered and then take the opposite side and swear up and down that this (the opposite side) was his point of view from the start of the argument, who will argue over the definition of a word and when the dictionary is produced to prove his argument wrong, will claim that Webster made a mistake? Well, we had one of these individuals in our tool-room, and it happened to fall to the lot of Davey, our apprentice, to actually "take a fall out of him," and he did it to the queen's taste. This "know-it-all" had traveled all over the United States and foreign countries. He had worked five years here and seven years there, was superintendent in Georgia three years, and so on. The total made his age to be about eighty-five years, according to his own tales. He was always able to mention incidents bearing on any subject that had come under his observation in this country or that, and was a veritable walking encyclopedia of wonderful experiences and observations.

One noon hour he was under exceptionally high pressure (hot air), and started off telling a thrilling tale of experience, assuming that all-important "big I and little you" air: "I tell you, boys, you do not have the mechanics to-day that we used to have. To-day the men in the shops cannot do what WE were obliged to learn when I was serving my apprenticeship. I remember one time when I was sailing from Africa to this country and when out about a week the propeller shaft broke clean straight across. We were in a sorry predicament. We did not have a lathe on board and, of course, the ship drifted helplessly. After two days and no signs of a vessel to rescue us, we decided to do something to repair the shaft.

"Say, how did you get the right- and left-hand thread in that big nut?"

"The shaft was twelve inches diameter, and almost everybody on board had some crazy suggestion to make as to the best way to repair the break. Well, sir, there happened to be just *one* mechanic on board, and do you know how he repaired that shaft? Well, I will tell you in a few words. This mechanic took a piece of soft wire and wound it around the shaft in a helix, measuring off the right pitch from coil to coil and putting a drop of solder here and there to hold the wire in place. On the other part of the broken shaft he did the same, only making the helix left-hand instead of right-hand. Thus he laid out left- and right-hand threads on the broken ends.

"Now this mechanic was ready for operations and everybody crowded around wondering what he was going to do next. Giving two men a three-cornered file each he started them to work on the ends of the broken shaft filing a thread guided by the wire that he had carefully wound around. It took just a day to file these threads and then we secured the broken ends of the shaft with a big nut and that shaft is working on that boat to-day!"

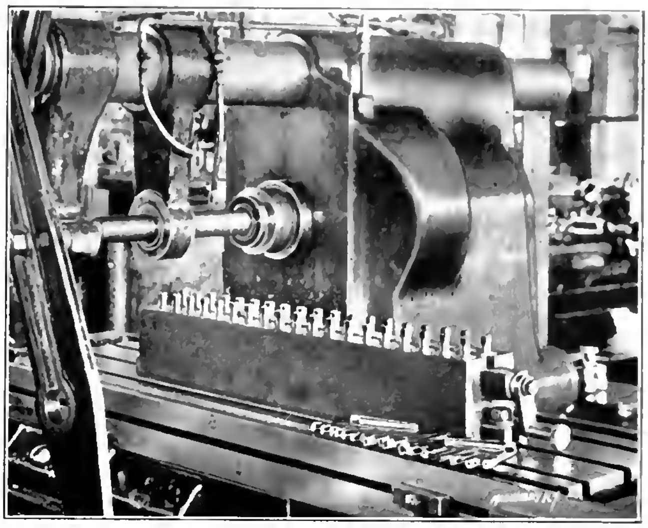
Davey, the apprentice, was first to speak, and he said "Say, how did you get the right- and left-hand thread in that big nut?"

"Why," said one of the boys, "while the two men were filing the thread in the shaft, that wonderful mechanic was gnawing out the nut with his teeth!"

* * *

MULTIPLE INDEXING FIXTURE FOR MILLING SQUARE HEADS

The illustration shows a fixture designed for milling square heads on 38 screws or taper pins at one time. Each piece is held in an individual work-spindle, these being arranged in two rows as shown. The fixture, when filled with work, is fed past two sets of straddle mills on the cutter arbor of the milling machine, which finish two sides of each head at one passage. By turning the crank shown at the end of the fixture, all the work-spindles are then indexed one quarter revolution, and fed past the cutters again, thus completing the square head.

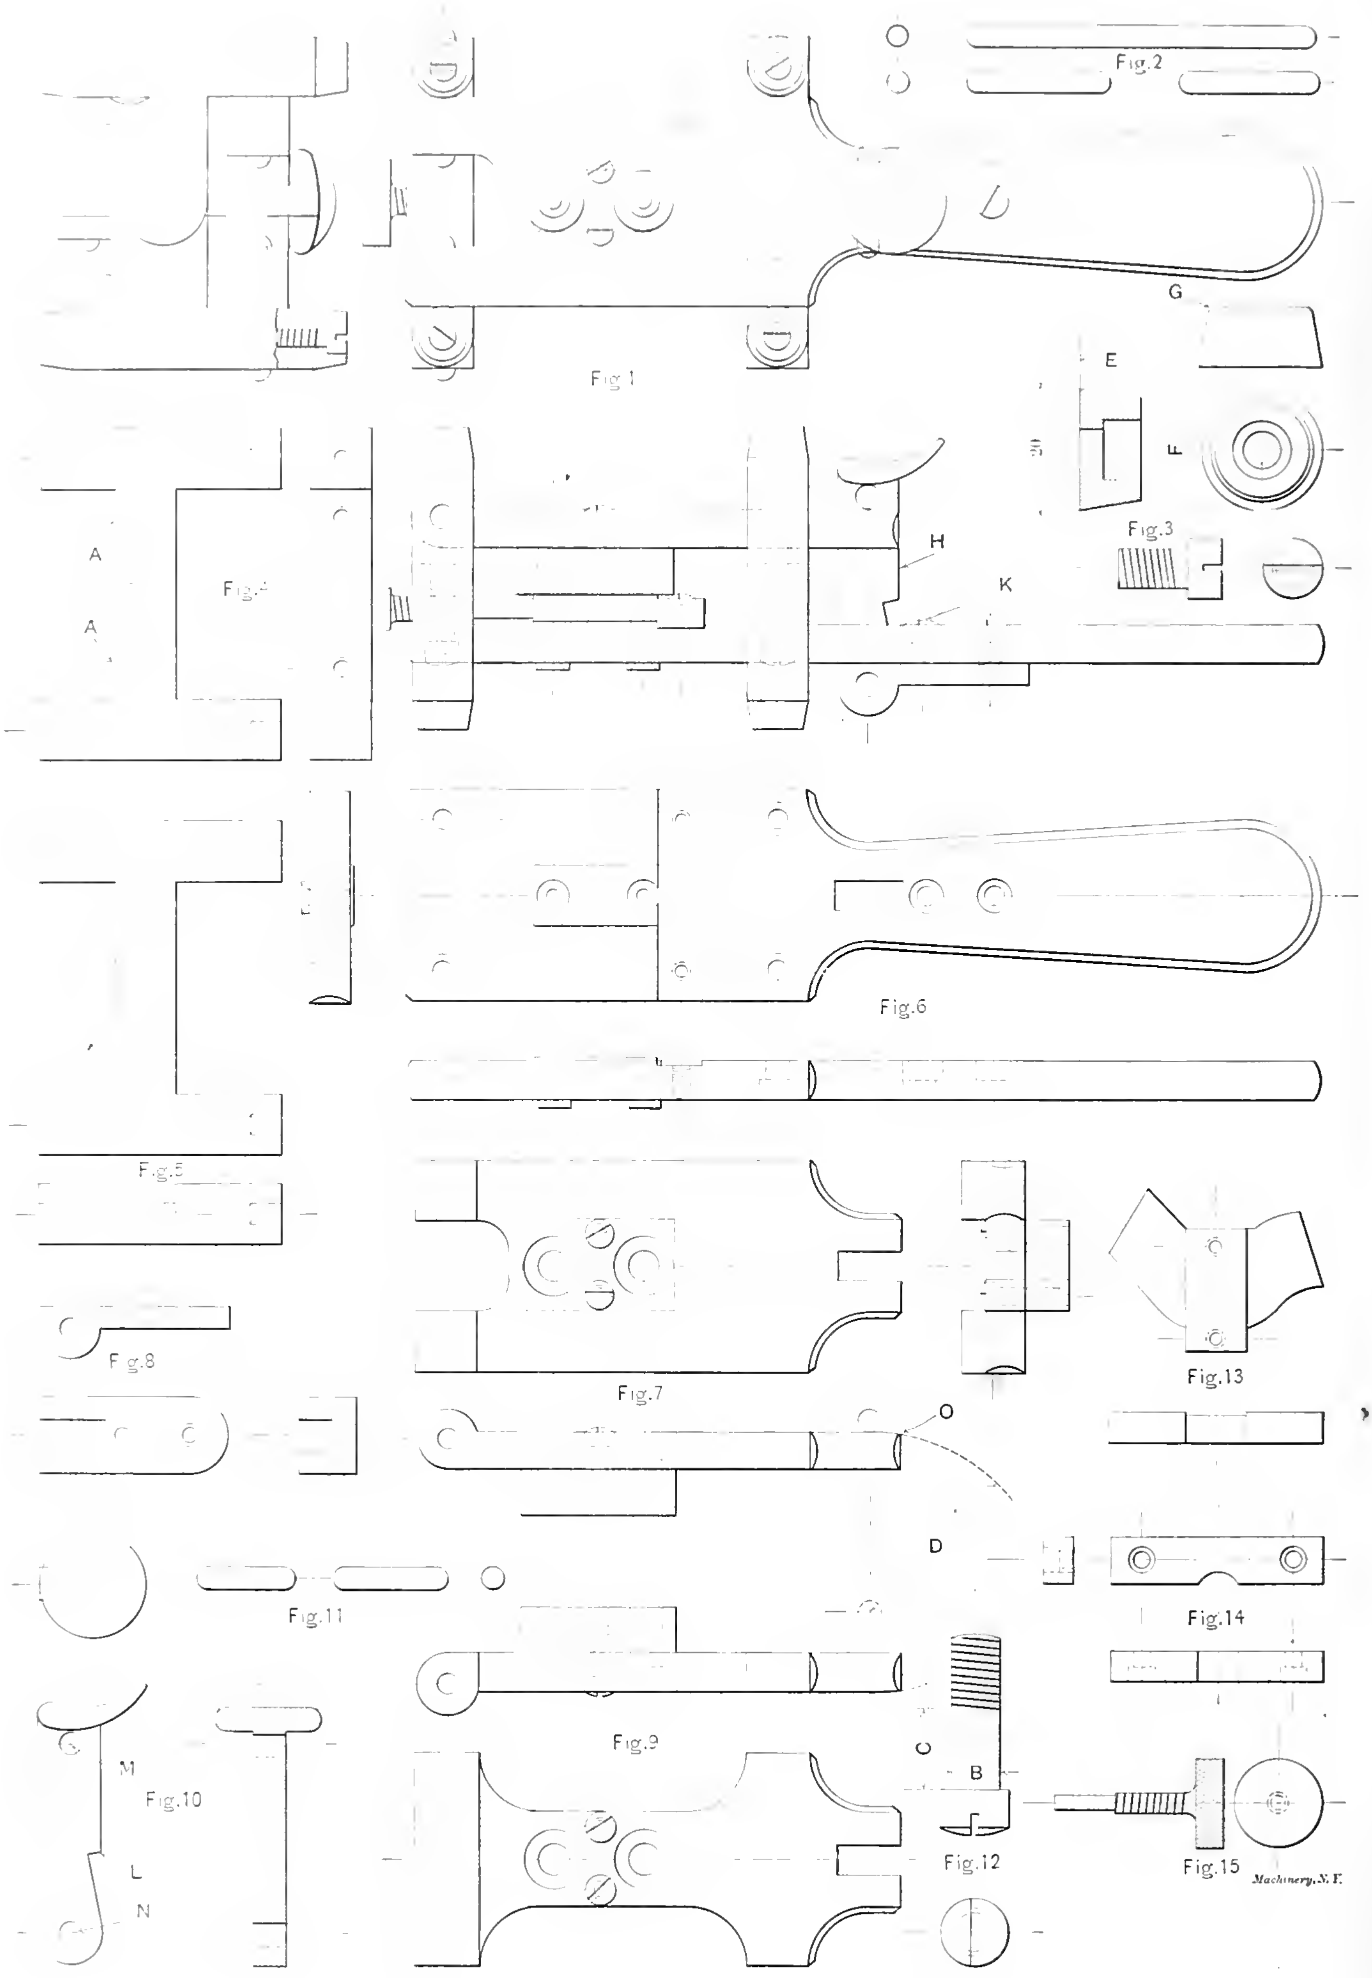


Fixture for Holding and Indexing simultaneously Taper Pins or Screws while Squaring the Heads

The construction is very simple. Each work-spindle has keyed to its lower end a worm-wheel, meshing with a worm running the full length of the fixture, and connected with the crank handle shown. Six revolutions of the latter index the work spindles simultaneously one-quarter revolution. The crank handle has an index pin for locating it in a holder provided in the base of the fixture. Bushings in the work spindles are changed to agree with the parts to be squared. For taper pins simple taper bushings are provided, into which the pins are tapped firmly enough to hold them. After the heads have been squared they are easily removed with a small wrench. Collar screws are firmly screwed into tapped bushings. After the heads are squared they also are easily removed with a wrench. This fixture is in use in the shops of the Landis Tool Co., Waynesboro, Pa.

* * *

The advantages of small additions of vanadium in cast iron are referred to by Mr. J. Kent Smith in the *Foundry*. Small additions of about 0.2 per cent of vanadium are advocated, and examples are quoted showing the increase in tensile strength due to this addition. It also appears that the material does not become harder, but that the increase in strength is obtained without sacrifice of the ease of working the metal. It is mentioned that a locomotive valve bushing of vanadium cast iron which had been in heavy service for twenty-two months showed no signs of abrasive wear, and the original tool marks were still in evidence. A pair of chilled rolls having 0.22 per cent vanadium, showed a wearing life three times that of ordinary rolls made by the same firm without vanadium.

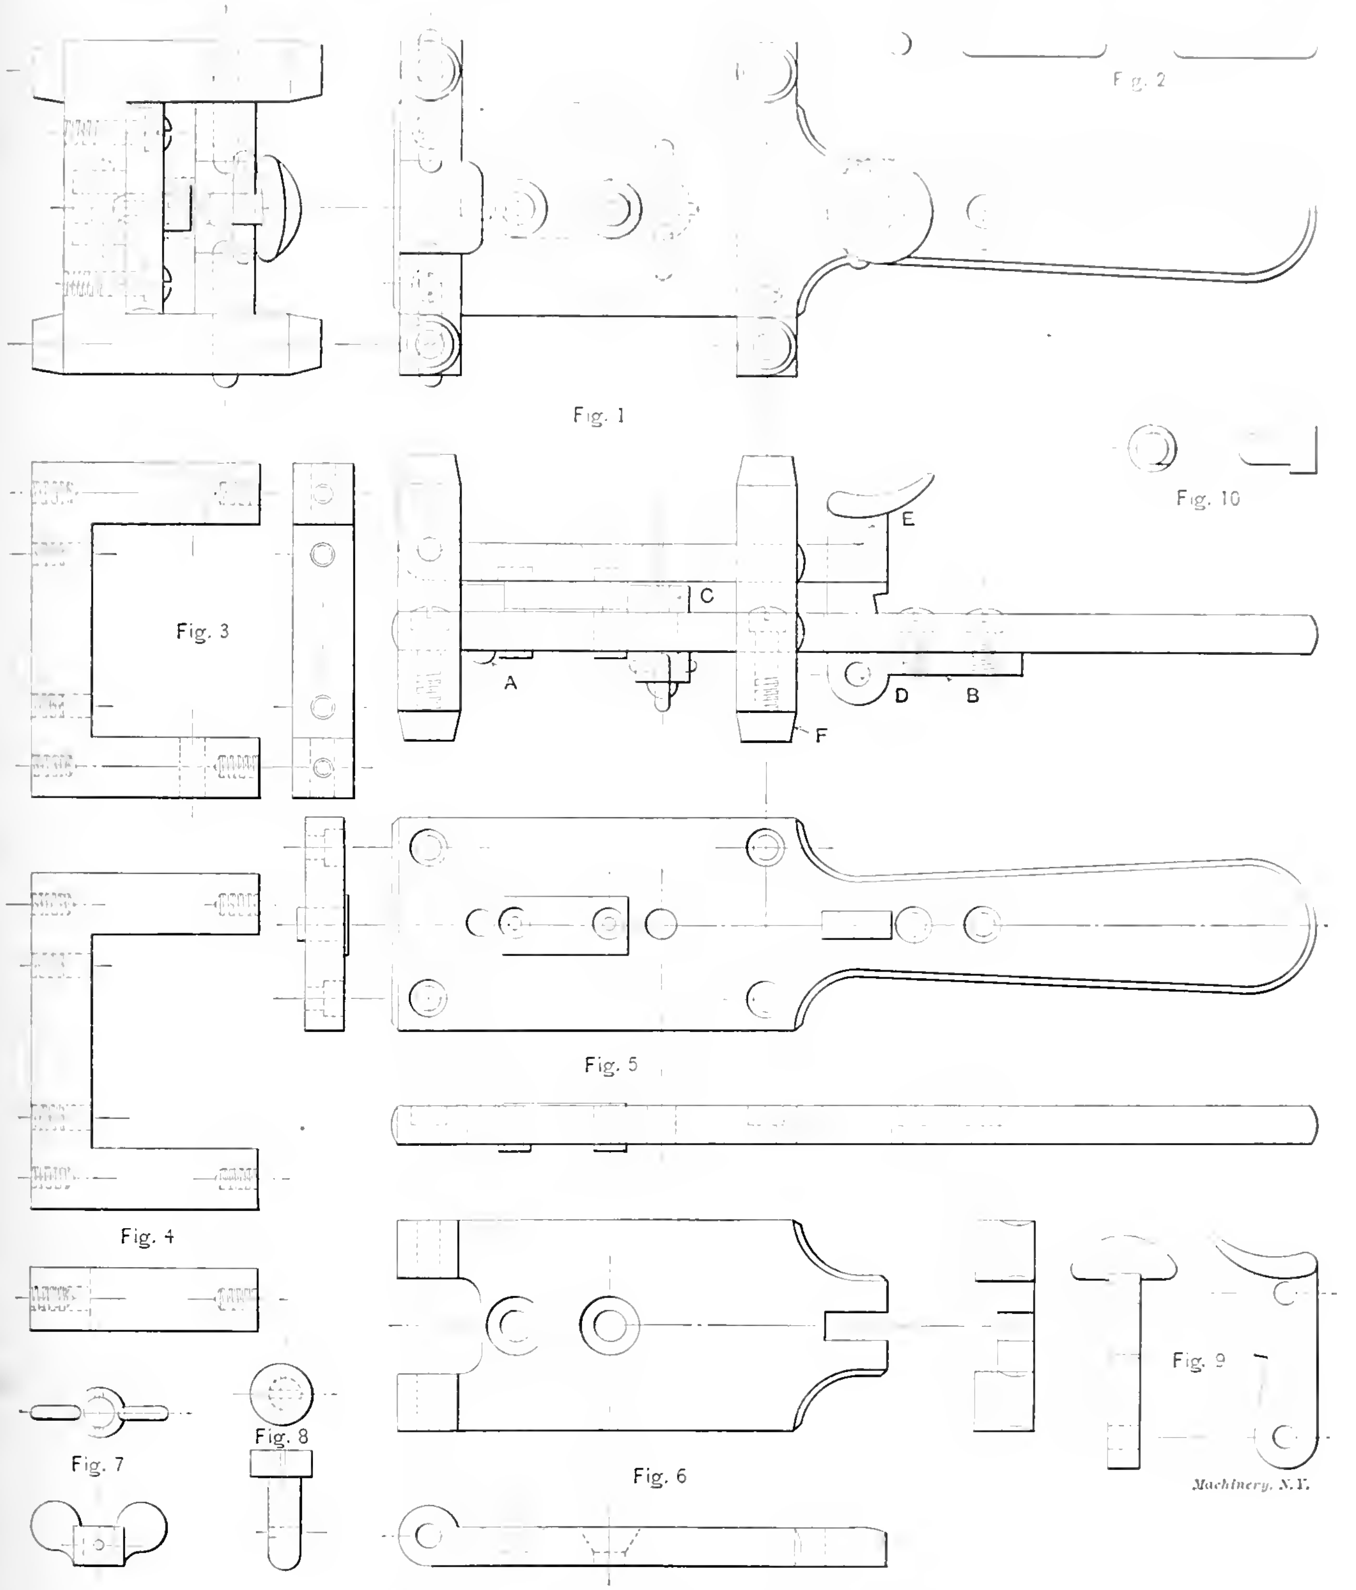


Standard Jig Design No. 1 for Manufacturing Small Interchangeable Parts

STANDARD DESIGNS OF JIGS AND FIXTURES FOR THE MANUFACTURE OF SMALL INTERCHANGEABLE PARTS—1*

FRANK P. CROSBY†

It is a fact well known to most tool designers and toolmakers that no two tool designers usually develop a special tool in the same manner. But little has been done in the way of standardizing the general outlines of jigs and the methods of clamping and locating the work. In the manufacture of large machinery, such standardization is difficult to secure, but in the case of small interchangeable parts it is possible to standardize the design of jigs and fixtures to a considerable extent. In the present series of articles the author will endeavor to show a number of examples of designs of jigs where most of the general features of the jigs are laid out according to a definite standard. The illustrations accompanying the articles will show the jigs referred to both assembled and in detail, and the experienced tool designer will find it more profitable to study the drawings directly than to have to follow a lengthy description of the devices. The descriptions will, therefore, be made as concise as possible, being confined to the most essential points.



Standard Jig Design No. 2 for Manufacturing Small Interchangeable Parts

Design No. 1

Design No. 1, shown in the accompanying full page illustration, is a drill jig for drilling and counterboring a needle bar

---

* The following articles on the subject of jigs and fixtures have previously been published in MACHINERY: Milling Fixtures, November, 1905, to February, 1906; Drill Jigs, November, 1906, to January, 1907; Jigs and Fixtures, April, 1908, to April, 1909. See also MACHINERY'S Reference Series No. 3, Drill Jigs; No. 4, Milling Fixtures; and Nos. 41, 42, and 43, Jigs and Fixtures.

Standard Jig Design No. 3, for Manufacturing Small Interchangeable Parts

cam for a sewing machine, the cam being shown in detail in Fig. 13. It is required that the rivet holes in this cam be drilled and counterbored.

Fig. 1 shows a plan view, elevation and end view of the assembled jig. The jig is shown closed, ready for operation, with the work placed in position. Fig. 4 shows the standard H-shaped frame which can be employed for a great variety of small details of different shapes. The frame has holes tapped for the screws holding the feet, and is provided with the required drilled and tapped holes for the adjusting screw, the frame screws *A* and the hinge pin. The frame screw holes are reamed to a depth of one-half of the thickness of the frame cross-bar. Fig. 12 shows the frame screws in enlarged detail; the diameter at *B* should fit accurately the holes in the lower plate, Fig. 6, and also the reamed part of the holes in the frame, Fig. 4. By making the screws in this manner they serve the purpose of both screws and dowels. The dimension *C* of the screw, Fig. 12, should be a trifle less than the whole distance through the plate and one-half the distance through the frame, in order to permit the screw to bind properly. The diameter of the body part *B* of the screw is 0.005 inch larger than the outside of the threaded portion. The frame shown in Fig. 5 is an exact duplicate of that shown in Fig. 4, with the exception that no holes for the hinge pin and adjusting screw are here required. In Fig. 3 is shown an enlarged detail of the washers serving as feet for the jig, and also of the screws holding the washers to the jig. These parts are made of machine steel and case-hardened. The depth *E* is, on all sizes, made one-half of the diameter *F* and the corner *G* is chamfered to prevent scratching the drill press table. The counterbore in the washer is made a trifle deeper than the length of the screw head, to prevent the head from projecting outside of the counterbore.

Fig. 6 shows the lower plate, firmly held to the frames by the four frame screws already referred to. This plate contains the jig bushings which are shown in place. Fig. 7 shows the top or hinged plate, which is provided with a case-hardened bearing which holds the work against the lower plate by the pressure of the clamp latch *H*, Fig. 1. The arc with the radius *D* is struck from the center of the pin about which the clamp swivels. In Fig. 9 is shown a modification of the hinge plate. The construction is lighter, which in some cases is desirable. The plates are provided with ample clearance holes for drills and counterbores. In Fig. 2 are shown the hinge pins for both of the styles of upper plates. These pins are made from drill rod. In Fig. 8 is shown the latch holder which is attached to the bottom plate by two screws, as shown at *K* in Fig. 1. The latch itself is shown in Fig. 10. It has a notch cut at *L* to allow it to swivel so that its binding pin can clear the end *O* of the hinged plate. The latch can be made up as a standard part except for the pin hole *N*; the pin hole *M* only is drilled, and the hole *N* is left until the dimension from the center of *M* to *N* is known for any particular jig being made. This piece is case-hardened after it has been fitted. In Fig. 14 is shown the stop for the work which is attached to the lower plate and enters a slot in which it is held by two screws. In Fig. 15 is shown the adjusting screw which is also a standard detail. The pins in Fig. 11 are for the latch; these are made from drill rod and hardened.

Design No. 2

Design No. 2 shows a jig for drilling the same part as in Design No. 1, with a slight variation in details. Here also an assembled drawing consisting of plan view, elevation and end view, is shown. In this case both the upper and the lower plates of the jig are placed on the same side of the cross bar of the frame. This permits the plates to be set as close together as required for any piece of work to be drilled in this style of jig. Figs. 5 and 6 show the details of the lower and upper plates, respectively, and Figs. 3 and 4, the details of the frames. In Fig. 9 is shown the latch which is of the same kind as that shown in the Design No. 1. Fig. 7 is a wing nut with the threads removed and is also one of the standard parts used. In Fig. 8 is shown an eccentric cam which may be used in a great many different jigs, and which provides for a convenient means for clamping the work in place. This eccentric cam is turned by means of the wing nut, which is pinned to its stem as plainly indicated in Fig. 1. The stop shown in Fig. 10 is placed at the end of the work opposite the cam, and the work is held between this stop and the cam. The stops can be made standard. They should be made to the same dimensions as the screw heads so as to suit the holes made by the screw head counterbores. The other parts required for the jig, the hinge pins, Fig. 2, the pins *E* and *D* for the latch, as well as the bracket *B*, and the feet, are standard parts of the same dimensions as used in Design No. 1.

Design No. 3

The jig designated as Design No. 3 is used for drilling the two pieces shown in Fig. 8. The only difference between the two pieces is the variation of the width *A*. These pieces are drilled from three sides. In Fig. 1 is shown the assembled jig with the work in position, in Fig. 6 the lower plate with all the bushings in place, and in Fig. 7 the upper plate which is fitted with a projection which clamps the work on the side *C* in Fig. 8. The upper plate is also provided with a clearance hole at *D* for the counterbore. Fig. 3 shows the stop against which the work is held by the binding screw *E*. This stop is made from machine steel and case-hardened and fits into the recess shown at *F*, Fig. 6. The clamping screws *G*, Fig. 1, hold the work firmly against the wall *H*. In Figs. 4 and 5 the frames are shown; both of the frames are alike with the exception of the binding screw hole at *K* in Fig. 5 and the hinge pin holes at *L* in Fig. 4. The upper plate or leaf is held in position by the latch *M*, Fig. 1, which is shown in detail in Fig. 9. Figs. 12, 13, and 14 show the binding screws in detail. Fig. 15 shows the method of making up the standard latch for different jigs, the dotted lines indicating how the latch is finished to different lengths required.

General Remarks

Upon examination of the illustrations shown as Designs 1, 2 and 3, the tool designer will be surprised to find to how many small parts these general designs can be applied, and he will realize that with slight modifications, a variety of jigs can be made up from parts most of which can be kept in stock. The drawings have been made in the same manner as they would be made for shop use, with the exception that dimensions have been left off. Complete details are shown, as this is most essential to the proper making of the tools. It is a great mistake not to show the work in detail, as is sometimes the practice in jig and fixture work, because but little extra time is required in the drafting-room, and that time is more than made up for by the ease with which the tool-maker can understand the construction of the tool. The liability of mistakes is also largely eliminated and there is no need of verbal explanations as is otherwise often the case.

* * *

LIGHT GASOLINE MOTORS

In the July, 1908, number of MACHINERY there appeared an illustrated description of the Adams-Farwell multiple-cylinder gasoline engine built for an aeroplane flying machine that is remarkable for extreme lightness. It has a capacity of 36 horse-power (figured by the A. L. A. M. rule) with a weight of only 97¼ pounds. The weight per horse-power, therefore, is only 2.7 pounds. To produce one horse-power or the equivalent of lifting 33,000 pounds 1 foot high in one minute with a dead weight of only 2.7 pounds was and is a most remarkable achievement. Whether the flying machine ever develops into a commercial possibility or not, the fact that experimental work on it has enabled us to develop power with such remarkably light engines, means much for many other businesses in which light motors are desirable. It is interesting to compare the weight of this motor per horse-power with the massive engines constructed in the time of James Watt. Then, and many years later, it was the common belief and practice that great weight was essential in large engines. The development of the marine engine did much to show the fallacy of this idea, and the later development of the automobile engine still further discredited it. The airship motor is the last word to date.

TRUING A BENCH LATHE BED

WALTER GRIBBEN*

The bed of the lathe that is much used naturally wears hollow just in front of the head-stock, and this is particularly the case with a bench lathe, as this type is used largely for chuck work. Such a lathe had been in almost constant use for nearly twenty years, so it was thought advisable to true up the bed. A cast iron templet of the shape shown in Fig. 1 was first made. The length of this templet was about two-thirds that of the lathe bed, and two V grooves were planed in it that were duplicates of the grooves in the bottom of the tail-stock. The templet was made in the form shown so that it would resist bending or torsion, and yet not be very heavy.

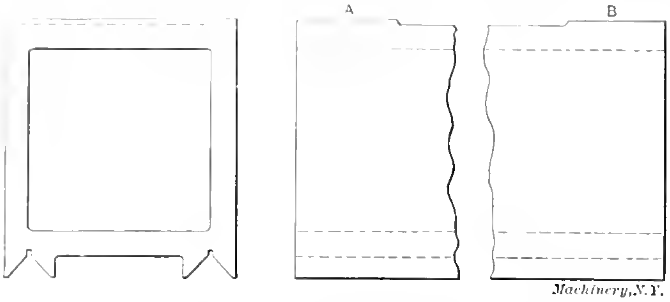

Fig. 1. Master Surface Plate used in Scraping the Ways of the Lathe Bed

The distance between the V's of the lathe bed was determined by means of a microscope held vertically in the slide rest as shown in Fig. 2. A brass block *A* was made with a V groove in the bottom to fit the V's on the lathe bed. On the top of this block two fine lines were scribed, one being parallel to the lathe bed, and the other at right angles to the first, but not quite touching it. This second line was to ensure the observations both being taken at the same part of the first line, in order to eliminate any error that might arise from want of parallelism between this line and the bed. The block *A* was first laid on the front V and the microscope sighted on the marks on its surface, which appeared through the microscope as shown at *B*. As indicated, the eye-piece of the microscope has cross lines arranged like the letter X. By adjusting the cross feed-screw and the block *A* along the bed, the intersection of these lines was made to coincide with one edge of the longitudinal line at a point opposite the transverse line. When the block and microscope were set, the reading of the cross feed micrometer was noted. The block was then placed on the back V of the lathe bed, after which the cross slide was moved until the intersection of the cross lines again coincided with the line on the block as before. The reading of the cross feed micrometer was again taken, and a comparison of the two readings noted, allowance being made for the number of complete turns that had taken place. By this method the distance between the V's from apex to apex was obtained. A gage with hardened and lapped ends was then made, of 5/16-inch drill rod, to exactly this dimension. This gage was enclosed in a wooden jacket as shown in the end view at *A*, Fig. 3, to prevent changes in its length from the heat due to handling. The lower side of the jacket, and also the side against which the strip *a* is screwed, were both made parallel to the length of the drill rod, so that when the enclosed gage was laid on the cross rail it would be parallel with the latter.

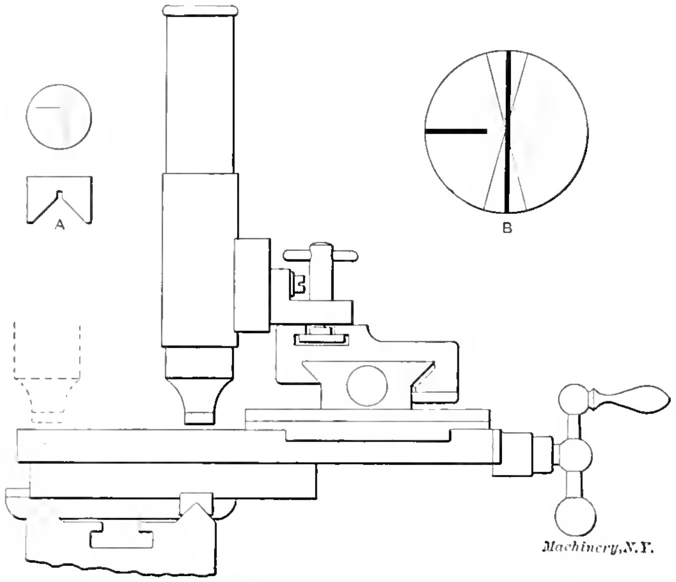

Fig 2. Obtaining the Distance between the Ways by the Use of a Microscope

The templet casting was first placed on the planer in the position shown in Fig. 1, and the feet *A* and *B* planed. Care was taken not to clamp the casting down any tighter than was necessary during this operation. It was then turned over so that the planed surfaces rested on the platen to which red-lead had been applied in order to determine if both feet touched it throughout their entire area. This was found to be the case, so the V's of the templet were next planed. The dial indicator *B* was clamped to the cross rail of the planer as shown in Fig. 3, and the saddle brought into contact with it while planing one V. The gage *A* was then interposed between the saddle and the indicator while planing the other V, the saddle being so adjusted for the finishing cuts that the indicator read the same in both cases. When the head was swung over to plane the other slope of the V's, of course the indicator had to be moved to a new position on the cross rail. The same scheme was also used to space the two positions of the parting tool that was used to cut out the bottom of the grooves, preliminary to planing the V's.

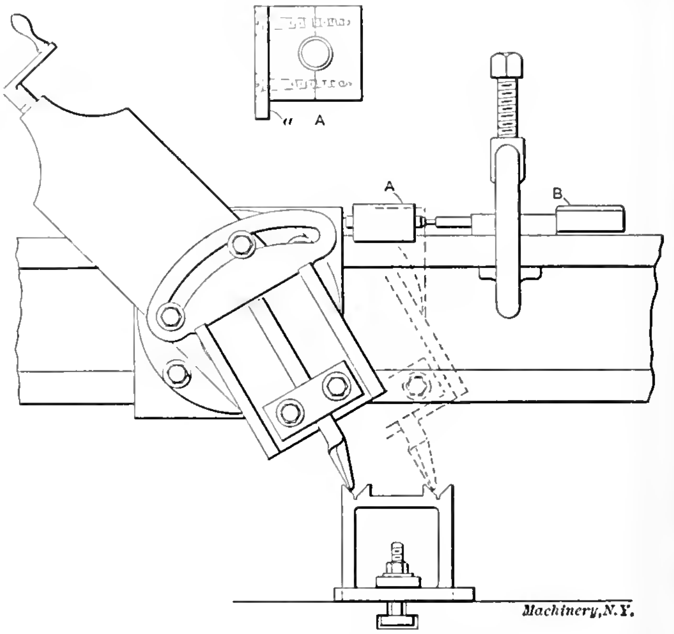

Fig. 3. Planing the V's in the Master Surface Plate or Templet

After finishing the planer work on the templet, it was tested with a spirit level both for wind and straightness. Two pieces of 3/8- by 5/8-inch rolled brass were drilled, tapped, and the face *a* (Fig. 4) carefully turned at one chucking; these pieces were then screwed on the chuck. The finishing cuts for both pieces were taken with the same setting of the milling cutter so as to make them exact duplicates in regard to the location of the V-surfaces in relation to the faces *a*. The method of testing the templet for wind is shown in Figs. 5 and 6. The templet was supported on the bench by three leveling screws, *C* and *D* being at one end while *E* was at the other. The two brass pieces *B* were then laid in the V grooves near one end of the casting, and a ground spirit

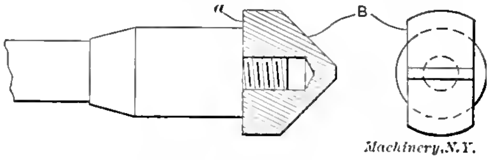

Fig. 4. Method of Machining the Small V-blocks used as indicated in Figs. 5 and 6

---

* Address: 314 Halsey St., Brooklyn, N. Y.

level laid on top of them as shown. The screws *C* and *D* were then adjusted until one end of the bubble coincided with one of the marks on the vial. Then the blocks *B* were moved to the other end of the casting, and the level applied as before. The bubble moved to the mark with which it coincided before, thus showing that there was no wind in the V's that could be detected with that particular level. It was not a precision level, but was a great deal better than the ordinary blown level. The vial was ground true on the inside, while the outside was marked transversely by lines about 1/10 inch apart, the curve of the vial being such that the travel of the bubble from one mark to the next represented a change in direction of the base, amounting to .012 inch per foot. By using a magnifying glass, much smaller variations than this could be detected. As an accurate straight-edge of sufficient length was not available for testing the straightness of the V's, they were verified by using the spirit level and the blocks *B* as shown in Fig. 6. The blocks were first placed near one end of the casting, and the screw *E* adjusted until one end of the bubble coincided with one of the marks of the vial. The blocks and level were then moved to different positions along the length of the groove, and as the bubble remained in the same position, it was assumed that the planing was straight enough for the job in hand. In order to true up the V's of the lathe bed, a thin layer of Prussian blue was applied to the V grooves of the templet which was then moved along the bed to transfer the coloring matter to the parts that needed scraping down. After a sufficient amount of scraping, the V's on the bed showed a bearing throughout their entire length when the templet was applied.

* * *

Most of the penny-in-the-slot machines are worked by "victimized power"; that is, power derived from the patron or "victim." The patron furnishes the muscle that works the mechanism as well as the cent that releases the operating machinery. Strange to say, the element of action on the part of the user is an important factor in the success of some of these machines. It appears that many of the users of these machines enjoy pulling a lever; they somehow feel that they are getting more for their money than if they simply pressed an electric button. A certain fortune-telling machine was first put out with an electric motor driving the machinery. The patron only had to deposit his coin and place his hand on a slab in which there are many projecting studs to have his fortune told. The machine did not prove to be a "money puller." The motor was discarded and a long lever was substituted, which must be pulled each time a fortune is told. This machine yields a handsome income. The experience adds to our knowledge of the curious phases of human psychology.

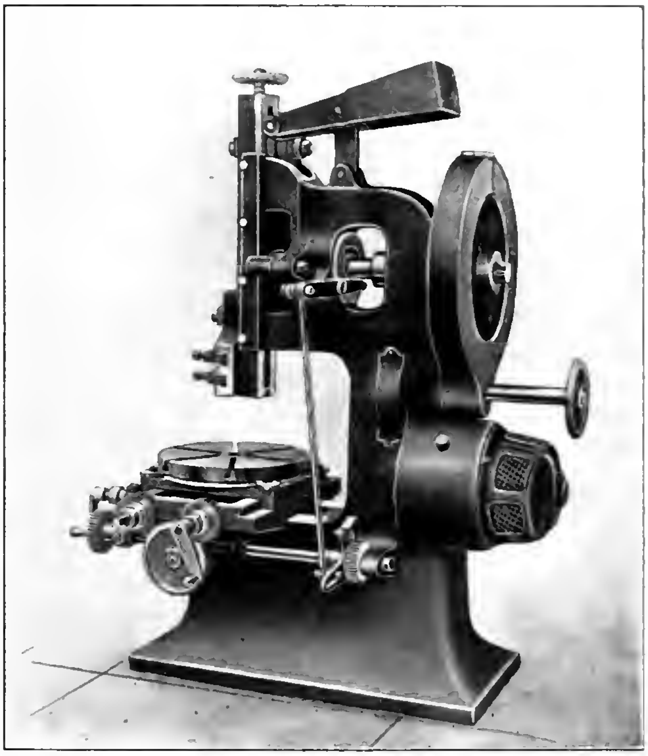
* * *

The "bleeding" of pine trees for their resin has generally been regarded as injurious to the timber, and in the specifications of many architects and railway companies, the "bled" timber is excluded. Investigations have been undertaken by the Forest Service of the United States Department of Agriculture in order to ascertain to what extent such timber is injured. The results of these tests indicate, however, that the "bled" timber is as strong as the "unbled" if of the same quality otherwise; that the weight and strength is not affected by the "bleeding"; and that the durability is the same of "bled" as "unbled" timber.

ENGLISH TYPE OF ELECTRICALLY-DRIVEN SLOTTER

JAMES VOSE

The slotter illustrated herewith is one of the line built by John Stirk & Sons, Halifax, England. The distinctive feature of this machine is the motor drive which, as will be seen, forms an integral part of the design. Incidentally this feature has proved of value in an unexpected direction as under the revised tariff of one of the British colonies, if a motor forms an integral part of a machine, as in the present case, the duty on the electrical portion is on a lower scale than if the same size motor was applied as an attachment. The motor for this machine may be of the direct-current, constant-speed, shunt wound, or direct-current, variable-speed, interpolar type. The motor being built into the machine economizes space and adds to the rigidity of the design. The number of strokes arranged for varies from 20 to 60 per minute, a gear box being used in conjunction with the constant-speed motors. The length of the stroke ranges from 6 to 24 inches. The table diameter is 24 inches, and its longitudinal and transverse movements are 12 and 15 inches, respectively. The machine will take work up to 46½ inches in diameter on top of the table. Both longitudinal, transverse and rotary power feeds having a wide range, are provided. The size of machine shown is equipped with a 2½ H. P. motor. The complete weight of the slotter is approximately 5,500 pounds, and the price F. O. B. is $735.00.



Electrically-driven Slotter with a Motor which forms an Integral Part of the Machine

[There are doubtless advantages in having the motor an integral part of an electrically-driven machine, but it has been demonstrated by American machine tool builders, that what is gained in the way of compactness and rigidity is more than offset by the disadvantages of such design. In event the motor of a machine, of which it forms an integral part, is incapacitated by the burning out of an armature or otherwise, the machine will have to remain idle until repairs can be made, unless, as is not probable, the defective motor can be replaced by another. If, however, the machine were driven by a standard motor, which was simply bolted to the frame, the latter could easily be removed and replaced by another if necessary. In a shop where electrically-driven machines are in use, it is more than probable that such a motor would be available, and, consequently, it would not be necessary to keep a valuable tool idle.—Editor.]

ROLL GROOVING MASTER TOOLS*

M. B. STAUFFER†

The method of making the master tools which are used to make the cutting tools for grooving flour-mill rolls, is described in the following (since a large per cent of mill rolls are 9 inches in diameter, I shall treat that size tool):

The blanks are first made as shown in Fig. 1, the outside being rough turned. They are then gashed, as shown in Fig. 2, with the proper number of teeth, which ranges from eight to twelve. After keyseating the blank it is placed on the milling machine arbor in proper relation to the cam *D*, as shown in Fig. 3. It is desirable to have the cam operate as shown, as the tool will then be positively withdrawn from the work and interference will be avoided.

The circular attachment is placed on the milling machine table and set so that its center line coincides with the center of the blank *A*.

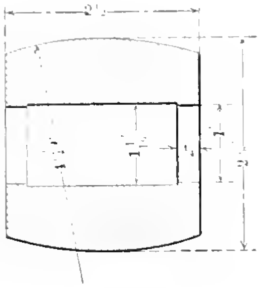

Fig. 1. Rough-turned Cutter Blank

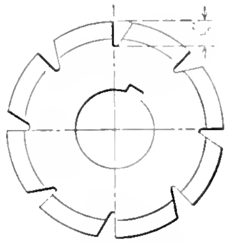

Fig. 2. End View of the Gashed Blank

On the circular attachment is placed the auxiliary tool slide *B* which should be arranged with a positive stop. For the finishing cut, the point of the turning tool must be 4½ inches from the center of the attachment. The feed screw nut must be disengaged from the feed screw and a spring or weight attached to the table to keep the stop *C* against cam *D*. The tool should be set to the same height as the center of the arbor.

We are now ready to proceed with the finish turning and simultaneous relieving of the lands. After turning the blank, the tool shown in Fig. 6 is inserted in the slide. This tool must have enough clearance to allow for the advance of the cam. The first serration should be to the full depth, as shown in Fig. 4, and the positive stop should then be set. It will be understood that when the tool just touches the blank it must be 4½ inches from the center of the attachment. The indexing is done by use of the dial on the hand-wheel shaft of the circular attachment. It is imperative that the indexing be accurate or the cutting tools will not work well and may break the corrugations on the rolls.

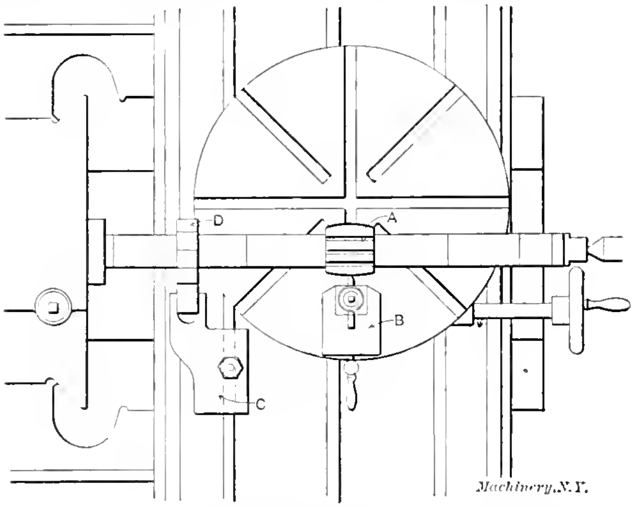

Fig. 3. Milling Machine arranged for Finish Turning and Serrating the Cutter

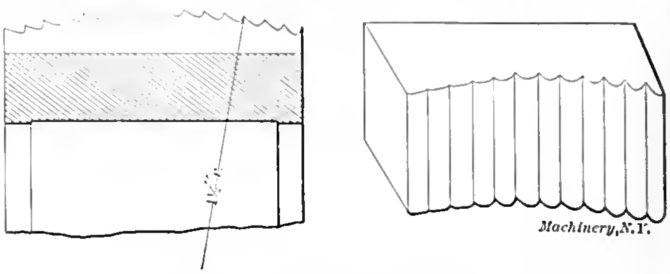
The depth of the serrations depends entirely on the style of corrugation. The one shown is commonly called the "saw tooth" corrugation and is 1/16 inch deep when standard, having 1/16 inch pitch.

The clearance will not be ideal but near enough for all practical purposes. The tools will be superior to the old style tools which were made without clearance, and which burnished the metal into shape instead of cutting it. When finished, the cutters look like the one shown in section, Fig. 4.



Figs. 4 and 5. Section of the Cutter, showing a Serrated Tooth, and One of the Grooving Tools

A convex cutter without serrations will be found very useful for milling the cutting tools, Fig. 5, concave. The cutters may be hardened in oil and need not be drawn to more than 400 degrees Fahrenheit. They must be carefully handled and should be used only on well-annealed stock, or the sharp points will be quickly destroyed.

---

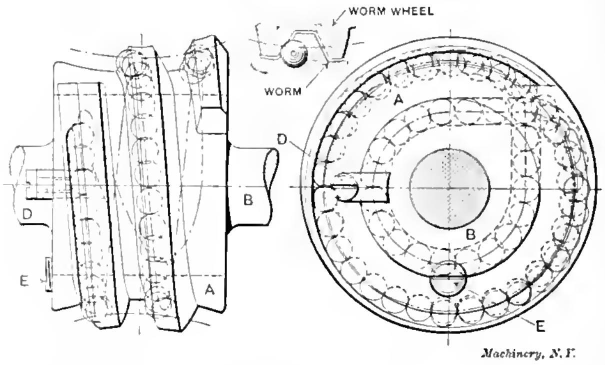
A BALL-BEARING WORM

Some years ago there was described in the various technical papers a ball-bearing nut, designed by the Sprague Elevator Co. for use in passenger elevators. A helical row of balls was interposed between the threads of the nut and those of the screw, to receive the thrust of the load. A suitable transferring tube led the balls from the top of the nut back to the bottom (or *vice versa*) where they again entered the space between the nut and the screw. The balls thus followed through their path in a continuous stream furnishing a rolling contact between the screw and the nut to take the pressure of the load.

Fig. 6. Tool for Serrating the Cutter Teeth

In the accompanying illustration, taken from *Le Genie Civil*, is shown a worm which is a counterpart of the Sprague Elevator screw. The acting face of this worm is channeled to form a race for an endless row of hardened steel balls, which are led at one end of the thread through an internal return duct, re-entering the race again at the other end of the thread. The construction is plainly shown in the engraving.

The worm is of the globoid or Hindley type, with a concave or "hour-glass" shape. The threads are cut on a shell *A*, which is mounted on a body *B*, to which it is held by screw *E* which prevents it from moving and thus as well from turning. A channel of such shape as to retain the balls is cut in the acting face of the worm. A corresponding reversed helical groove is cut in the periphery of the body *B* to lead the balls back again, suitable connecting holes being drilled between the grooves in *B* and those in the teeth in *A*. The channel is filled full of balls through an opening, closed by a cover and screw at *D*.



A Worm whose Contact with the Wheel is made on Ball Bearings

This ball bearing worm is built on what is known as the Système Parrouff et Arlaud. The scheme is interesting, but it appears that there would be a sliding movement in a direction radial to the axis of the worm which the ball bearing will not take care of. It must be admitted, however, that the construction shows great ingenuity.

AUTOMATIC MILLING MACHINE ATTACHMENT FOR MANUFACTURING INTERNAL GEARS

In the *Zeitschrift des Vereines deutscher Ingenieure* of March 20, 1909, is described a slotting attachment for the milling machine, particularly adapted to cutting the teeth of internal gears, and for doing internal slotting in general which requires the indexing of the work. Fig. 1 shows the attachment applied to a milling machine, while Fig. 2 gives the details of its construction.

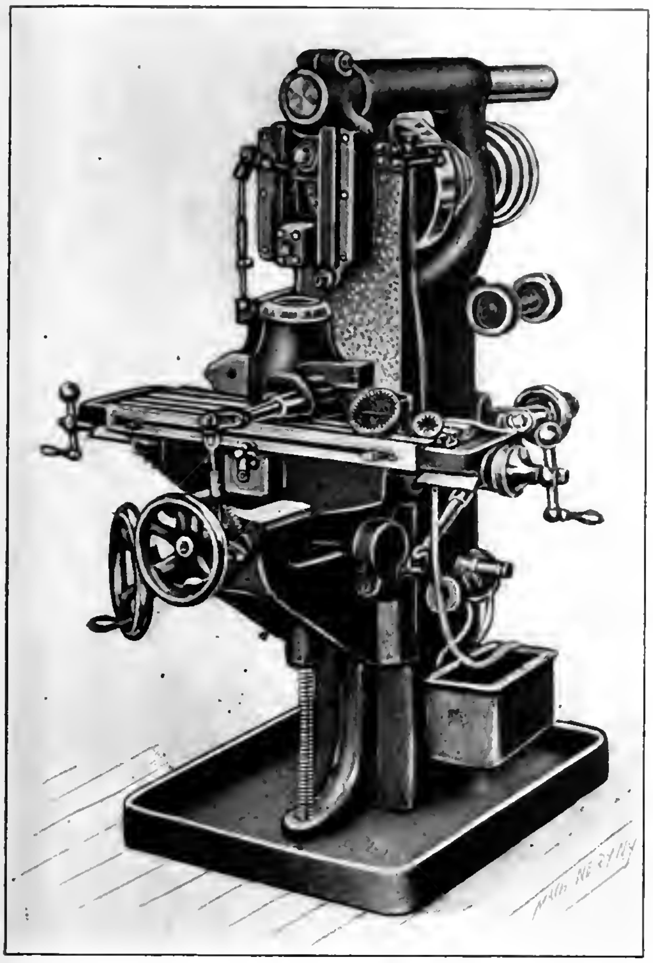

Fig. 1. Slotting Attachment to Milling Machine for Cutting Internal Gears in Quantities

This device consists of two parts—the slotting attachment proper, and the work holding and indexing device. The slotting attachment consists of a ram *A*, which slides in ways in the body of the device, and is driven by a crank-pin attached to the milling machine spindle. The length of stroke is adjustable. The body of the device is fastened to the supporting arm of the milling machine, and is screwed to the column as well, to prevent motion sideways. The work *M* is gripped in a chuck *H*, bored to receive it, and held by dowel pins and screws to the spindle *S*. The work is indexed at each stroke of the tool on the up movement of the ram. This is effected by stud *B* on the ram *A*, operating through the connections *C* and *D*. The vertical plunger *E* has rack teeth cut in it, engaging the teeth in the gear *F*, which in turn meshes with pinion *G*. The latter engages the rack teeth of the horizontal plunger *I* and is thus moved positively forward at the end of the up stroke of the tool. It is drawn back again by the spindle as soon as the tool slides forward to descend. Connection is made by the rack *I* and a lock bolt *N*, so that the latter is withdrawn as *I* moves forward, leaving locking wheel *L* and index ratchet *K* free to revolve the work spindle and the work. A dog on rack *I* engages a stop, not visible in the illustration, which turns the index ratchet *K* and at the same time the chuck *H* and the work. At the conclusion of the movement locking bolt *N*, under pressure of spring *P*, slides back, locking the spindle and the work in the new position. Lock disk *L* and ratchet *K* must have the same number of teeth as the gear to be cut.

When a complete revolution of the work has been made by the means described, the saddle is moved outward slightly along the slide, thus setting the work for a new cut. This is effected by lever *W*, shown in dotted lines, which is pressed upward by dog *R* on a plate keyed to the spindle. By this means, through rod *V*, the arm *U* is operated, and the ratchet wheel turns the cross feed screw slightly, thus setting the work to depth for a new cut. Adjustable dog *T* limits the amount of feed. Provision is made throughout this attachment, by adjustable connecting rods and universal joints, for setting the machine up for work of widely varying dimensions.

This method of cutting internal gears has some advantages over the method of cutting them with an internal attachment in the automatic gear cutter. The drive for the cutter by the latter method is far from satisfactory, and it is necessary always to provide in the work a large clearance space for the cutters to run out into. Using the slotting attachment shown herewith, a narrow groove will suffice to give clearance. The indexing of the work at every stroke, and the provision for stopping the feed when the proper depth of cut has been reached, make the device automatic, so that the operator is free to attend to other work. There remains only the necessity for occasionally cleaning the work of chips, where the clearance space provided is unusually small.

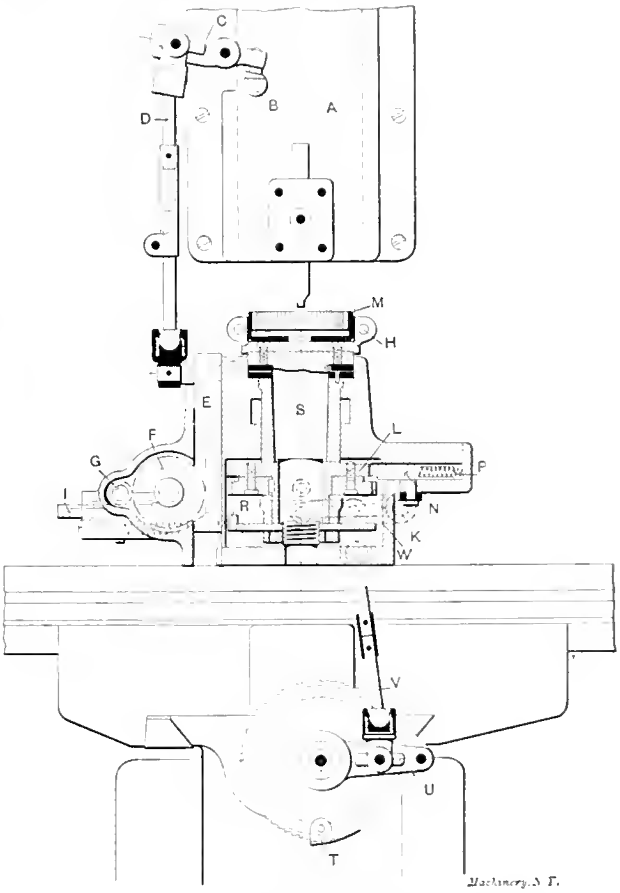

Fig. 2. The Mechanism of the Automatic Slotting Device for Internal Gears

* * *

The total exports of machine tools from Germany in 1908 amounted to 58,522 metric tons, and the total imports in the same year to 5,843 tons. The exports increased by 500 tons, while the imports decreased by 2,300 tons, from the previous year. Germany's best customer for machine tools is Italy, with Austria-Hungary a close second. France, Belgium and Russia also take a great deal of their machine tool supply from Germany. Of the imports of machine tools, more than 50 per cent came from the United States.

Matthew J. O'Neill, Secretary.

Fred E. Rogers, Editor.
Ralph E. Flanders, Erik Oberg, Franklin D. Jones, Ethan Viall,
Associate Editors.

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit exclusive contributions from practical men on subjects pertaining to machine shop practice and machine design. All accepted matter is paid for at our regular space rates unless other terms are agreed on. All copy must reach us by the 5th of the month preceding publication.

JULY, 1909

PAID CIRCULATION FOR JUNE, 1909, 20,947 COPIES

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 650 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

LIMITATION OF MACHINE CAPACITY

The improvement in machine tool capacity during the last few years, since the introduction of high-speed steel, apparently has brought designers in sight of the ultimate limit of profitable capacity on certain machines which require manual operation. When the efficiency of the machine reaches the point where the handling of the product to and from it requires as much time as the actual operation, the opportunity for profitable increase of mechanical efficiency has become small, and it soon vanishes beyond that point. Further gain can only be made by dispensing with the operator, making the machine automatic, and the moment this is done an entirely new set of conditions is created.

To illustrate the point, take the case of high-speed drilling. Several months ago we referred to a drilling machine that on test had make the remarkable record of drilling cast iron with a 1½-inch high-speed drill at the rate of 29 inches per minute. So rapid was the downward travel of the spindle that it was necessary to set the feed throw-out stops before starting in order to prevent drilling into the platen underneath, even when the work was raised an inch above it! Suppose this piece had four holes, 4 inches deep, to be drilled. Then the actual drilling time required would be, say, 34 seconds. The time for lifting the casting upon the machine, adjusting the drill to the drilling positions and its removal would be, say, one minute, the best that could be done. That is, the handling time is nearly double the drilling time, and the actual drilling time bears a smaller and smaller relation to the handling time as the mechanical efficiency is increased, soon becoming so small a fraction of the operator's time after even time is passed, as to make further increase of mechanical efficiency unprofitable.

In the case of driving-wheel lathes, the production has reached the figure that makes the labor cost of handling the wheels greater than the operator's wages. Further improvement must be in the direction of reducing this labor cost, or, to put it more plainly, after a certain degree of mechanical efficiency is attained, it becomes more profitable to make further improvements outside the machine to reduce the labor and time of handling the material by devising extraordinary means for handling the work with speed. There is, however, the possibility of so highly developing a machine and its attendant features as to throw the shop out of balance because of lack of coordination of other departments. Often in such cases the highly developed machine cannot be profitable to the shop until the other parts are brought up somewhere near the leader's productiveness. There is the fact to be considered in all cases, that greatly increasing mechanical efficiency means a large increase of investment and consequent interest and depreciation charges. These at some point become so great that further increase of labor-saving capacity is actually unprofitable.

* * *

HIGH-GRADE STEEL FOR STAYBOLTS

The recommendation of Mr. H. B. Wille in his American Society of Mechanical Engineers paper, "A New Departure in Flexible Staybolts," to use small diameter spring steel stem staybolts instead of the large diameter iron bolts commonly used, is one that should receive the attention of locomotive builders and all concerned with the difficult problem of locomotive boiler upkeep.

It is evident to anyone who has studied the problem that the iron staybolt cannot withstand the severe service imposed on it, because the elastic limit of the material is constantly being exceeded. There apparently is no practical way to avoid it, notwithstanding the activity of inventors of flexible staybolts. The difference in temperature between the outer and inner plates of the firebox section of the boiler may sometimes be 300 degrees F. or more. Using the proper coefficient of expansion, a simple calculation shows that the deflection of two adjacent staybolts four inches apart is $0.0000066 \times 300 \times 4 = 0.0079$ inch total movement, which, equalized on two bolts, makes 0.00395 inch movement imposed on each staybolt perhaps only four inches in length, or less, rigidly secured in opposite plates. Often the total movement of the inner plate is all in one direction, thus throwing the total deflection on each. Experiments have shown that the best one-inch iron staybolt subjected to the vibratory test, wherein one end is rigidly secured and the other is revolved at the end of a radius of 3/32 inch and under a tension load of 4,000 pounds, breaks with about 6,000 vibrations.

It is no wonder then that staybolt breakage is a common trouble in locomotive boilers. The elastic limit of the material is exceeded whenever a boiler is cooled off for washing or repairs, and doubtless many times every day under heavy steaming. Observation has shown that the fire-box sheets are in continuous motion relative to the outer sheets, because of the varying temperature.

The recommendation to use spring steel stems with soft ends that can be riveted over, appears to be a common-sense solution of the problem. These bolts with 7/16-inch stems have a tensile strength of 32,000 pounds, and withstand vibratory tests of 500,000 to 1,000,000 vibrations.

Steel of high elastic limit and tensile strength can be used in many places where no other material will be successful. The automobile has shown constructors and designers the need of such materials, and the growth of the use of high-grade alloy steel as a consequence is one of the best evidences of increasing expert metallurgical knowledge and production. In steam engine construction, the use of spring steel piston rods and connecting-rods would undoubtedly lessen failures, balancing troubles, friction, and to some extent, condensation of steam on the piston rods because of reduced diameter.

* * *

Realizing the importance of water power, the United States probably will withdraw some of the land under public domain on which are valuable water power sites. Mr. George O. Smith, director of the United States Geological Survey, has recommended to the Secretary of the Interior that 236,365 acres of public land be withdrawn which are located in Utah, Colorado, Wyoming, Montana, Idaho, and Oregon. Various powerful corporations have been acquiring valuable water powers in the west with a view of monopolizing these natural power privileges which with the development of long distance transmission, have acquired in recent years values almost undreamed of a generation ago.

THE PRESERVATION OF IRON AND STEEL

The present age of iron and steel is one of great waste, particularly of so-called permanent structures, because of the rapid deteriorating effect of rust. The great problem for the metallurgical engineer is to find some means for protecting iron and steel from the corrosive tooth of time. Our great steel bridges, instead of being permanent, are rapidly decaying, as no satisfactory means have been found to stop the insidious action of rust. In great cities, particularly in Pittsburg, may be seen buildings sheathed with sheet steel in an advanced state of rust, great holes having appeared in roofs and sides. A few years more of decay will cause the buildings to tumble into ruins. It is a startling fact that the durability of wooden and steel structures is in favor of the wooden structures, barring the liability of the latter to be destroyed by fire. A paper on the preservation of iron and steel was read by Mr. Allerton S. Cushman before the British Iron and Steel Institute, in which the importance of the subject was impressively worded, and we quote from it as follows:

"Increasing consumption of the world's supply, and constant decay of materials menace the future of the human race. It is evident that carbon from which we derive energy, and iron which provides the possible means of providing energy are the materials which should particularly engage the attention of those who are studying the problems of conservation. The annual production of pig iron in the United States alone grew from 13,789,242 tons in 1900 to 25,307,191 tons in 1906, and while for the year of 1908, owing to industrial conditions, it decreased to about 16,000,000 tons, it seems sure to again show an increase in the near future. How much of this enormous and constantly increasing world's product of iron and steel is wasted for the lack of adequate preservation? Where will the growth of the demand stop, and how many years will the world's ore supply stand the drain upon it? These questions are of vast importance, and the answers can only be vaguely guessed. One thing seems certain: civilization must learn to conserve more efficiently its store of iron and steel already manufactured, and seek methods of preventing the almost resistless tendency of iron to return to its union with oxygen from which it was won only by the vast consumption of quantities of the fast dwindling coal supply. It is not generally realized that about four tons of coal or its equivalent is used for making one ton of finished steel from the ore. If steel could be by any means whatsoever ennobled, and thus protected from decay due to corrosion, future conditions for all years to come could be viewed with complacency. There exists in Delhi, India, an iron monument that since the beginning of history has been exposed to the weather without the result of decay, and yet this column has been provided with no protective coating other than that which the atmosphere has itself formed upon it. It is probable that with all our boasted knowledge we could not build its like. Yet the art is not necessarily lost forever. It is simply a case of whether or not it is worth our while to rediscover it."

* * *

THE MORSE DRILL TAPER SHANK TANG

The number of methods of restoring broken tang twist drills to a new period of usefulness that have been devised within the last few years is good evidence, though none was required, of inherent weakness in the Morse taper shank. The tangs on the large sizes of drills cannot long withstand the heavy torsional stress imposed by the powerful drilling machines of the present time, and large numbers of drills are damaged by twisting off the tangs in heavy drilling. The need of means for restoring such damaged drills to service has been commonly felt, but notwithstanding the fact that hundreds of concerns were throwing thousands of drills away as scrap, practical methods were not provided to check the waste until lately.

The weakness of the Morse shank made so apparent in recent years emphasizes the great advance made in the power of the present-day machine tools. Years ago when the Morse twist drills with taper shanks were brought out, machine tools rarely had sufficient power to twist off the tangs of drills in regular work, such accidents being the exception rather than the rule. If tangs were twisted off the fault was generally in poorly-fitted shanks and defective collets. The use of machine steel for collets was productive of a large number of failures of this character, and probably defective collets are largely responsible for damaged drill shanks now, but in the rush of modern manufacturing, it seems practically impossible to keep all drill press equipment always up to the mark. The enlarged tang and other means for increasing the torsional strength of the twist drill shank have come as a matter of necessity.

The manufacturers of machine tools and of twist drills should agree on a set of new standard drill shanks with enlarged tangs, and while conferring on this matter, they will find the time opportune to consider the advantages of the "Jarno" taper of 0.600-inch taper to the foot, over the mixed common tapers of approximately ⅝ inch per foot. But, while the manufacturers are influential in bringing about needed changes of this nature, the users are to be reckoned with; and their present equipments are a formidable obstacle to a common standard, no matter how advantageous it may be. A change in tapers and tangs can be brought about only by concerted action of the leading makers and users, and no doubt even then it will be slow.

* * *

CORPORATION TAXATION

At the annual banquet of the Ilion Board of Trade, Ilion, N. Y., Mr. Fred J. Miller, assistant to the president of the Union Typewriter Co., New York, spoke on "Corporation Taxation" in part as follows:

"Without having especially looked into the matter, I take it for granted that Ilion has encouraged the growth of manufactures within her boundaries; that she has endeavored in all proper ways to encourage those of her citizens who have endeavored to do things calculated to build up and develop the town, and one of these ways is by the proper handling of taxation. In these days taxation of industrial enterprises is attracting a good deal of attention, and with your permission we will consider briefly some of the things which a community can do, by means of taxation, to encourage manufacturing enterprises.

"It ought to be obvious that a town which aims to grow should encourage as much as possible those things which cause growth, and discourage as much as possible those things which retard growth; to encourage the workers—the doers of beneficial things, and to discourage drones or those whose influence is adverse to healthy growth. This can be done by means of taxation. We often hear of towns which offer, as an inducement for the location of new manufacturing establishments, exemption from taxation for a term of years. This is, however, sometimes objected to by already established industries, especially when engaged in the same line of business, and which are often taxed heavily—I think properly objected to.

"Taxation, it seems to me, should not be levied upon the commonly accepted, but nevertheless socialistic principle, that the amount paid should be in proportion to ability to pay, but should rather be levied in proportion to the direct pecuniary benefits received by the taxpayer from the community or from the governmental organization for the support of which taxes are collected. In too many communities the opposite course is followed with the result that those who are doing most to build up the town are the most heavily fined for doing it, while those who are doing nothing to build up, but are reaping the pecuniary benefits of others' efforts, are most lightly touched by taxation.

"Such is the effect of levying comparatively heavy taxes upon factories and their equipment, upon business buildings and the goods within them, and upon the houses and furniture of citizens, while at the same time levying taxes proportionately much lighter upon vacant lots and unutilized land which is being merely held at prices that more or less completely anticipate future development and the demands of population.

"Let me not be misunderstood. I refer in a general way to the principles that should govern in a town which wishes to grow, and call attention to the fact that by assessment and taxation those things which do most to build up a town can be discouraged or encouraged, and that those things which do most to retard its growth can also be discouraged or encouraged."

The principle of promoting manufacturing industries by equitable distribution of the tax burden, making the land the basis for all assessments, is one of undeniable importance to manufacturers wherever located, and we think that whatever be their politics or creed, practically all will agree with Mr. Miller's sentiments, even though the basic idea is the fundamental one of the Henry George single tax theory.

* * *

The experiments undertaken by the Pennsylvania Railroad with concrete telegraph poles have been so successful that an increase is to be made in the use of these poles on the company's lines.

A NEW DEPARTURE IN FLEXIBLE STAY-BOLTS*

There is practically no literature on the subject of stay-bolts, and in particular, none on flexible stay-bolts. The increasing size and pressure of boilers make this subject of vital importance to railroads and to those responsible for the management of that type of boiler in which the firebox is stayed by a large number of bolts. The boiler of the consolidation locomotive, now the prevailing type in freight service, contains about 1,000 bolts less than 8 inches long and about 300 of greater length. The large types of Mallet compound locomotives now meeting with much favor have a much larger number, there being 1,250 short and 300 long bolts in locomotives recently constructed.

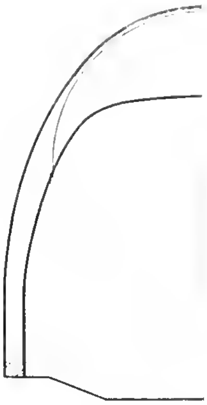

Fig. 1. Section of Firebox, showing Center-lines of Stay-bolts

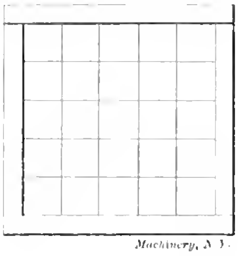

Fig. 2. Faggott Piling of Iron for Stay-bolts

In recent years some form of flexible stay-bolt, that is, one having a movable joint, has been very extensively used in the breaking zone of locomotive boilers, but their high cost and the difficulty of applying them, the binding at the joint caused by rust and scale, and the fact that their use throws an additional service on the adjacent bolts because of lost motion, has militated against their more general use.

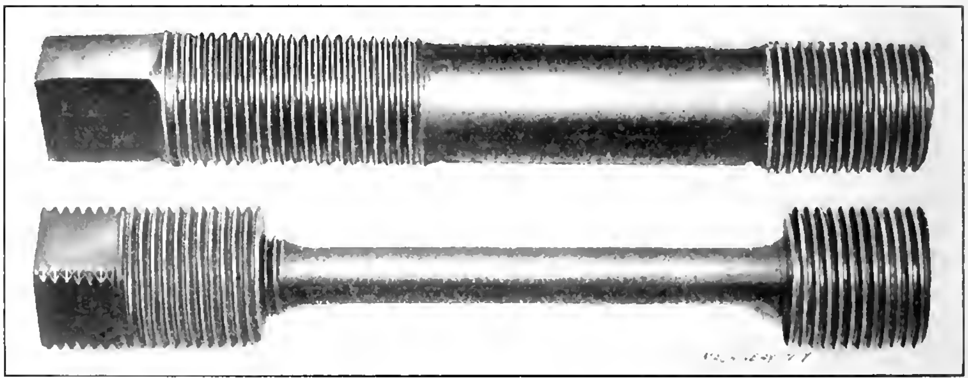

Fig. 4. Spring Flexible and Regular Iron Stay-bolts of Same Tensile Strength

It is well known that stay-bolts fail, not because of the tensional loads upon them, but from flexural stresses induced by the vibration resulting from the greater expansion of the firebox sheets than of the outside sheets, but notwithstanding the general acceptance of this theory, engineers have designed stay-bolts solely with respect to the tensional loads. It is quite general practice, it is true, to recess the bolts below the base of the thread, and this has effected a slight reduction in the fiber stress, but practically no effort has been made to design a bolt to meet the flexural stresses or even to calculate their magnitude. This is surprising in view of the simplicity of the calculations to which the ordinary formulas for flexure apply.

Fig. 3 Flexible Spring Steel Stay-bolt

Let F = fiber stress,
E = modulus of elasticity,
I = moment of inertia,
D = diameter of bolt,
N = deflection,
L = length of bolt between sheets,
W = load.

We then have

$$W = \frac{2FI}{DL} \qquad (1)$$

$$N = \frac{WL^3}{3EI} \qquad (2)$$

Substituting W in (1) in equation (2) we have

$$N = \frac{2FL^2}{3ED} \qquad (3)$$

$$F = \frac{3EDN}{2L^2} \qquad (4)$$

This formula shows that the stress increases in direct proportion to the diameter and decreases as the square of the distance between the sheets.

The application of the formula to service conditions gives the following stresses:

Conditions: Bolt spacing, 4-inch centers.
Assumed expansion, 0.04 inch.
Length of bolt, 6 inches

Type	Diameter of Bolt	Flexural Stress
Iron	1⅛ inch	51,500
Iron	1 inch	45,000
Iron	⅞ inch	39,400
Spring steel	1-inch ends, 7/16-inch stem	19,700

Iron is universally employed in the manufacture of these bolts and it is not good practice to exceed a fiber stress of 12,000 pounds per square inch. It is apparent that stay-bolts in the zone which meets the expansion of the sheets are stressed above the elastic limit and must necessarily fail from fatigue. Fractures always originate at the outside sheet at the point where the bending moment due to the movement of the furnace sheets is greatest. The fractures usually start from the base of a thread and gradually extend inward. Manufacturers of stay-bolt material have endeavored to minimize failures and to meet the unusual conditions of an iron stressed beyond its elastic limit by the supply of specially piled iron arranged with a view to breaking up the extension of the initial fracture. For this reason iron piled with a central section of small bars and an envelop of flat plates has met with much success for this class of service. In a further effort to secure an iron specially adapted to this class of work various forms of shock, vibratory and fatigue tests have been imposed. No design has yet been produced, however, which permits the employment of material of elastic limit sufficiently high to resist the flexural stresses, although a large class of material particularly adapted to the purpose is available. It is obvious that the remedy does not lie in the use of a slow-breaking material, but in the employment of material of sufficiently high elastic limit to meet the conditions of service. It is also possible to reduce the diameter of the bolt greatly by the use of such a material, thus proportionately reducing the fiber stress in flexure.

Stay-bolt material, however, must possess sufficient ductility to enable the ends to be readily hammered over to make a steam-tight joint and to afford additional security against pulling through the sheets. To meet these conditions the bolt illustrated in Fig. 3 has been designed. The stem is of the same grade of steel as that used in the manufacture of springs. It is oil-tempered and will safely stand a fiber stress of 100,000 pounds per square inch. Its high elastic limit makes

---

* Abstract of paper by Mr. H. V. Wille, read before the May meeting of the American Society of Mechinical Engineers, at Washington, D. C.

it possible to reduce the diameter to 3/8 or 7/16 inch or even less. The ends are of soft steel, and it is thus possible to apply and head up the bolt in the usual manner.

The employment of a stem of the diameter indicated reduces the fiber stress in flexure to less than one-half that in the ordinary type of bolt. It has hitherto been impossible to employ in stay-bolts any of the steels containing chromium, nickel, vanadium, etc., possessing properties especially adapted to this class of work, but these steels can readily be used in the stem of the bolt described. This stem can be flexibly secured to the end in one of the customary ways, but the flexibility of the bolt does not depend upon a flexible connection. A type of bolt with a relatively inflexible connection, usually one in which the stem screwed into the ends with a running fit, has met with the most favorable consideration. Such a bolt is flexible as a spring is flexible, in that it can be deflected to meet the requirements of service without exceeding the elastic limit. In fact the stem may be of a number of pieces, either of plates or small rods, thus increasing its flexibility.

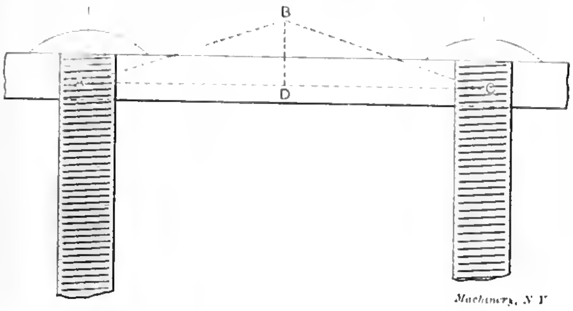

Fig. 5. Manner in which Plates Buckle with Rigid Stays

The actual breaking strength of the bolt sizes ordinarily employed is shown in the following statement. These bolts were recessed to the base of the thread and tested in the same form as that in which they are employed in service. For comparison, the approximate weights of the usual length of bolt are also given. These weights are for bolts over the entire length, including the squared ends for screwing the bolts into the sheets.

ACTUAL BREAKING STRENGTH OF STAY-BOLTS

Type	Nominal Diameter	Actual Breaking, Pounds	Weight, Ounces	Vibrations
Iron...............	1 inch	32,500	20	6,000
Iron...............	$\frac{7}{8}$ inch	24,500	15	5,200
Spring steel stem..	1 inch ends, $\frac{7}{16}$ inch stem	32,000	10	500,000

The vibrating test was made by clamping one end of the bolt in a machine and revolving the other end through a radius of 3/32 inch, the specimen being 6 inches long from the end of the right head to the center of the rotating head. A tensional load of 4,000 pounds was also applied to the bolts. The best grades of iron bolts break on being subjected to from 5,000 to 6,000 rotations, whereas the spring steel bolts were vibrated 500,000 times without failure, and on some of them the test was continued without failure to 1,000,000 vibrations. These tests demonstrated that the bolt is not stressed beyond the elastic limit under these severe conditions, and that the probability of its failure in less severe conditions is very remote.

The extent of the expansion which can take place in the fire-box of a boiler can readily be calculated:

Distance between stay-bolts, 4 inches.
Temperature of inside sheet, 400 degrees F.
Temperature of outside sheet, 100 degrees F.
Coefficient of expansion, 0.0000066.

Then the expansion between two bolts will equal: $0.0000066 \times (400 - 100) \times 4 = 0.0079$, and each bolt will deflect 0.00395 inch. It has been shown that this amount of deflection will stress the usual type of bolt (about 6 inches long) beyond the elastic limit. In practice, however, one bolt may hold rigidly, throwing the entire deflection on the adjacent bolt, or neither bolt may deflect and the sheet will then buckle. Under this condition the neutral axis will assume the form *ABC*, Fig. 5, and the length *AB* will equal 2.00395 inches and the sheet will buckle to an extent, $BD = \sqrt{2.00395^2 - 2^2} = 0.125$ inch. It is obvious that the repetition of a force sufficient to buckle a sheet $\frac{1}{8}$ inch must ultimately lead to a crack in the furnace sheets. If, however, the bolt deflects, allowing the sheet to normally expand, the latter will be relieved of these extraneous loads.

A bolt of sufficient flexibility to deflect under the forces following expansion, and of material which will not be stressed beyond the elastic limit in resisting these forces, will greatly assist in reducing the cost of boiler maintenance by eliminating broken stay-bolts and reducing the stresses in the furnace plates. If in addition the bolt has a smaller diameter, the life of the furnace plates should be further increased, as such a bolt will interpose less obstruction to the circulation of the water in the water legs.

HORSE-POWER FORMULA FOR AUTOMOBILE ENGINES

In the August, 1907, issue of MACHINERY, engineering edition, a horse-power formula for gasoline engines, adopted by the Association of Licensed Automobile Manufacturers, was given. This formula is

$$H.\,P. = \frac{D^2N}{2.5},$$

where D = diameter of cylinder in inches,
N = number of cylinders.

According to a paper read by Mr. James L. Miller before the Glasgow Technical College Scientific Society, this formula gives, however, in general, an underestimate, especially for the larger sizes, and the following formula, which gives better results, is recommended:

$$H.\,P. = K \times D\,(D - 1) \times (R + 2) \times N.$$

In this formula

K = constant = 0.197 for commercial and touring cars and 0.33 for racing cars,
D = diameter in inches,
$R = \frac{\text{stroke in inches}}{\text{diameter in inches}}$ = ratio between stroke and bore,
N = number of cylinders.

Applying this formula to a four-cylinder engine with four inches diameter of cylinders and five inches stroke gives 31 H. P., which could be obtained from such an engine at quite moderate speeds. The Automobile Manufacturers' formula gives in this case only 25.6 H. P.

CHILLED CAST IRON LATHE TOOLS

A contributor to the *Mechanical World* mentions that he has tried chilled cast iron tools with considerable success when turning plain work. The shank of the tool was about ten inches long by two inches square, and the cutting portion was made of the ordinary round-nose shape, suitable clearance being provided, but no top rake employed. The required hardness of the tool nose was obtained by a chill-box. The molten metal which enters the chill-box is rapidly cooled, and when removed from the sand the tool nose is extremely hard. All that is necessary is to grind it, and it is ready for use. A decided feature of its characteristics is its ability to cut cast iron which has been chilled through being poured into damp molds. Tools of this kind, it is stated, have, in a number of cases, saved partly machined work from being scrapped, when the best brands of high-speed steel were unequal to machining the cast iron. Tools of this type are handy to have around for occasional jobs which show themselves unamenable to ordinary methods. The use of chilled iron tools dates back many years. Its use at Lister's Works, Darlington, England, to turn chilled iron rolls, was mentioned in Moore's Guide, a heterogeneous collection of receipts and formulas for mechanics, grocers, lawyers, doctors, etc., published a long time ago. Some chilled rolls had been made so hard that carbon steel tools could not be used. One of the workmen suggested that if the chilled iron was harder than hardened steel, it might be found that a chilled iron tool might be made to cut as it could be made as hard or harder than the roll. The suggestion was successfully followed.

A SPRING WHEEL FOR THE AUTOMOBILE

In order to avoid the trouble and expense connected with the pneumatic tire, a number of wheels of different types have been constructed, all with the object in view of obtaining a resiliency equal to that of the pneumatic cushion, by the use of springs. Practically all of these spring wheels have employed radial springs, spring spokes or hub springs, and the objection has been that all of the load at a given time is concentrated on a few of the springs. With the springs arranged radially, there is also a tendency for the wheel to "dish," because of the lack of rigidity against lateral shocks. The American Spring Wheel Co. of Cleveland, Ohio, has placed upon the market a wheel which is both novel and ingenious in its construction, and one which, judging from its design, and the results of the tests, is applicable not only to pleasure, but also to commercial vehicles.

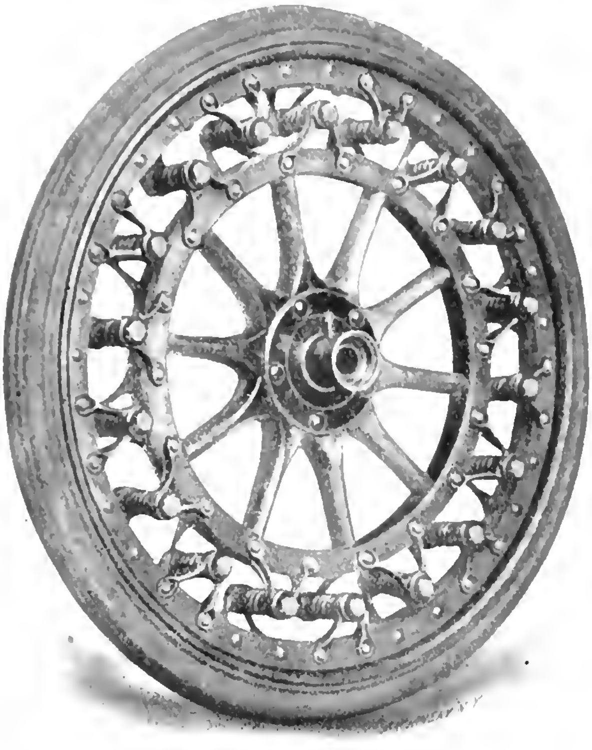

Fig. 1. The Seaton Spring Wheel for Automobiles, Trucks, etc.

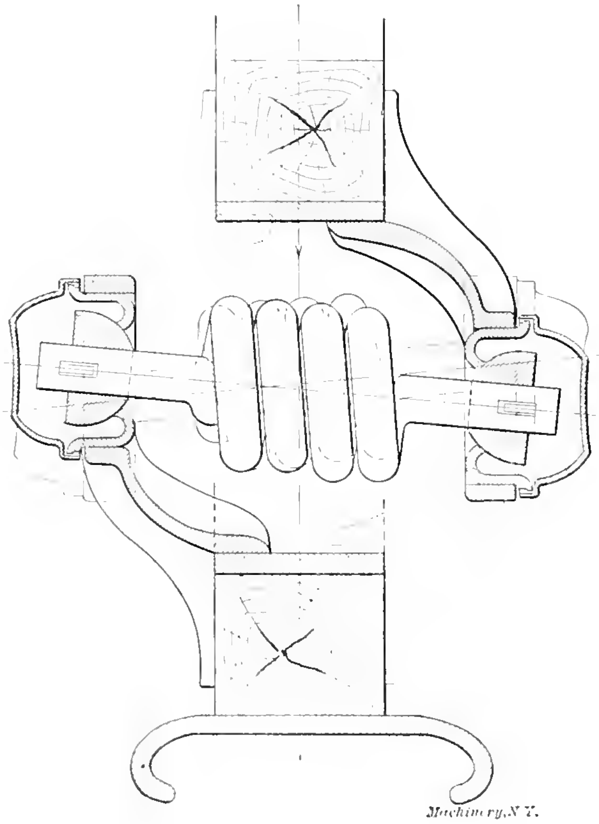

Fig. 2. Action of the Springs under Load

This wheel, which is known as the Seaton spring wheel, is constructed in two parts, an inner wheel or hub, and an outer part with a solid rubber tire, which corresponds to the felloe and tire of the ordinary wheel. These two parts are connected by springs set parallel to the axis of the hub, and with their ends held in brackets which extend radially from the two main parts of the wheel. As will be seen by referring to the engraving, Fig. 1, one end of each alternate spring is connected to the bracket of the inner rim, and the other to the bracket of the outer rim. These connections, however, are not rigid, as the ends of the springs are attached to their brackets by ball-and-socket bearings. A detail of one of these springs with the bracket and bearing in section, is shown in Fig. 3. The brackets *A* are turned to fit the steel-bound felloes to which they are bolted, and they are also bored to fit the case-hardened cups *B* which form the seats for the bearings. The hemispherical balls *C* are slotted for the cotter-pins *D*, which pass through slots in the spring at each end, thus holding it in place. There are three slots of slightly varying depths cut across the flat of each of the half balls, so that springs of different lengths may be assembled with practically the same tension. By this construction each spring is enabled to accommodate itself to varying shocks, and by reason of the movement allowed by the ball bearing it is, practically speaking, only subjected to a straight pull. The springs in the assembled wheel are under an initial tension or stretch, of about 1/16 or 3/32 of an inch, in order that each one will take its full share of the load or shock at every point of the revolution. This spring arrangement, as is evident by examining the illustrations, gives the wheel considerable lateral strength. The normal position of the springs is parallel to the axis of the wheel, but when the inner section is subjected to a load, it moves downward against the tension of each spring which is also displaced from its parallel-to-the-axis position, as indicated in Fig. 2. As this downward

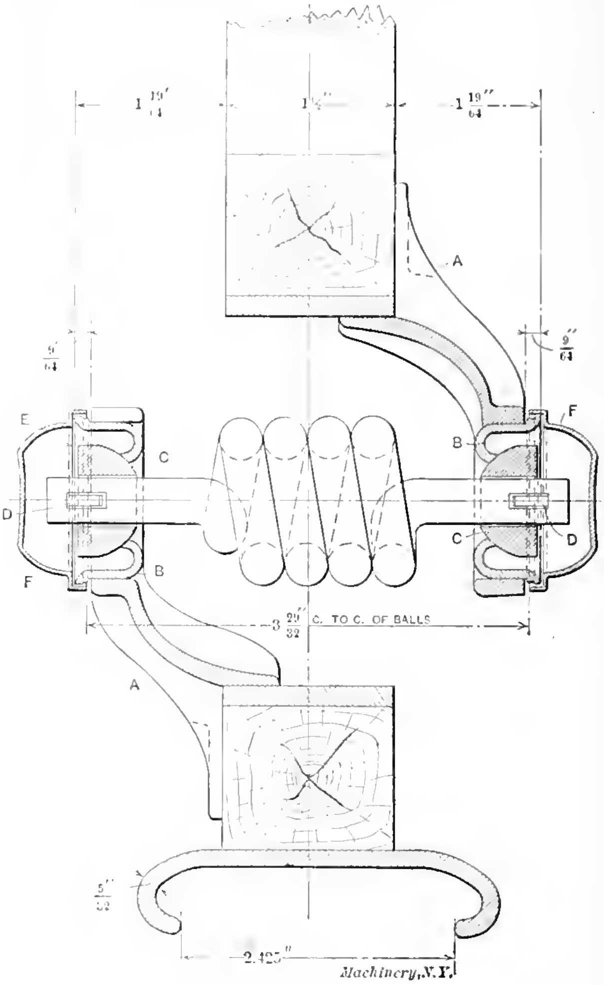

Fig. 3. Detail of the Bracket and Spring, showing the Ball and Socket Bearing

movement of the inner wheel takes places, the hemispherical parts of the spring bearing roll in their seats and, consequently, the springs, as before stated, are subjected to a stress which is parallel to their axes.

The bearings are lubricated with hard grease which is placed into the cavities *E* (Fig. 3). As is well known, grease is a lasting lubricant, and it also has the advantage in this case of protecting the bearing by its gradual outward flow, from dirt and other gritty substances which might otherwise enter from the inside. The lubricant itself is kept clean by the caps *F* which are held in place by a flattened part of the rim, which engages with a collar on the bearing cups *H*.

The one feature of the construction of this wheel which is basic in principle, and indicative of careful thought, is the arrangement of the springs, and the most valuable feature of the wheel from a mechanical point of view, lies in the fact that the load is evenly distributed over all the springs. This, of course, makes the use of a comparatively light spring possible, which adds to the resiliency of the wheel. It is said that the riding qualities of the Seaton wheel compare favorably with the rigid type equipped with a pneumatic tire.

Mr. Hubert H. Ward, Mr. William E. Metzger, formerly of the Everitt-Metzger-Flanders Co., of Detroit, and others have organized the American Spring Wheel Co., to manufacture the wheel in this country, while the International Spring Wheel Co. has been incorporated to handle the foreign patents. Mr. H. L. Olmstead, formerly assistant engineer of the Brown Hoisting & Conveying Co., of Cleveland, has been made mechanical engineer for the American firm.

FORMULAS FOR STRENGTH OF FLAT CIRCULAR PLATES*†

WM. F. FISCHER‡

When a flat circular plate becomes deformed under the action of a given load *W* applied normal to its surface, as shown in Fig. 1, the upper fibers *B* of the material are subjected to compressive stresses both radially and circumferentially, while the lower fibers *C* are subjected to tensile stresses both radially and circumferentially. This is caused by the fact that the plate, when bending, tends to assume a spherical shape. Stresses therefore, appear in the plate in a manner as indicated in the lower view in Fig. 1. The deformation of the plate as shown in an exaggerated scale in Fig. 2, tends to decrease the length or circumference of the upper fiber *B*, while it tends to increase the length of the lower fiber *C*. In the lower view in Fig. 1, the full lines with their arrows show the direction of the radial and circumferential compression stresses in the fibers on the upper side of the plate, and the dotted lines with their arrow heads show the tension in the fibers on the lower side of the plate.

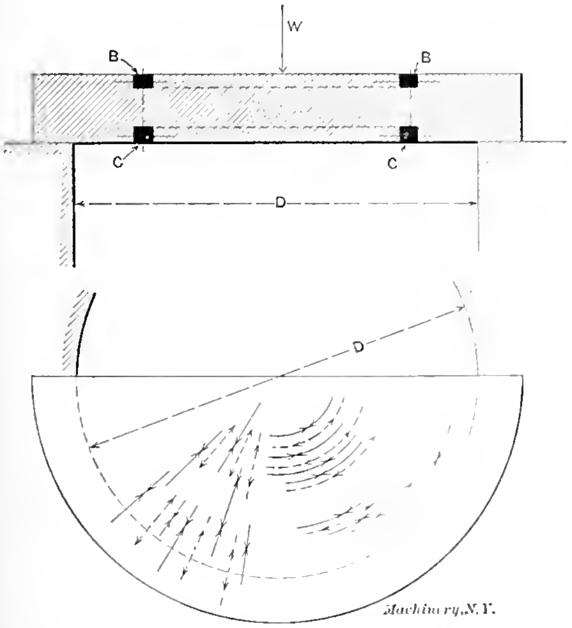

Fig. 1. Stresses in Flat Circular Plates Loaded at the Center

In the accompanying Supplement, several sets of formulas for circular plates are given, selected from different authorities. The formulas are presented as given by the various writers, and then the different quantities "safe load," "unit stress," "thickness of plate," etc., as deduced from the given formulas, are shown. The tables given should be considered as a part of a complete set of tables giving formulas of flat plates, four of which were published in the Supplement to the June, 1909, issue of MACHINERY. Table V refers to rectangular plates, and Tables VI, VII and VIII to circular plates.

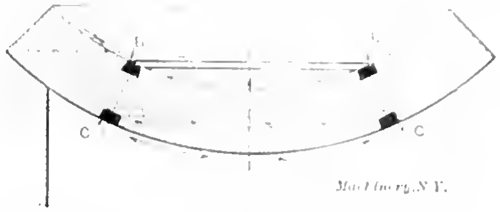

Fig. 2. Deformation of Loaded Flat Circular Plates shown in Exaggerated Scale

Exact formulas for finding the bending moments in flat circular plates and the resistance of plates to the stress created by pressures normal to their surface have not as far as the writer knows, been determined. The formulas given are founded on certain assumptions and must be considered merely as approximations. This, of course, is also indicated by the variations in the formulas given by the various writers on the subject. The formulas should be used with caution, and such formulas as give results on the safe side should be preferred. In deriving formulas of this character, all assumptions should be made so that the error is on the safe side.

ZEPPELIN'S LAST RECORD—THE DE BAUSSET VACUUM AIRSHIP

Count Zeppelin's new air-ship covered a distance of about 850 miles in 37 hours, starting from Friedrichshafen, Germany, May 30. Unfortunately the air-ship collided with a tree on the return trip from Bitterfeld. The impact smashed in the bow, but damages were repaired in a few hours and the return flight to Friedrichshafen was resumed. The success of Zeppelin's mammoth air-ship has caused some enthusiast to predict that a transatlantic trip will be made possible within a year, inasmuch as it is claimed that the possibility of such a trip is merely a question of fuel and supplies.

The success of this air-ship has also revived the De Bausset vacuum air-ship plan, which was promoted—and ridiculed—about twenty years ago. The plan of Dr. De Bausset was to build a huge steel cylinder over 700 feet long, internally stiffened so as to resist the external air pressure when the contained air was pumped out. It was the idea that a large vessel thus made of steel could be given sufficient buoyancy by pumping out the air to cause it to rise. The advantage of the plan, of course, is that there is no danger from explosion as in the case with gas. Another advantage is that the buoyancy of the balloon can be increased and decreased at will by simply pumping out the air or admitting it as the case may require. It is claimed that De Bausset had worked out his plan for a ship 744 feet long, having a diameter of 141 feet, the total displacement being about 11,000,000 cubic feet. The displaced air at sea level and at a temperature of about 65 degrees F. would weigh about 400 tons, which, of course, would be the measure of buoyancy, minus the weight of the cylinder, car, machinery, supplies, etc. It was calculated that the vacuum air-ship could be built so as to have a net lifting power of about 124 tons. The plan of interior construction by which the enormous pressure of the atmosphere could be resisted by a structure sufficiently light to answer balloon purposes has never been revealed. It is said that De Bausset had worked out the plan satisfactorily, but he never revealed it to others. The skin of the cylinder was to be made of rolled steel, ¼ inch thick. Beyond that nothing of the interior details is known, except that the air was to be exhausted by four powerful pumps, driven by electric motors, supplied by rolled batteries. C. A. McCready, of the New York Produce Exchange, is responsible for the effort to revive the project.

THICK CYLINDERS*

P M GALLO[†]

The calculation of the thickness of cylinders for a given pressure has been so much discussed, and so many formulas have been deduced, some theoretical and others empirical, that there seems to be little to add. Yet this subject is so little understood that every experienced engineer relies on his own experience, and in most cases uses no formula at all, except a kind of proportional one, that is usually all right for limited pressures and sizes of cylinders, but which conforms neither with theory nor practice; but "it does the work," as the uninitiated say. Some formulas, although published in reputable engineering hand books, are absolutely worthless. Others, again, are good for high pressures but valueless for low pressures, and *vice versa*.

The writer has had considerable experience in this line of work, having designed the complete hydraulic, steam, and pneumatic power transmission system for the largest tube and pipe mill in the world, and has, therefore, given this subject considerable thought.

Commonly Used Formulas

In low pressure work the general practice is to make the thickness of the metal = diameter × unit pressure ÷ twice the allowable working stress of the material, and add to this a variable quantity to allow for unsound castings and possible unknown stresses, or

$$t = \frac{DP}{2S} + a \qquad (1)$$

Where t = thickness in inches,

D = diameter in inches,

P = pressure in pounds per square inch,

S = allowable tensile stress in pounds per square inch,

a = variable quantity.

The quantity a varies with the size of the cylinder and the pressure, and with the conditions under which the cylinder is operated.

For high pressures Lamme's formula is usually used and gives reliable results. This formula, transformed for practical application, is:

$$t = r\left[\sqrt{\frac{S+P}{S-P}} - 1\right] \qquad (2)$$

Where t = thickness in inches,

S = allowable tensile stress in pounds per square inch,

P = working pressure in pounds per square inch,

r = internal radius.

This formula is arrived at theoretically and expresses the exact relations between the tensile stress and the working pressure of an elastic material, with the exception that it does not take the lateral contraction of the material under stress into consideration; this can be omitted for practical purposes, since the variation of the quality of the material, unsound castings, and conditions of service, more than counterbalance the gain by considering the lateral contraction.

For those that care to note the difference between Lamme's formula and the one considering lateral contraction, the latter, for cast iron and steel, using the same notation as before, is given below.

$$\text{For cast iron } t = r\left[\sqrt{\frac{4S+P}{4S-4P}} - 1\right] \qquad (3)$$

$$\text{For steel } t = r\left[\sqrt{\frac{3S+P}{3S-4P}} - 1\right] \qquad (4)$$

Whereas Lamme's formula is the same for any material, the latter formula varies with the material, since the lateral contraction varies. This contraction is about 1/4 for cast iron and 1/3 for steel.

For pressures ordinarily used in hydraulic work formulas (3) and (4) give a thinner cylinder than (2); but for very high pressures, such as occur in guns and sometimes in intensifiers, formulas (3) and (4) give thicker cylinders than (2). Unless one is positive of a high-grade material and sound castings, cast iron should not be used on pressures over 2,000 pounds per square inch.

Formulas (2), (3) and (4) are deduced on the supposition that the inner laminae of a cylinder rupture first, and the moment rupture occurs, the stress on the material is increased, due to the diameter being increased by the starting rupture, and the rupture continues to the outer lamina, or, commonly speaking, the cylinder is "burst." Accordingly, the formulas give such a thickness that the pressure on the inner lamina does not exceed the allowable tensile stress, provided the assumed working pressure is not exceeded. The pressure on each succeeding lamina varies as the square of its radius. For the deduction of Lamme's formula, see Merriman's "Mechanics of Materials."

Since these formulas are deduced from the above assumptions, there must be some limited working pressure for each assumed allowable tensile stress, which, if exceeded, will produce a stress on the inner lamina exceeding this allowable tensile stress, even if the cylinder were made infinitely thick. We will now inspect Lamme's formula to find this limited working pressure. By making $P = S$, we have

$$t = r\left[\sqrt{\frac{S+S}{S-S}} - 1\right] \text{ or } t = \infty.$$

Therefore, S is, theoretically, the limit of working pressure; of course, practically it is much lower than this for economical reasons. The writer takes the thickness equal to the radius as a practical limit; if greater thickness is required a higher value for S is used, and consequently a lower factor of safety, or a better grade of material is employed.

In formula (4) make $P = \frac{3}{4}S$, then

$$t = r\left[\sqrt{\frac{3S+0.75S}{3S-3S}} - 1\right] \text{ or } t = \infty,$$

In this formula the limit of working pressure is $\frac{3}{4}S$, showing that the thickness increases much more rapidly as the pressure increases than it does in formula (2). In formula (3), again, $t = \infty$ for $P = S$.

Another formula frequently used is

$$\frac{t}{r} = \frac{P}{S}\left(1 + \frac{P}{S}\right) \qquad (5)$$

This is an empirical formula giving results agreeing very closely with those obtained by formula (2) for limited pressures; it does not give the true relation between S and P, and it is simply a modification of (1) with the quantity a replaced by the factor $\left(1 + \frac{P}{S}\right)$ which factor does not vary correctly with increased pressures and stresses. Make $P = S$ and we get

$$\frac{t}{r} = \frac{S}{S}\left(1 + \frac{S}{S}\right) = 2$$

or the thickness is equal to $2r$; even if we make $P = 2S$ we get a thickness apparently sufficient for the pressure; but to find what the actual tensile stress produced will be under such a pressure, we are compelled to resort to formula (2). The formula (5) is theoretically and practically wrong.

Conditions Governing the Thickness of Cylinders

Having investigated various formulas used for calculating the thickness of cylinders and given a fair average practice, we will now go into the conditions that govern the thickness of cylinders.

1. Two castings taken from the same cast vary widely as to chemical and physical qualities and soundness, depending on what part of the cast each is taken from, conditions of mold, etc. Castings from different casts vary still more.

2. There is a limited thickness below which casting is impossible; this varies with the kind and quality of metal and the skill of the men.

3. Castings handled by unskilled crane men receive very severe shocks and knocks, often producing stresses far in excess of the stress produced in service.

---

* For additional information on thick cylinders, previously published in MACHINERY, see Design of Thick Cylinders, July, 1907, engineering edition, and the articles there referred to. See also MACHINERY'S Reference Series, No. 17, Strength of Cylinders.

[†] Address: 362 Lilly Ave., Pittsburg, Pa.

4. In hydraulic systems, the cylinders are subjected to shocks, the magnitude of which depends largely on the design of the system, the service for which the cylinder is used, and the construction and method of operation of the valves.

As far as the variation of the chemical and physical properties are concerned, that is taken care of by the factor of safety. The soundness of the casting is taken care of by allowing an additional amount of metal; this varies with the kind of material, being more for cast iron than for brass, for instance. The amount to be added increases in a certain ratio as the diameter increases, and decreases in a certain ratio as the pressure increases. The increasing pressure requires more body to the metal; therefore, the casting is sounder and less metal need be added. In fact, for pressures above a certain limit this addition of metal can be omitted altogether.

The amount of the addition depends on the quality of the metal and the allowable tensile stress, and should be proportioned accordingly by the designer. With a good quality of metal, the castings can be made thinner, and yet be sound. With a higher allowable tensile stress, the castings are thinner for a given pressure than with a lower, and consequently more metal must be added to make a sound and reliable casting.

The limit of thickness below which casting is impossible varies with the quality of metal used, and should be decided by the designer's experience and judgment.

From the conditions enumerated, the writer has deduced a formula, conforming with theory and practice, which can be used for any working pressure high or low and any allowable tensile stress. For the primary thickness for the pressure, formula (2) is used. Then add two quantities, one increasing as the diameter increases, and one decreasing as the diameter increases (but not in the same ratio as the first quantity), and both decreasing as the pressure per square inch increases. Following is the formula:

$$t = r\left[\sqrt{\frac{S+P}{S-P}} - 1\right] + \frac{S-P}{S}(0.452 - 0.0061\,D) + \left(\frac{S-P}{S+P}\right)^5 0.023\,D \qquad (6)$$

The notation is the same as previously given.

Now let us inspect this formula:

Make $P = S$ and we get

$t = \infty + 0 + 0$,

which is theoretically correct.

Now let us make $P = 0$ and we get

$$t = 0 + (0.452 - 0.0061\,D) + 0.023\,D,$$

which is the minimum thickness. For a two-inch cylinder this would be $t = 0.4398 + 0.046 = 0.4858$ inches, and for a thirty-inch cylinder, $t = 0.269 + 0.69 = 0.959$ inch, or for a sixty-inch cylinder, $t = 0.086 + 1.38 = 1.466$ inch. These thicknesses are within the limits of possibility of casting, and the formula is, therefore, correct from a practical standpoint.

Diagram for Calculating Thick Cylinders

From the diagram, Fig. 1, the thickness of cylinders can be taken directly for any working pressure up to 5,600 pounds per square inch, and for the commonly used fiber stresses.

The line AB is the base line on which the fiber stress curves are constructed. A 32-inch diameter cylinder was the maximum considered in plotting the curves, but the diagram can be made to read up to 40 inches diameter by extending the diagonals, reference from the fiber stress curves always being made to the base line AB. By letting the diagonals encroach on the fiber stress chart, the limit will be the full extent of the chart; the 5,600 line or the maximum diameter of cylinder would thus be 96 inches diameter. The formula is developed for a maximum diameter of cylinder of 74 inches, above which the second term of the right-hand member becomes negative.

The location of the fiber stress curves with respect to each other is proportional to the respective fiber stress values measured along the ordinates. For if $S = 7{,}000$ pounds per square inch is required, divide a number of intervening ordinates between the 6,000 and 8,000 pound curves in half and draw a smooth curve through the points thus located. If $S = 6{,}500$ pounds is required, the points are located one quarter of the length of the intervening ordinates above the 6,000 pound curve. Therefore, any number of curves can be plotted with little trouble.

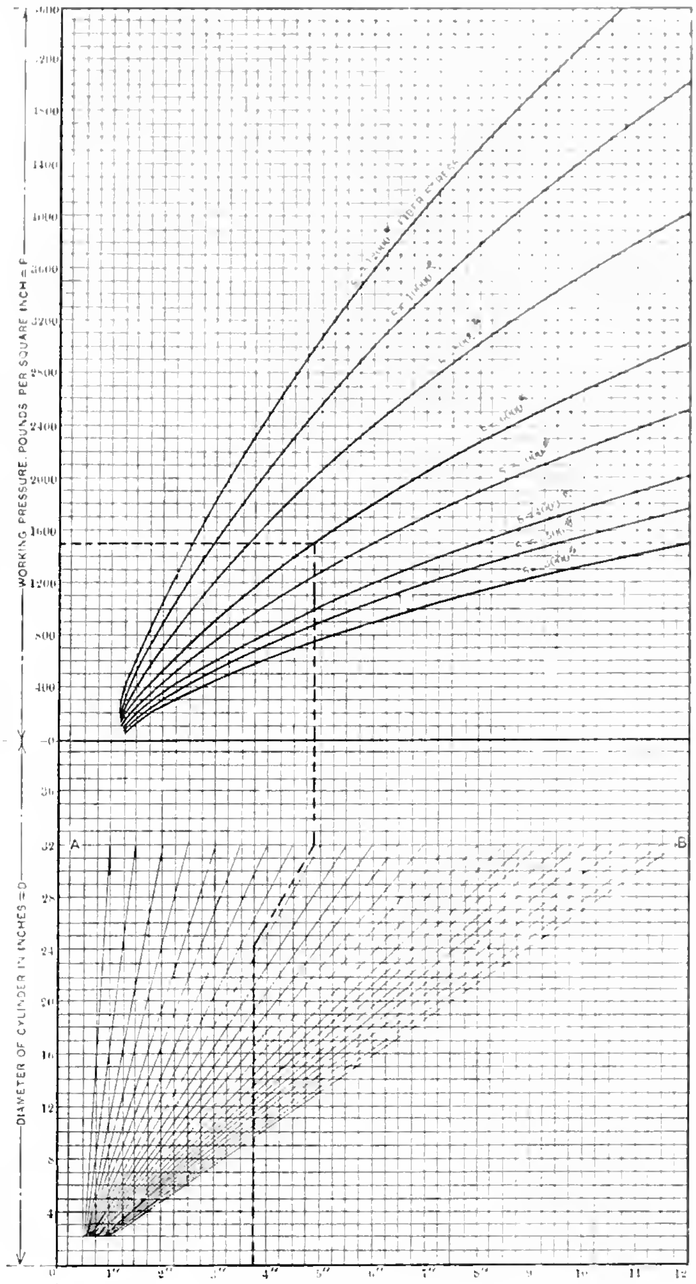

Fig. 1. Diagram for Calculating Thick Cylinders

Formula on which diagram is based:

$$t = r\left[\sqrt{\frac{S+P}{S-P}} - 1\right] + \frac{S-P}{S}(0.452 - 0.0061\,D) + \left(\frac{S-P}{S+P}\right)^5 0.023\,D$$

in which t = thickness of cylinder in inches,

S = allowable fiber stress in pounds per square inch,

P = working pressure in pounds per square inch,

r = internal radius of cylinder in inches,

D = internal diameter of cylinder in inches.

Example of use of diagram: Required, thickness of cylinder, D = 24 inches, P = 1,500 pounds, S = 6,000 pounds.

Follow horizontal line from P = 1,500 to 6,000-pound curve; then follow vertical line down to base-line AB; then diagonal line until opposite 24 inch diameter; then vertical line to bottom scale, where the thickness (= 3¾ inches) is read off.

For intermittent stresses, such as for cylinders for steam and hydraulic work, $S = 3{,}000$ pounds for cast iron, $S = 5{,}000$ pounds for ordinary brass, and $S = 10{,}000$ pounds for steel castings is ordinarily used by the writer.

For steady or gradually applied stresses, such as pipe line fittings, cast pipes, pneumatic cylinders, etc., the stresses should be: for cast iron, $S = 3{,}500$ to $4{,}000$ pounds, for brass, $S = 6{,}000$ to $7{,}000$ pounds, and for steel castings, $S = 12{,}000$ pounds per square inch.

If the cylinder is turned on the outside and bored, the thickness given in the chart is too high for working pressures up to 500 pounds, and the thickness can be decreased by the following amounts with safety. Let T be the thickness required and let t be the thickness taken from the diagram, then

$$T = t - \frac{500 - P}{500}(0.31 + 0.0146\,D),$$

in which D = diameter of cylinder. It will be seen that for 500 pounds $T = t$.

For pressures of 2,000 pounds and over, cast iron should not be used, especially if subjected, additionally, to bending and tensile stresses due to external forces, as the factor of safety becomes too low, and the thickness prohibitive; even when an extra good quality of cast iron is used, such as gun iron, 2,000 pounds is about the safe limit, because it is not possible, in most cases, to determine the maximum pressure due to shocks, etc. Even if the pressure due to shocks comes within a reasonable limit, the cast iron will not last long under repeated shocks. An idea of the life of materials under repeated blows or shocks can be found in Merriman's "Mechanics of Materials."

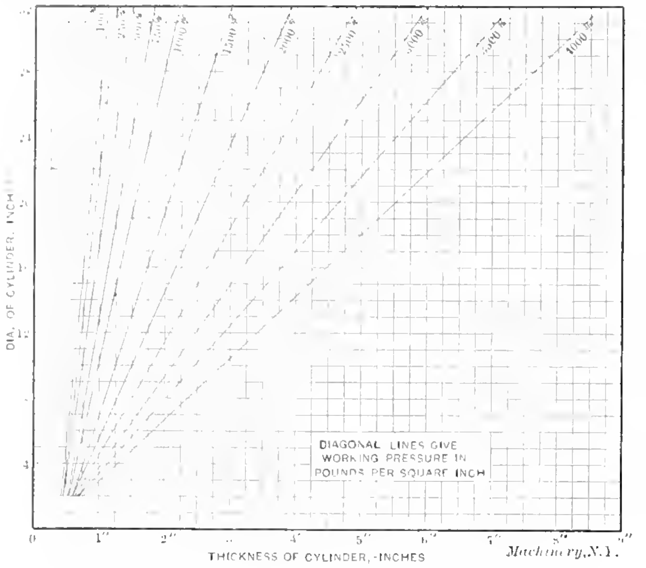

Fig. 2. Diagram for Cylinders with 10,000 Pounds per Square Inch Fiber Stress

In low pressure cylinders, the thickness of metal is much greater than the working pressure requires, but must be such to obtain a good sound casting, and the actual pressure that could be put on such a cylinder without exceeding the allowable tensile stress of the material can be found by the following formula:

$$p = S\,\frac{R^2 - r^2}{R^2 + r^2} \qquad (7)$$

Where R = the outer radius, the remainder of the notation being the same as before.

To find the tensile stress that a given pressure produces, simply transpose the above formula and solve for S; thus,

$$S = p\,\frac{R^2 + r^2}{R^2 - r^2} \qquad (8)$$

Having now developed a practical formula for cylinders for any pressure and tensile stress, and inspected various existing formulas, there remains little more to say except that many formulas, in general, are correct for the conditions and assumptions for which they were developed; but owing to the authors of these formulas and engineering handbooks failing to state these conditions and assumptions, combined with the inability of the majority of engineers and draftsmen to apply formulas correctly, often impossible results are obtained, and the formulas are always doomed as being unreliable and incorrect. Of course, the man that uses them is never at fault. It may therefore be well to state a few points as to the application of the writer's formula.

The thickness obtained is the true thickness of the cylinder rough or finished. If the plunger works by displacement, as it generally does in hydraulic work, or with non-compressible fluids, t is the rough thickness. If the cylinder is finished, t is the finished thickness. If the cylinder is to be rebored, t must be figured for the rebored cylinder, and the amount allowed for reboring must be added on the inside, even if a steel tube is to be forced into the rebored cylinder to obtain the original diameter. If the cylinder is subjected to shocks, this must be allowed for. In hydraulic work the shocks can usually be calculated approximately; not necessarily what the effect of the shocks actually will be, but the maximum effect under working conditions. In well designed piping systems the effect of shocks in a high pressure system is, contrary to general opinions, less than in a low pressure system for the same work.

Calculate the thickness for the static pressure, and investigate this thickness for tensile stress produced by the possible maximum shock under working conditions; if the stress comes within reasonable limits the cylinder is satisfactory. For cast iron the maximum tensile stress due to shock should not exceed 4,000 pounds when often repeated, or 4,500 pounds when rarely repeated. For brass 6,000 to 7,000 pounds, and for steel, 15,000 to 17,000 pounds are average values.

In case of hydraulic test pumps, especially as used for testing pipes, where the pipe is first filled with low pressure water before the test pressure is applied, no matter how suddenly the pressure is applied, the stress in the material cannot rise above that due to double the working pressure, since the water is not in motion, or inappreciably so. But in cylinders operating plungers, a maximum stress many times greater than the initial static pressure may result owing to the inertia of the moving water suddenly brought to rest. If the cylinder also acts as a support, the thickness need not be increased, even if the compressive stress is nearly equal to the allowable tensile stress, a case found in hydraulic accumulators, where the plunger remains stationary, and the cylinder carries the balancing weight and resists internal bursting pressure at the same time. Yet, mathematically, the square root of the sum of the squares of the compressive stress and the tensile stress due to the weight and working pressure should not exceed the allowable tensile stress of the material. If the cylinder supports a weight producing a tensile stress, additional metal must be provided to resist this stress, exclusive of that which resists internal bursting pressures. This additional metal may be in the form of ribs, provided the thickness of the ribs is equal to the thickness of the cylinder, so as to prevent stresses due to unequal cooling or contraction. If the cylinder is subjected to bending, an additional amount of metal must be provided, the moment of inertia of which, about an axis through the center of the cylinder, is sufficient to resist the bending stress.

In addition to the diagram, Fig. 1, a diagram for 10,000 pounds fiber stress only is given in Fig. 2, showing the plotting of the curves and how the thickness increases with the working pressure. It also shows plainly that the formula (6) deduced is a straight line equation, and gives the reader a better idea of the ratio of increase in thickness than the general diagram, Fig. 1.

The writer has applied formula (6) for nearly all conditions of service, and also compared numerous values computed therefrom with the thickness employed under similar conditions by reputable manufacturers, and found, in general, a very close agreement and in many cases an exact agreement. This certainly seems to prove the reliability of this formula.

* * *

According to the *Sheffield Daily Independent*, over $1,500,000 of foreign capital has been invested in Great Britain as a result of the new Patents Act. English workman are, for the most part, employed in these new industries, but some of the foreign manufacturers have brought over foremen from their own plants, and in some cases, English mechanics have been taken abroad to be initiated in the methods of manufacture of the foreign patented articles, which are now to be manufactured in Great Britain. Up to the present time, nine patents have been revoked by the Comptroller-General.

THE MANUFACTURE OF CRANK-SHAFTS

A great deal has been published from time to time in MACHINERY and other mechanical journals describing odd jobs of crank-shaft turning and devices especially rigged up for this work, but little has been said regarding the important operations on crank-shafts which precede the turning of the pins and journals, and practically nothing has been published giving a complete description of the methods followed in plants where crank-shafts are made on a manufacturing basis. For this reason the following article describing in detail the methods used by the A. P. Witteman Co., of 112-116 North Broad St., Philadelphia, Pa., manufacturer of high-grade crank-shafts, has been prepared in order to give a general idea of the methods followed in the manufacture of crank-shafts.

The reason why the making of crank-shafts has become an important item as a specialized manufacture during the last decade is explained by the great demand created by the growth of the automobile and motor boat industries. Many manufacturers of engines for automobiles and motor boats have found it advantageous to buy the crank-shafts for their machines completely finished from firms making a specialty of this line. In order to meet the growing demand, the present shop of the A. P. Witteman Co. at Thurlow, Chester, Pa., about 15 miles south of Philadelphia, was built and equipped in 1907, and the demand for the company's product appears already to make a new addition necessary, inasmuch as the machining department of the shop is now running day and night, employing two shifts of men, the total number employed being about sixty.

When deciding upon the manufacture on a commercial basis of any article sold in a competitive market, there are two methods to follow; one is to decide upon the use of the cheapest methods of production and enter into competition on the basis of low price; another is to disregard the question of cheapness of production if cheapness is not consistent with the obtaining of the best results in the final product, and to use only those methods which are most certain to insure a uniform and reliable product, irrespective of cost, thus selecting the field of competition on the basis of quality. When deciding to manufacture crank-shafts for the trade, the A. P. Witteman Co. chose to follow the latter course, because it was evident that the demand of the market was for a high-grade crank-shaft which could be made light in weight and yet be capable of standing high stresses. Another deciding factor of commercial importance was that while the competition would be keen in the low priced, cheaply made crank-shafts, the competition in a high quality product would be far less formidable, as the tendency of modern manufacture, unfortunately, is to sacrifice quality for cheapness of production. That the Witteman Company adopted the right course when deciding upon quality rather than low price is evidenced by the success the company has met with. Reference will be made in the following to various methods which will indicate the tendency outlined above of looking to quality first, irrespective of the fact that cheaper methods can be used to obtain what on the surface would appear to be the same results; and in this connection it is safe to say that in many other lines of manufacture, makers would find competition less keen if they devoted more time to the quality of their product rather than to reducing the price of production.

Fig. 3. A Large Crank-shaft Forging under the Steam Hammer

Fig. 4. A Collection of Huge Tongs, Fullers and Breaking-down Tools

Material Used for Crank-shafts

For high-grade crank-shafts, alloy steels are used almost exclusively, vanadium, chrome-nickel and nickel steel being the three classes of steel used by the Witteman Co. For crank-shafts subjected to less severe stresses, a good quality of open-hearth steel is also used.

The vanadium steel used, after having been subjected to proper heat treatment as explained in detail in the following, will have a minimum tensile strength of 150,000 pounds per

square inch and an elastic limit of 127,000 pounds. This is the highest grade steel that can be used for crank-shafts and is also the most expensive, its price being about fifty per cent more than that of regular 3½ per cent nickel steel.

The chrome-nickel steel used has a minimum tensile strength of 140,000 pounds per square inch and an elastic limit of 110,000 pounds. These figures, of course, refer to the steel after having been subjected to the required heat treatment. The nickel-steel used contains 3½ per cent nickel, and has tensile strength of from 110,000 to 120,000 pounds per square inch, and an elastic limit of 80,000 pounds. While the nickel steel does not possess as high a tensile strength or elastic limit as the vanadium and chrome-nickel steels, it is preferable in cases where extreme strength is not the most important object, partly because it is cheaper, partly because it is easier to obtain nickel steel of uniform quality, and partly because it is not a material requiring such expensive heat treatment as the other alloy steels. Vanadium and chrome-nickel steel require the utmost care in the heat treatment and while being worked in the forge shop, if satisfactory results are to be obtained. With proper facilities, however, and when thorough care is being used, vanadium and chrome-nickel steels make a superior product possible, although of course, the price is necessarily considerably higher.

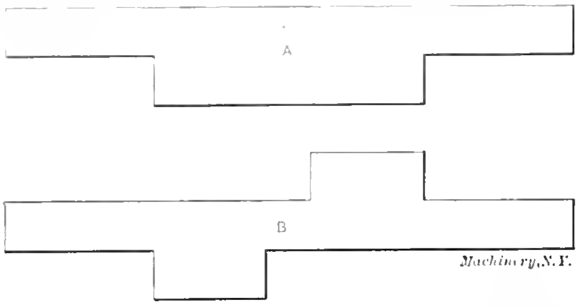

Fig. 5. Comparison of Two Methods of Forging a Two-throw Crank-shaft

The ordinary open-hearth steel which has proved itself best suited for crank-shafts contains from 0.35 to 0.40 per cent carbon, and possesses a tensile strength of from 80,000 to 90,000 pounds per square inch, and elastic limit of from 40,000 to 45,000 pounds.

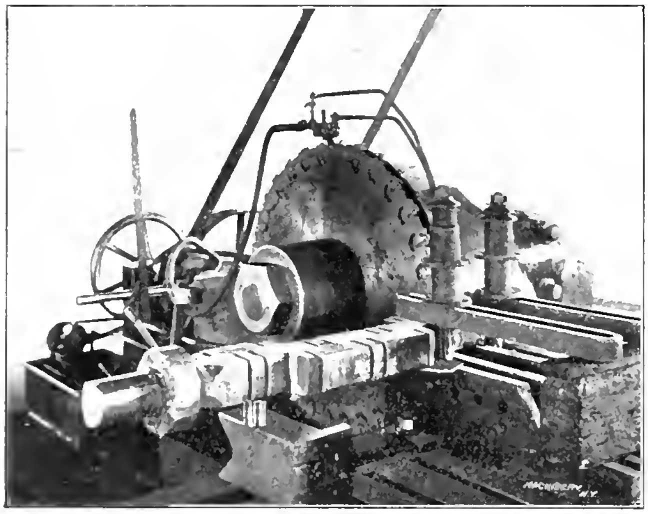

Fig. 6. Sawing out the Blocks between the Webs of the Crank-shafts

Forging Crank-shafts

All crank-shafts are forged from square billets the size of which vary from 4 to 14 inches square, according to the size of the crank-shafts to be made. While it is cheaper to make the crank-shafts from billets which have approximately the same thickness as the thickness of the webs of the crank-shaft, and a width determined by the throw of the finished crank, because of the saving in the expense of forging, it being merely necessary to draw out the ends for the journals, no reduction in the thickness of the billets being required, this method is not conducive to obtaining the best results. When a square billet is used, all parts receive approximately the same amount of hammering, and a solid forging free from flaws and with increased ability to resist stresses is obtained. Practically twice the amount of work in the forging, however, is required when following this method, because the work must go twice under the steam hammer, once for reducing the billet to the proper thickness, and a second time for drawing out the ends of the journals and forging the projections for the cranks.

The billets are heated in a furnace, a front view of which is shown in Fig. 1. The material is put into the furnace in the evening and left to soak over night, the heat being kept constant by means of a pyrometer attached to the furnace and shown to the right in the illustration. All alloy steels are heated to a temperature of 1,800 degrees F. It is very important that the steel be worked at this heat, as, if not hot enough, it is liable to crack; and if over-heated, chrome-nickel steel, in particular, crumbles under the hammer. The furnace is fired with soft coal, and a return arrangement for the combustion gases is provided, by means of which the gases are carried back into the furnace after having once passed over the grate, thus insuring perfect combustion, with the result that practically all of the heat of the gases is extracted before they pass up through the chimney. When working open-hearth steel it is not as necessary as in the case of alloy steels to keep the furnace at one constant temperature. The heat used for open-hearth steel can vary from 2,200 to 2,500 degrees F. without impairing the quality of the finished product.

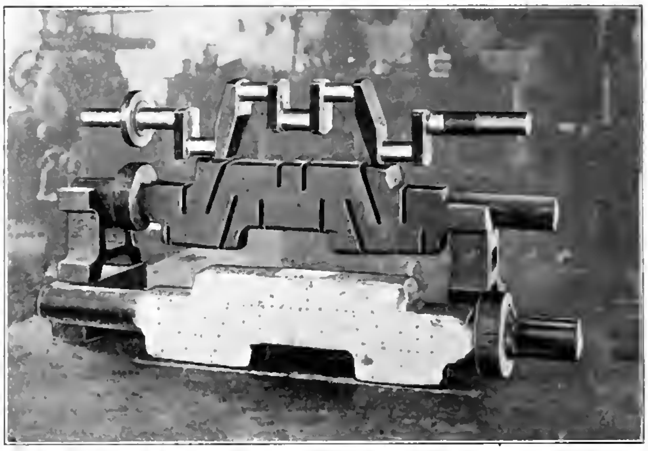

Fig. 7. Inclined Web Crank-shaft at Different Stages of Completion

When the square billets have been heated over night in the furnace, they are worked down under the steam hammer during the next day to the proper thickness, the reduction in thickness being about fifty per cent. After having been hammered down, the billet is again placed in the furnace so as to regain the proper temperature for working, and is then taken out and blocked out under the steam hammer to the proper shape and size for the crank-shaft. When blocked out under the steam hammer, two or three men handle the forging by large tongs supported by chains, while another man operates the hammer and still another handles the fullers and other tools required for blocking out the forging. In Fig. 2 is shown a crank-shaft forging ready for the final heat treatment, and in Fig. 3, a large forging under the steam hammer, the size of which is just to be calipered. This illustration shows plainly the method used for supporting the work, and the means for turning it on the anvil.

One of the greatest expenses for the equipment of the forge shop is met with in providing the great variety of tongs, fullers and breaking down tools required. A respectable looking collection of tongs and other tools, rather larger than those which the ordinary blacksmith is used to handling, is shown in Fig. 4. Crank-shafts have been forged, the finished weight of which has been 5,800 pounds, and the shop is equipped to take care of all work up to three tons. The crane equipment and the steam hammer, however, are of a size permitting work up to five tons to be handled, if necessary.

The capacity of the 4,000-pound steam hammer used is four tons of open-hearth steel per day, or two tons of alloy steel. The reason why the production per day of alloy steel crank-

shafts is so much less, is the greater care that must be exercised when working this steel, and consequently the work must be carried on at a slower rate.

No crank-shafts are drop forged in this shop, because a drop forged crank-shaft is not as reliable as one forged in the manner outlined above.

Another method employed which differs from the commonly accepted practice, is the manner in which all two- and four-throw crank-shafts are made. Instead of forging them as shown at *A* in Fig. 5, blocking them out and then twisting them on the journal bearing between the cranks, the forging is made as shown at *B*, in which case each crank can be blocked out directly from the forging, thereby avoiding any twisting after the forging has been once completed. Crank-shafts made in this manner are stronger, more reliable, and more certain not to contain any fractures in the metal, but they are more difficult to make. Six-throw cranks, of course, must be twisted, but by laying out the projections for the cranks on both sides of the forging the same as in the case of two- and four-throw cranks, it is possible to avoid twisting any crank more than to an angle of 60 degrees. In this way the material is displaced comparatively little as compared with the displacement when the crank is twisted through an angle of 180 degrees.

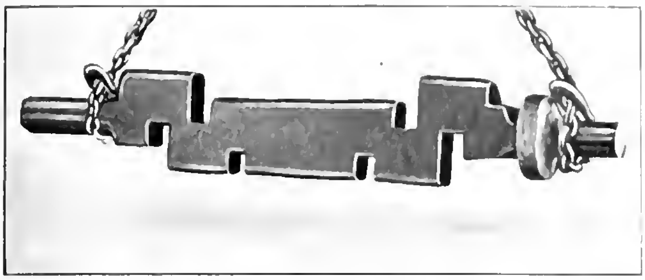

Fig. 8. Six-throw Chrome-nickel Crank-shaft, Sawed, Drilled and Blocked out, ready for Rough Turning previous to Twisting

Heat Treatment after Forging

When the forging operation is completed, nickel steel, then at a temperature of about 1,400 degrees F., goes direct from the steam hammer to the annealing pit, where it is covered with lime and permitted to remain for about twenty-four hours. This relieves the strains that would be set up by unequal cooling.

Chrome-nickel steel, after having been worked to shape at the hammer, and reduced to a temperature of about 1,500 degrees F., is immersed in cotton-seed oil, where it is permitted to cool thoroughly. It is then put back into the furnace, which is now kept at a temperature of 1,200 degrees F. for twenty minutes. This process draws the temper. The forging is then taken out of the furnace and packed in lime, in which it remains for twenty-four hours, the same as nickel steel.

Vanadium steel is quenched in oil immediately after coming from the steam hammer at a temperature of about 1,500 degrees F. The temper is then drawn at a temperature of 1,000 degrees F. in the furnace for about five minutes, and the forging is then permitted to cool in the open air.

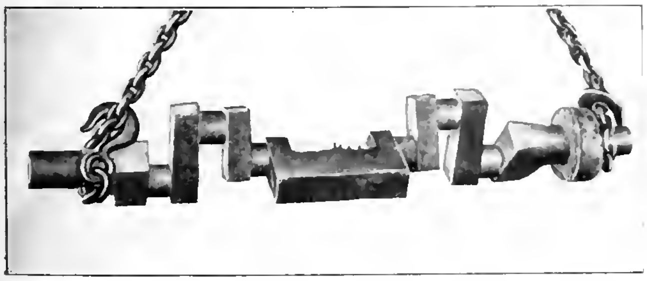

Fig. 9. Crank-shaft in Fig. 8 after having been Rough-turned on the Journals and Twisted

Machining Operations

The forgings are now ready for the machining operations. As the alloy steels are very difficult to machine, a low cutting speed is necessary, and it has been found that No. 5 Burgess high-speed steel works best for cutting this class of steel, when heat treated as previously described. The same steel is also used for the inserted blades in the saws used for cutting out the blocks for giving a rough form to the cranks.

When entering the machine shop the forgings first pass to the laying out table, where they are properly laid out and marked for the blocking out of the various cranks. They then pass to the saw where cuts are taken as shown in Fig. 6. The saw is double, so that both of the cuts required for each crank are made simultaneously, the distance between the saws, of course, being easily adjustable. For crank-shafts which have inclined webs, the saw cuts are also made inclined to the same angle as the web, so that no subsequent heating and bending of the webs will be required. No additional strains are thus set up in the web, and the material in the forging is not disturbed, which insures a more uniform and more reliable crank-shaft. A crank-shaft of this type is shown in Fig. 7, where the bottom view shows the forging as it comes from the forge shop, and after having been laid out and marked on its front surface. The middle view shows the same crank-shaft after the saw cuts have been made, but before the blocks between the saw cuts have been removed, while the crank-shaft on the top has been completely blocked out and rough turned on its pins and journals. This view shows in a general way the method for transforming the heavy rough forging into a slender crank-shaft.

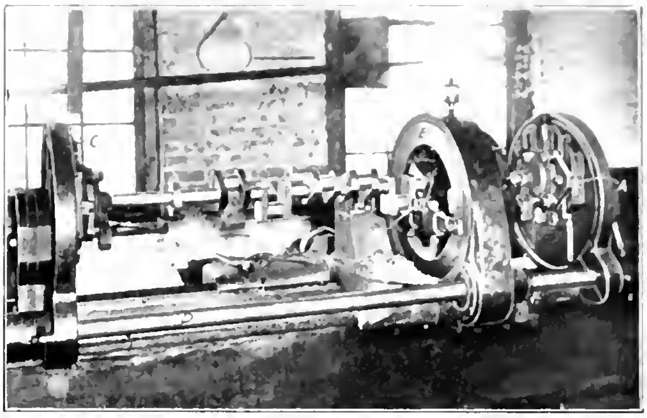

Fig. 10. Crank-pin Turning Machine

When the saw cuts have been made, the crank-shafts pass to the drill press where one or more holes, according to the size of the crank-shaft and the width between the webs, are drilled between the saw cuts made for each crank. Only a very thin rib of material is left between the drilled holes and the saw cuts, so that the part between the webs of the crank can easily be knocked out by a hammer or sledge. It has been found that flat twisted drills are far superior for this work to the ordinary twist drill; in fact, the ordinary high-speed twist drills would not stand up for the severe duty required of them when cutting alloy steels. When drilling vanadium or chrome-nickel steel, cotton-seed oil is used for lubricant, but for drilling nickel or open-hearth steel, as well as for the sawing operation, nothing but ordinary cutting compound is employed. In Fig. 8 a six-throw crank-shaft, sawed, drilled and blocked out between the webs, is shown.

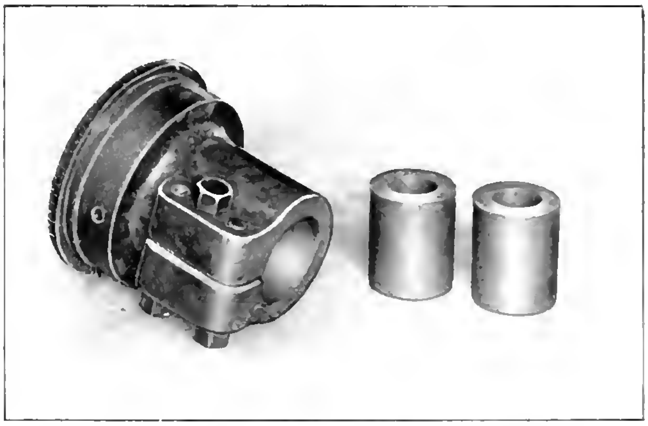

Fig. 11. Holder and Bushings for Finish Turning Crank-pins

When the cranks have been blocked out, all two- and four-throw cranks, which, as previously explained, are not twisted, go to the journal turning machines where the journals are rough turned to about 1/8 inch over standard size. Such cranks as must be twisted also go to the journal turning machines, where the journal pins between the cranks are rough turned to about 1/2 inch over size, after which the crank-shafts go back into the forge shop where they are heated and twisted to the required angles. When twisting, it is very important that the heat for alloy steels be as nearly 1,800 degrees F. as possible, as a lower heat will cause cracking, and a higher heat makes the material crumble under the tools. The twisting of the crank-shafts requires special skill on the part of the operators, as the pin in which the twisting must be done is often very short, which makes the operation a difficult one. In Fig. 9 is shown the same six-throw crank-shaft as is shown in Fig. 8, after the journals have been rough-turned and the crank-pins twisted to their respective angles. The short length of the journal pin between two adjacent cranks should be noted.

When returning to the machine shop, the crank-shafts pass again to the journal turning machines where the journals are rough-turned to 1/8 inch over size, the same as for the crank-shafts which are not twisted. These journal turning machines are ordinary lathes, the shafts being held on centers. They then pass to the crank-pin turning machines, one of which is shown in Fig. 10, where the pins are rough-turned to 1/8 inch over size. These machines deserve some additional explanation. The machine consists principally of a head-stock and tail-stock, on the spindles of which are mounted face-plates at *B* and *C*, and a driving head *E*. The face-plates are driven by spur gearing from a shaft *D* in the back of the machine, as shown in the engraving. From this shaft is also driven the driving head *E*, which is provided with clamping arrangements for holding and driving the crank-shafts by gripping the web, as shown at *F*. The object of this is to have the drive placed as near as possible to the crank-pin being turned, so as to avoid the twisting strains incidental to driving the crank-shaft from a point not in the immediate vicinity of the pin.

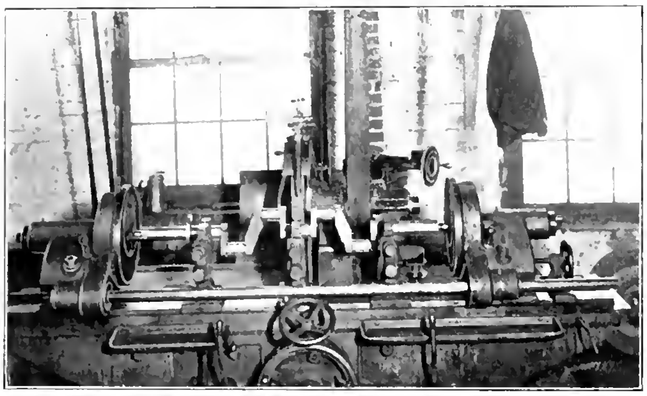

Fig. 12. Grinding the Crank-shaft Journals

The face-plates are fitted with ways and slides, the latter having centers on which the crank-shaft is held. The slides are adjustable, and at *A* graduations are provided so that the slides can be set at the required position for turning cranks of different throws; the machine has a capacity of turning crank-shafts up to 6 inches throw. When the pins are finish-turned the centers are removed together with the bracket in which they are mounted, and instead a bushing holder as shown in Fig. 11 is mounted on the face of the slide. Various sizes of bushings can be clamped in this holder, two of which are shown to the right in the illustration. The ends of the crank-shafts revolve in these bushings, thereby insuring that the crank-pins and journals will come in a fixed relation to each other, something that would not be possible to obtain if the crank-shaft was supported on centers when the pins were finish-turned.

When the crank-pins have been rough-turned, the surplus length of the forging which is from 2 to 3 inches longer than the finished crank-shaft, is cut off and the ends again centered. The journals are then turned on the ends for the bushings in Fig. 11, already mentioned, and the crank-pins are then finish-turned while the crank-shaft is held in these bushings. One-thirty-second inch on the diameter is allowed on the pins for grinding. The webs are finished in the same operation as the pins, in the crank-pin turning lathes. Afterwards the journals are finish-turned to 0.008 inch over the finished size. The crank-shafts are now ready for grinding.

A regular Landis grinder is employed with the regular crank-pin grinding attachment, and the pins and journals are ground to size, the limit of accuracy of all ordinary work being within 0.0005 inch over or below the standard size. The webs are then finished in a shaper and during this operation the crank-shaft rests on its pins and journals, thus insuring absolute balance and preventing more material being removed from one side than from the other. While milling the sides of the webs is by far quicker and cheaper, it is much more difficult to obtain uniform results in this manner. It has been concluded that to insure absolute truth, the shaper is preferable for this class of work.

The crank-shafts are now finished except in cases where they are required to be hollow, in order to make them lighter. In such cases holes are either drilled in the drill press or bored in the lathe through the crank-pins and shaft. Hollow shafts of this description are largely used for high-speed automobile and motor boat engines.

The careful development of the definite methods employed for the heat treatment and the general procedure of the work through the forge and machine shop is due to Mr. Henry P. Arnhold, superintendent of the shop. Mr. Arnhold was for six years with the Tindel-Morris Co. before he engaged with the A. P. Witteman Co., and at the former place he developed some original methods and machines for the manufacture of crank-shafts. E. O.

* * *

In the Bureau of Standards, Washington, D. C., are doubtless the most sensitive balances in existence. They are used only for comparison and are kept, as far as possible, in a room maintained at a constant temperature and free from all outside disturbing influences. The Bureau of Standards is located several miles from the center of Washington in a region comparatively removed from manufacturing industries and railroads. The scales or balances are enclosed in hermetically sealed cases and the weights are manipulated from outside by means of levers which are so ingeniously constructed that the weights may be transferred to the scale pans and then reversed so as to check results. So sensitive are these balances that it is necessary for the operator to stand some distance away, as the heat of his body will affect the balance and cause it to vary, particularly if he stands at one side so that one weight is affected by the heat more than the other. A curious action has been discovered in the manipulation of these delicate balances, which is that a minute quantity of air penetrates the pores of the balance weights, even though gold plated as is common practice. The inflow and outflow of this minute quantity of air at various seasons of the year is said to affect the specific gravity of the weights, and to be detectable by the balance. On account of the variation produced by even such small factors, it is strongly advised by the Bureau that all weights be made in one piece and not with a screwed handle as is a not uncommon practice. The screwed handle weight has a small cavity at the bottom of the hole into which the handle is screwed, and in this cavity and the interstices of the threads is imprisoned a small amount of air. The effect of this imprisoned air is said to be very disturbing to accurate work. The screwed handle also affords opportunity for fraudulent practice, and for this reason also is discouraged.

* * *

Statistics published in the *Archiv für Eisenbahnwesen* give the total mileage of the railways in the world as follows: Europe, 199,385 miles; Asia, 56,294 miles; Africa, 18,519 miles; North America, 268,058 miles; South America, 34,911 miles; Australasia 17,700 miles. Since 1897 the world's railway mileage has increased 140,000 miles or 23.5 per cent. The total amount of capital invested in railways approximates $49,000,000,000. This corresponds to an investment of $31.50 per each inhabitant of the earth.

MACHINE SHOP PRACTICE*

SHRINKING AND FORCING FITS

When heat is applied to a piece of metal, as is commonly known, a certain amount of expansion takes place which increases as the temperature is increased, and also varies somewhat with different kinds of metal, copper and brass expanding more for a given increase in temperature than iron and steel. When any part which has been expanded by the application of heat is cooled, it contracts and resumes its original size. This expansive property of metals has been taken advantage of by mechanics in assembling various machine details. A crank-pin, or other part, which is held in position by being tightly fitted into a hole, is first turned a few thousandths of an inch larger than the hole; the diameter of the latter is then increased by heating it, and after the pin is inserted the heated part is cooled, causing it to grip the pin with tremendous pressure. This is what is known as a shrink fit.

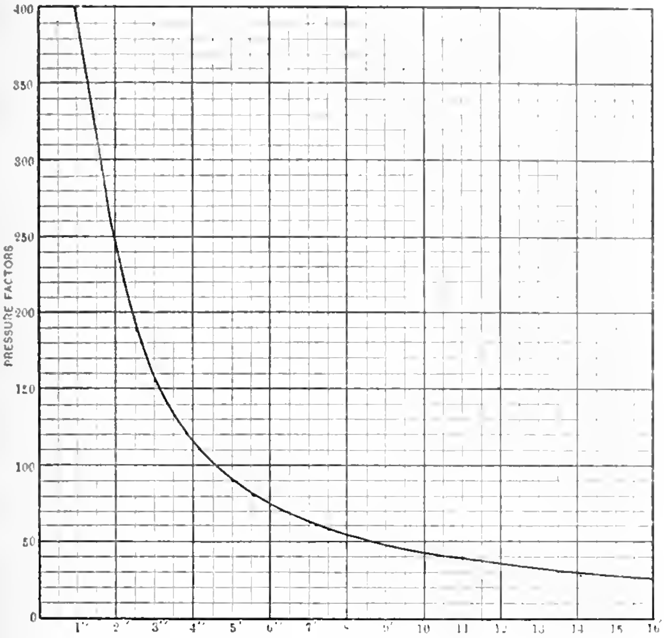

Fig. 1. Pressure Factor Curve used in determining the Allowance for Forcing Fits when a Certain Tonnage is required

A force fit is the term used when a pin, axle or other part, which is somewhat larger than the hole into which it is to be inserted, is pressed into place by a hydraulic press, or other means. The crank-pins and axles for locomotive driving wheels are usually inserted in this way, while the tires are always shrunk on their wheel centers. These tires are first bored a trifle smaller than the diameter of the wheel center, and then heated sufficiently to allow them to pass over the latter. Cooling water is then applied, which causes the tires to contract and grip the wheel center tightly. When old tires are to be replaced by new ones they are, of course, easily removed by again heating them. The shrinkage allowances for tires adopted by the American Railway Master Mechanics' Association are as follows:

Center diameter, inches...	38,	44,	50,	56,	62,	66.
Allowance, inches	0.040,	0.047,	0.053,	0.060,	0.066,	0.070.

Whether parts are assembled by being pressed into place or by the shrinking method, depends somewhat upon circumstances. To press a tire, for example, over a wheel center, would be rather an awkward and difficult job, owing to its size and shape. On the other hand, a pin is easily forced into place with a hydraulic press, but if such a tool were not available, the hole could be heated and expanded sufficiently to permit the insertion of the pin by sledging, or even by hand. The hydraulic press is more economical for most work, and in addition there is an advantage in its use in that the exact pressure or tonnage required to force the part in is indicated by a gage, while there is more or less uncertainty connected with a shrink fit. If the allowance when turning a pin for a shrink fit were too great, the part into which the pin was fitted might be broken when it was cooled owing to the excessive pressure, whereas by the use of a press this danger is largely eliminated as the approximate pressure required is known and the gage indicates just what the pressure is. Tests have demonstrated however that a shrink fit is superior to a force or press fit as the assembled parts are held more securely. Let us assume that holes of the same diameter are bored in the centers of two cast iron disks of the same size and that two pins are turned to exactly the same diameter and a given number of thousandths of an inch larger than the holes. Now, if one of these pins is pressed into place and the other is assembled by shrinking the difference in the pressures required to start the pins out will be considerable the pin which was shrunk in requiring much more pressure than the pin which was pressed into place. The force required to start these same pins by twisting or turning them in their holes would also be much greater for the shrink fit, therefore, when assembling such work as a large built-up crank shaft, or other parts which will be subjected to severe torsional stresses, it is preferable to shrink the parts together as described in the Shop Operation Sheet accompanying this number.

TABLE OF ALLOWANCES IN THOUSANDTHS OF AN INCH FOR FORCING AND SHRINKING FITS

Shrinking Fits				Forcing Fits					
					Allowance			Allowance	
Diameter	Allowance	Diameter	Allowance	Diameter	Minimum	Maximum	Diameter	Minimum	Maximum
2	0.0026	10	0.0112	2	0.003	0.005	10	0.010	0.013
3	0.0036	11	0.0122	3	0.005	0.006	11	0.011	0.013
4	0.0048	12	0.0134	4	0.006	0.008	12	0.011	0.014
5	0.0058	13	0.0144	5	0.007	0.009	13	0.012	0.014
6	0.0070	14	0.0156	6	0.008	0.010	14	0.012	0.016
7	0.0080	15	0.0166	7	0.009	0.010	15	0.014	0.016
8	0.0090	16	0.0176	8	0.009	0.011	16	0.014	0.017
9	0.0100	..	......	9	0.010	0.011		...	.....

The accompanying table gives the allowances for both forcing and shrinking fits in thousandths of an inch. After investigating considerable data collected in various shops it has been found that these allowances for different diameters represent a fair average value as taken from common practice. In some railroad shops, however, the allowances are greater than here given, while in other branches of manufacturing they are less.

The ultimate tonnage, or the pressure finally required to force a pin or other part into place, depends not only upon the allowance for the fit, but also upon the length of the bore or the area of the surface of the fit. For example, if a pressure of 20 tons is required to force a pin halfway into a crank disk, approximately 40 tons will be the ultimate pressure; therefore if a certain tonnage is required, the proper allowance may be determined by the formula

$$A = \frac{2P}{a\,(P\,F)}$$

Where A = the allowance in thousandths of an inch.
P = the ultimate pressure in tons.
a = the area of the fitting.
$P\,F$ = a factor which may be found by the use of curve, Fig. 1, which is reproduced from one of MACHINERY'S Data Sheets.

Let us assume that we are to fit a crank pin into the disk shown in Fig. 2, and that neither the allowance nor pressure are given on the drawing. The average ultimate pressure in tons, commonly used, ranges from 7 to 10 times the diameter in inches. Taking 8 as a factor we would then have $8 \times 4 = 32$ tons. The area of the fitting equals $4 \times 3.1416 \times 5\frac{1}{2} = 69$ square inches; and the pressure factor for a diameter of 4 inches is 115, as will be seen by referring to the curve in Fig. 1. Substituting these values in the formula we have:

$$A = \frac{2 \times 32}{69 \times 115} = .008 \text{ inch}$$

---

* With Shop Operation Sheet Supplement.

This formula is intended for steel plugs pressed into cast iron hubs; but it should be remembered that a formula for forcing fits can, at best, only give figures which are approximate, because there are a number of factors which enter into the problem that cannot be taken into consideration. The kind and quality of the material into which a part is pressed, the smoothness of the pin and bore, as well as the taper and rotundity of either part, and the mass of metal surrounding the hole, all affect the pressure required in assembling. When a pin or other part is pressed into a hole a second time, the allowance for a given tonnage should be somewhat diminished, because the surface of the bore is more smooth and the metal more compact. Then there is the personal factor which is much in evidence in work of this kind. As machinists do not have the same sense of touch, and as some are more careful when taking measurements than others, the results in the way of tonnage for parts which are supposed to be duplicates, often vary considerably when the work is done by different men.

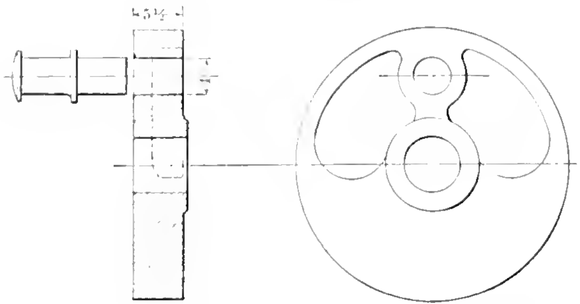

Fig. 2. An Example of the Work assembled by a Forcing Fit

By examining the formula given in the foregoing, it will be seen that the allowance for a given diameter and pressure will be greater as the area of the fitting is diminished, and *vice versa*. When parts are ready to be assembled, variations in the ultimate tonnage required can only be obtained by varying the allowance. The area of the fitting should, however, be great enough so that the allowance will not be excessive. If an effort is made to secure an ultimate pressure of say 8 or 9 tons per inch of diameter, by increasing the allowance to compensate for a small area, the resulting tensile stress upon the hub when the part is pressed into place, may be great enough to strain the material beyond its elastic limit. It is better, therefore, to secure the required ultimate pressure by changing the area of the fitting rather than the allowance, which should remain practically constant for a given diameter; of course, the length of the fitting as well its diameter are usually determined by the designer.

INVOLUTE GEARS, STANDARD

In a letter by Mr. P. V. Vernon, engineer of Alfred Herbert, Ltd., Coventry, England, published in the May 28, 1909, number of *Engineering*, he heartily advocates the cooperation of the committees appointed by the Institution of Mechanical Engineers and the American Society of Mechanical Engineers to formulate a standard of involute gears. As the matter now stands these committees will proceed independently, whereas in the opinion of Mr. Vernon they should take joint action. A great deal of experimenting is now going on in Great Britain in gear tooth forms, but as the experiments are not made under any central authority, it is doubtful that they will result in a standard that is likely to be universally adopted. The suggestion of cooperation on the part of the two committees is one worthy of serious attention. The subject is of great importance and it would be a pity to have two distinct standards adopted if it is possible to agree on a common standard.

* * *

A correspondent to the *Engineering* (London) calls attention to the fact that there is still in use, near Fairbottom, England, a Boulton and Watt engine working at three pounds pressure. The requirements of "modern industrial conditions" evidently have not yet reached that part of the world.

MINIMIZING THE TIME OF DRILLING OPERATIONS—1

ALFRED SPANGENBERG*

Rapid drilling in a shop is very necessary. It is, of course, important from the standpoint of economy in drilling, but the main feature to be considered is the fact that when work is sent to the drills, generally it is then in steady progress of manufacture, and under ordinary conditions, some of the assemblers will be found waiting for the drilling operations to be finished. The object of this article is to analyze thoroughly the elements that enter into the problem of rapid drilling and point out some of the usual defects in methods and processes.

The Machine Tool

The starting point for minimizing drilling costs naturally will begin with a discussion of the machine tool. There are several types of drilling machines, each adapted to a certain class of work. Sensitive drill presses having from one to four spindles are convenient for light work. The spindles have vertical movements by means of hand levers, and are balanced by coiled springs. The table is counterbalanced by a weight and may be swung around as well as raised and lowered. These machines drill holes up to ½ inch diameter. Besides having the advantage of high speed, the drive, which is some form of friction drive, lessens the danger of breaking drills.

The box column, high-duty type of drill press having a table of the knee type, is the best form for comparatively small work that requires extreme accuracy and is drilled without the use of drill jigs. On account of the great rigidity of this type of drill, it is particularly well adapted for the manufacture of jigs and fixtures. For this work, however, better results will be obtained by substituting a compound table so that the work remains clamped to the table until all the drilling or boring operations are completed.

Gang drills which consist of several stationary overhanging arms bolted to a common base and having a common work table are economical where several operations have to be performed on one hole. One operator usually runs the gang.

Radial drills are most convenient for handling heavy work, where a number of holes have to be drilled at different points. This type of drilling machine has a wider range of usefulness than any other, but from the very nature of its design, it is imperative that the column and arm be made unusually stiff. The amount of work that can be turned out from a modern, high-duty radial drill, when driven by a variable speed motor of ample power and using the new flat-twisted drills, is astounding. A well-built, modern radial drill meets all general requirements for accurate drilling, tapping and reaming, but when extreme accuracy is required, and when the machine is used for boring, jigs are needed to guide the tools. Universal radial drills are very handy for large work having holes to be drilled on an angle; but for angular work that can be drilled by clamping it to the swivel shelf of a box table, or where angular work is only occasionally met with, the plain radial drill is to be preferred.

I recently witnessed an interesting job that was being performed with the aid of a universal radial. The drill spindle was swiveled to a horizontal position and used to drive and feed a boring-bar that was boring some holes in a heavy vertical spindle milling machine head and column. The work was bolted to a large angle plate secured to the floor. For boring the head, the bar was guided by means of the top bracket on the milling machine column. The head was then used as a jig to bore the column. The bar in each case was driven through a universal joint. A floor drill would, of course, have handled the job to better advantage, but none being available, the universal radial performed the job in a very satisfactory manner.

Radial drills are sometimes placed in gangs and driven from a single shaft, a very good arrangement for long, heavy work. A very efficient and inexpensive horizontal drill for drilling, tapping, reaming and boring, consists of a radial drill head mounted on a vertical column. This column should

---

*Address: 951 W. 5th St., Plainfield, N. J.

travel in suitable guides on a base having a surface for supporting the work.

Adjustable, multiple-spindle drills are designed for drilling, simultaneously, a number of holes in groups of square, circular or other geometrical forms. The spindle heads are provided with vertical adjustment on the arms to compensate for variation in length of drills or to enable drilling to be done at different levels, the amount of this adjustment varying according to the diameter of the spindles. In setting the spindles, the work jig is bolted to the table, the drills are inserted in the jig holes and the arms are adjusted to bring the spindles into proper alignment and are then clamped. These machines are often used without the aid of drill jigs by clamping the work against suitable stops on the table. There are three standard types of multiple spindle drilling machines: 1. The smaller sizes have the head fixed on the column and are provided with the knee type of table. The table is counterbalanced and its movements are controlled by adjustable hand- and foot-levers. This type is furnished with a No. 1 or No. 2 Morse taper hole in the spindles. 2. A heavier type consists of a work base having a column bolted to it. The head slides on this column and has a quick traverse by hand and power. A box table is furnished to hold small work. This is the type that takes a No. 3 Morse shank. 3. The largest size of multiple-spindle drills have a head sliding between two columns. The work table is mounted on wheels and is arranged to run on a track for bringing the work under the drills. This type is usually motor-driven and has No. 4 Morse taper holes. Any of these types may be furnished with a square, rectangular, or circular head. The spindles are all driven through universal couplings from a central gear. Power feed, automatic and positive stops are features common to all.

TABLE I. POWER DATA ON HIGH-SPEED STEEL FLAT TWISTED DRILLS TESTED ON POND RADIAL DRILL

Size of Drill, Inches	Peripheral Speed, Feet per Minute	Revolutions per Minute	Feed per Revolution	Number of Holes Drilled	Condition of Drill	Horse-power Consumed	Material Drilled
$1\frac{11}{32}$	150	426	0.016	9	Good	11.9	Cast iron plate, $2\frac{3}{4}$ inches thick
$1\frac{11}{32}$	185	528	0.016	30	Needed grinding	12.8	
$1\frac{11}{32}$	210	597	0.016	4	Burned off at point	17.9	
$1\frac{11}{32}$	85	241	0.016	2	Burned off at point	11.9	Machine steel, 4 inches thick
...	85	241	0.009	14	Needed grinding	7	

The value of multiple spindle drills for duplicate work manufactured in large quantities can hardly be overestimated. But for work made in lots of twelve pieces or less, it is often quite a problem to decide just what class of work this machine will handle more economically than the radial drill. This is because the time required to set the spindles of a multiple drill to a complicated layout, is an appreciable percentage of the total time required to complete the job. The layout often involves two or more settings of the work or the spindles, and this nullifying condition also enters into the problem. Provision should be made for tapping on these machines, as several holes can be tapped simultaneously.

General Requirements of Drilling Machines

Accurate tests have demonstrated that the average drilling machine should have fully double the driving power contemplated in its design. This is a point that must be considered carefully, and especially in the case of multiple-spindle drills. A proper increase in driving power means heavier motors, wider pulleys, stronger gearing and larger bearings. Immediately there follows the question of rigidity. Even at risk of reiteration, I want to emphasize the fact that ample driving power and rigidity are the vital features in a drilling machine. The fullest possibilities of economy attending the use of the new high-speed steel, flat-twisted drills cannot be realized unless these provisions are made. An idea of the amount of power required to drive these drills to their limit of endurance may be obtained from the data presented in Table I, which was obtained through tests recently made at the Pond Works of the Niles-Bement-Pond Co. It was desired to obtain power data for a $1\frac{3}{8}$-inch drill, but as several makes of 1 11/32-inch drills were available, these were used for the test, the object being to determine the amount of driving power required by selecting for the data the drill that would stand the maximum amount of speed and feed.

The very simplest form of driving mechanism is to be preferred. Undoubtedly the best type of drive is by a direct-connected 6 to 1 speed range motor through gears and splined shafts. I have never favored a speed box for the reason that they seldom stand for any length of time the severe usage imposed upon them. The feed range of a modern drilling machine meets all general requirements. In the writer's opinion a motor never should be mounted on top of the drill column. While this is the practice with some makers, the plan is open to the practical objection that the vibration caused by unbalanced mechanical and electrical elements in the motor, becomes a serious matter, especially in machines with a long overhanging arm. This trouble will be largely overcome, however, by bolting the machine to a solid concrete foundation. On account of the high speed at which modern drilling machines are run, it is important that they be provided with self-oiling bearings and ball-thrust bearings for the spindles. A reverse for the spindle in the form of positive clutches is handy for tapping. Machines that are frequently used for drilling steel should be provided with an oil pump and pan for taking care of the cutting compound. Drill presses that have the knee type of table which is fed by a rack and pinion should be provided with an adjustable counterweight. This is to compensate for varying weights of work that are placed on the table. When this provision is not made, the work table will fall like a drop hammer when the feed is released. In the type of multiple spindle drill with the sliding head, the drive for the rapid power traverse should be through a friction. When drilling deep holes it is, of course, necessary to frequently withdraw the drills from the holes for the purpose of removing chips and with the positive-driven traverse and automatic stop, much time is lost by having to run the head by hand past this stop. Better results would be obtained by using the friction drive and dispensing with the automatic stop. The head could then be run by power to any position, either in starting to drill or running to the bottom of the holes, without danger of breaking the drills or throwing the power traverse belt off. There would also be the added advantage of not having to run the feed by hand. Some of the smaller sizes of multiple spindle drills are not furnished with T slots in the table to clamp the work by or for use in fastening stops, on the supposition that work will not have a tendency to turn when several drills are operating simultaneously. While a majority of the work handled by these machines does not need clamping, it often happens that several operations have to be performed on a single hole, or the axes of two holes in a piece may lie at right angles, or several pieces having one hole in each may be placed side by side and drilled

TABLE II. SPEEDS AND FEEDS FOR HIGH-SPEED STEEL FLAT TWISTED DRILLS

Material—Cast-iron			Material—Steel		
Size of Drill	Speed, Revs. per min.	Feed per Revolution	Size of Drill	Speed, Revs. per Min.	Feed per Revolution
$\frac{1}{2}$	1150	0.010	$\frac{1}{2}$	535	0.006
$\frac{5}{8}$	920	0.010	$\frac{5}{8}$	425	0.006
$\frac{3}{4}$	760	0.012	$\frac{3}{4}$	355	0.006
$\frac{7}{8}$	655	0.012	$\frac{7}{8}$	305	0.006
1	570	0.012	1	265	0.006
$1\frac{1}{8}$	510	0.016	$1\frac{1}{8}$	235	0.006
$1\frac{1}{4}$	460	0.016	$1\frac{1}{4}$	215	0.006
$1\frac{3}{8}$	415	0.016	$1\frac{3}{8}$	195	0.008
$1\frac{1}{2}$	380	0.016	$1\frac{1}{2}$	180	0.008
$1\frac{5}{8}$	350	0.020	$1\frac{5}{8}$	165	0.010
$1\frac{3}{4}$	325	0.020	$1\frac{3}{4}$	150	0.010
$1\frac{7}{8}$	305	0.020	$1\frac{7}{8}$	140	0.012
2	285	0.020	2	135	0.012

simultaneously and in each case it would be necessary to use appropriate stops for holding the work.

High-speed Drills

The new high-speed steel, flat-twisted drills have been the most potent factor in reducing drilling costs. It is astonishing to note, however, that the tremendous enthusiasm attending their use is often confined to the primary installation; after that the drills are run far below the proper point of speed and feed and the ultimate increase in efficiency instead of being fully 300 per cent or more over that obtained with the older carbon drills, is nearer 50 per cent. Soon the important matter is lost sight of and the only real knowledge the firm possesses on the subject is that "We are buying and using regularly such-and-such a make of high-speed steel drills." In view of the lack of accurate information relative to the proper amount of speed and feed for the new high-speed steel flat twisted drills, Table II will prove interesting. The results shown may not, in all points, prove to be the limit of speed and feed, but are far in excess of those usually secured, so that they can be safely used as a basis upon which to work.

Many manufacturers of high-speed drills lay great stress on the length of time their drills will run without regrinding. This, however, is of very little importance, as the question is not how long a drill will run without regrinding, but how much should a drill be forced so as to produce the most work with a minimum expense for grinding. The crowding of the drilling machine is the important consideration. The question of how long a drill may run without regrinding sinks into the background when the grinding is done by automatic grinders. It is important to state in this connection that a large supply of drills already ground should be kept in the tool supply room, so that under no circumstances will the drill hands be compelled to wait for their drills. This important point is often overlooked. When drilling steel, the use of cooling agents, such as soft soap is highly desirable. These should be used very freely.

TABLE III COMPARISON OF STANDARDS FOR TAPER SHANKS ON DRILLS

Drill Makers' Standard for Taper Shanks		Pond Standard for Taper Shanks	
Size of Drill	Taper on Shank	Size of Drill	Taper on Shank
1/4 to 19/32	No. 1 Morse taper	3/16 to 31/64	No. 1 Morse taper
5/8 to 29/32	No 2 Morse taper	1/2 to 45/64	No. 2 Morse taper
15/16 to 1 1/4	No. 3 Morse taper	23/32 to 63/64	No. 3 Morse taper
1 9/32 to 2	No. 4 Morse taper	1 to 1 13/16	No. 4 Morse taper
......	....	1 7/8 up	No. 5 Morse taper

Miscellaneous Tools

The new sockets for driving drills and other tools with broken or twisted tangs have saved these tools from the scrap heap. Before these sockets were introduced, many firms avoided the trouble by ordering their tools with taper shanks larger than standard. In fact, this is just what the new sockets do—provide the tools with the next larger size of shank. Table III shows the standard adopted by the Pond Machine Tool Co. and also the drill maker's standard for taper drill shanks.

Whenever possible, tapping should be done in a machine on account of the time saved. Some form of safety tapping device will prevent the danger of breaking the taps. For tapping several holes simultaneously in a multiple spindle drill, when the holes are close together, these safety tapping fixtures cannot be used on account of their large diameter. In this case, ordinary tap-holders having a square hole to fit hand taps are used. The tap holder should be provided with a spring pin to keep the tap from dropping out. A plug tap is generally used for machine tapping in cast iron. For steel, the hole is drilled 1/64 larger than standard and two taps are used.

Rose reamers are very extensively used for reaming holes in jig work. These reamers have no cutting edges on the lands, and so permit the reamer to be guided in a cast-iron bushing. Inasmuch as the size is not adjustable it is essential that the wear of a rose reamer be reduced to the lowest limit, in order to ream a large number of holes of a uniform size. The standard form for rose reamers, as made by a number of manufacturers, is illustrated herewith. A study of the engraving will reveal the fact that it would be a decided improvement to cut all the flutes the entire length of the body. When made in the form shown there is no escape for the chips cut by the edge of the short flutes, especially when reaming to the bottom of a blind hole. The result is that the lands are soon cut and make a rough hole. Experiments and experience prove that a rose reamer having all the flutes cut the entire length and provided with a sufficient number to make the lands about 1/4 inch wide will outwear the other form 3 to 1.

Fig. 1. Standard Rose Shell Reamer—Life is Prolonged and Smooth Holes Result by cutting all Flutes entire Length of Body, enabling the Chips to Escape

All boring cutters and counterbore cutters should be made of high-speed steel.

The question of jigs naturally will come under the subject of tools. The great value of jigs as a factor in reducing drilling costs is so well recognized, however, and the subject has been so thoroughly threshed out in a series of articles recently published in MACHINERY, that no further comment is necessary.

* * *

DOES EDUCATION PAY?

W. L. CHENEY*

Does education pay? In the higher sense, yes; but from a financial standpoint it does not always pay its possessor.

The kind of education under consideration is an acquired mental equipment that enables its possessor to think more clearly and correctly than he naturally would. This may be acquired by thinking, and hence it is possible for a man to be wholly self-educated. The quicker and usual way is to study what previous thinkers have put on record, *i. e.*, "the books"; but when books are used blindly, and accepted as rules of thought or conduct, instead of as assistants to thought, they become a hindrance rather than a help.

All progress is the result of education; therefore education is good—so good and grand and fine that it should not be prostituted to commercialism. I therefore protest against certain advertising that is much in evidence, and which would be more appropriate to "Somefeller's Bitters" than to education.

Men are not paid for what they *know* but for what they *do*. If an education enables its possessor to do more or better things, it will, *other things being equal*, increase his money *earning* capacity in direct proportion (and it might decrease his money-*making* capacity—but that is another story).

However, other things are *not* equal, and two other factors must enter into the calculation. First, the number of men who have the same education; and, second, the demand for services that the educated men can render.

In consequence of these other factors, sometimes the man who comes out of the "other" door, or is on the "other" side of the desk, gets more money for his services. One door and one side of the desk cannot exist without the other, and both are therefore equally necessary and, in consequence, equally honorable, and should not be pictured otherwise.

The sort of advertising in question contains not only the possibility of raising false hopes, but also of promoting wrong and snobbish ideas and adding to class feeling, of which some people think there is already too much.

* * *

The Third Avenue Railroad Co. of New York has ordered experimental cars of two kinds to be placed in service with a view of supplanting the horse cars now in use on branch lines. One of the experimental cars will be a gasoline electric having a gasoline engine driving the dynamo which operates the car through the motors direct or by charging a storage battery. The other car will be of the pure storage battery type.

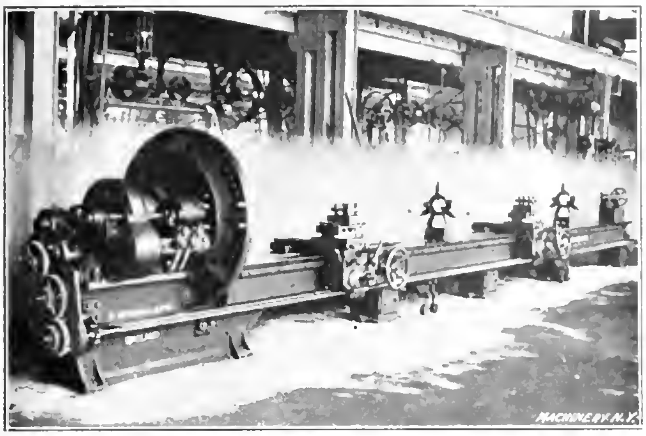
A KINK IN PHOTOGRAPHY

Some time ago I had to take a photograph of the lathe shown herewith. This lathe has a 28-inch swing and a 36-foot bed, and in one particular it is rather out of the ordinary. Normally, there are two complete lathes on the one bed, the headstocks being at the extreme ends and the tailstocks in the middle. One operator is at the back of the machine and one at the front, as usual. The rear lathe has a lead-screw and feed-shaft slightly less than half the length of the bed, while in front, as will be seen from the photograph, the lead screw and feed-shaft extend along the whole length. The novelty of the arrangement is that the carriage belonging to the rear lathe can be turned around to the front so that both carriages may be at work on the same job, one headstock and one tailstock being, of course, removed. Normally, however, the machine is worked as two independent lathes and as such was photographed by me and also by a professional photographer whom we generally employed when we wanted an extra good job.



The White Background for this Large Lathe was obtained by moving a Small Sheet from One End to the Other during Exposure

Anyone who has tried to block out a negative of a machine which has the shop for a background, knows that it is a difficult matter to tell which is the machine and which is the shop. It is always advisable to have a white sheet for a background so that the outline of the machine is easily discernible; in fact, the writer has taken scores of machines where no blocking out was necessary at all. The white sheet should be gently swayed during exposure in order to remove all creases, and dirty marks which would show if the sheet were still. This method is a good one to adopt if a large enough sheet is available; it is hardly practicable, however, to have a sheet big enough for a 36-foot lathe. The only thing then that can be done is to rig up a background that will enable the blocking out of the negative to be done more easily.

When the first photograph of the lathe was taken, a large sheet was suspended from the crane. This was made of a lot of white paper fixed up on cords very much like the family washing, and, in addition, a smaller sheet was held up by three men. It took about an hour to get the background fixed, so after once dismantling it (this was necessary in order to run the machine) I didn't like the idea of putting it all up again to take the other view; consequently I thought I would only use the small sheet, but instead of keeping it in one position, have the men who were to hold it walk from end to end of the machine during the exposure. This was done, and, as will be seen from the reproduction (which has not been retouched in any way) the idea was a success. It leaves the outlines of the machine well defined, and no time was required in putting up a background.

For all practical purposes, it is unnecessary to block this negative out, as the girder work, counter-shafts, etc., rather improve the appearance of the picture, besides giving some idea of the size of the machine. If, however, a pure white background is essential, the negative must be blocked out this can be much more easily done when a background is used.

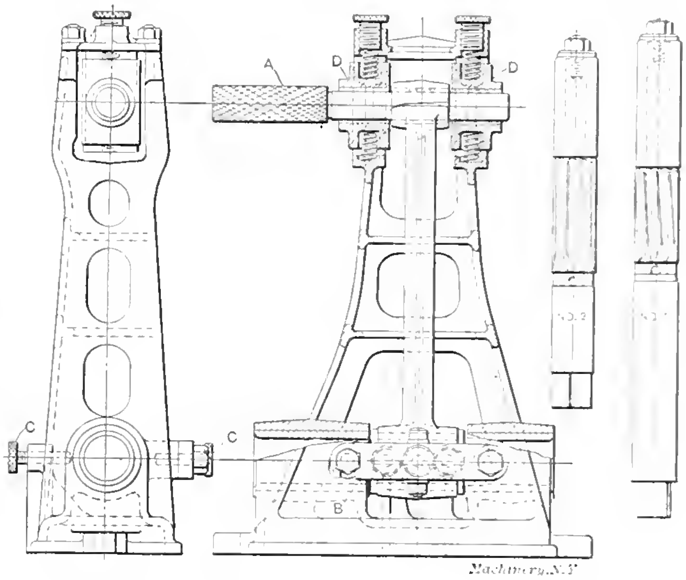
ALBERT CLEGG

Keighley, England.

FIXTURE FOR REAMING CONNECTING-ROD BEARINGS

The jig and tools shown herewith were designed for the purpose of eliminating, as far as possible, what I once heard a manufacturer call "a slow, money-eating process"—that of scraping. We began finishing the bearings of a lot of gasoline engine connecting-rods by first reaming with a standard hand reamer and then scraping them to a good bearing and running fit. This proved to be a slow method, for the connecting-rod bearings were so short that there was difficulty in starting the reamer straight, and it was also liable to chatter, which necessitated a great deal of scraping and bending to make the wrist and crank-pin bearings parallel. The jig referred to was first designed with the wrist-pin end solid, but this proved unsatisfactory as some of the rods had not been machined as accurately as a solid jig would require. To overcome this difficulty the jig was re-designed, and movable brass boxes *D* and springs were used. After this the jig worked satisfactorily and gave a variation of about six-thousandths of an inch, this being the limit allowed by the maker.

The connecting-rod was placed in the jig and held by the pin *A* and the pilot of the line reamer number 1. Then gate *B* was closed and the set-screws *C* locked against the rod to relieve any side strains or tendency the springs might have to pull when reaming. After this the reamer was run through the box reaming it to 0.002 inch below size. After this operation the rod was removed and reamed by the standard size reamer number 2. This method was found to be a satisfactory one, giving a true bearing which could be fitted with but little scraping (most of which had to be done upon the fillets) besides making the wrist and crank-pin bearings practically parallel.



Fixture designed to ream Bearings Smooth and Parallel and thus Eliminate Scraping

In fitting connecting-rod bearings I have found that babbitt bearings will wear longer by being fitted as closely as a good running fit will permit. On the other hand, I find that when using bronze it has proved better to make them a thousandth larger than the journal. If fitted closely they are inclined to seize, after which they pound quickly. For the process of scraping we found that a three-cornered file ground to the proper edge was one of the most satisfactory scrapers that could be made. It is a comparatively easy matter to hold the bearing in the hand and scrape it, whereas with a half-

round scraper, such as is customarily used, it is necessary to use a vise to hold the box and both hands to manipulate the scraper.

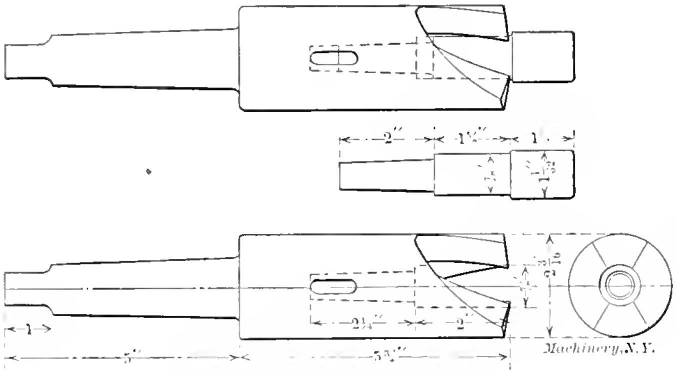
A box wrench should be used, when possible, for tightening the connecting-rod nuts. While this may seem a small matter, one has only to stand for a few minutes and watch a man with a clumsy monkey-wrench to see that the workman with a box wrench can not only do a much quicker and better job in tightening the nut, but does not bruise it during the operation—a consideration which amounts to quite a good deal on a finished product.

Salem, Mass. JOHN F. WINCHESTER.

FLUE-HOLE CUTTER OR COUNTERBORE

A special tool for the drill press, used in cutting the flue holes in the flue sheets of boilers is shown in the engraving. This tool is of tool steel and is made the size of the flue hole. The center hole is bored and tapered to fit a Morse No. 2 taper, and the center piece or guide shown, which is also of tool steel, is then turned and fitted. The jaws are next milled, and then both the tool and the center guide are hardened and ground to the exact size, clearance being given to the cutting edges.

The flue sheets to be drilled are first laid off, centered, and one-inch holes punched. They are then taken to a radial drill press and the holes are reamed out with a one and one-sixteenth inch drill, which takes only a short time and leaves a clean round hole for the center guide to work in. The tool illustrated herewith is then put in the drill press and used as a drill, the center guide being placed in the holes already made. The center guide pin is made removable so that the edges of the cutter can be ground easily, and also extends over the inner edge of the cutters, which makes the tool work very evenly. This cutter has been used in the D. & I. R. shops at Two Harbors, Minn., and its work is satisfactory.



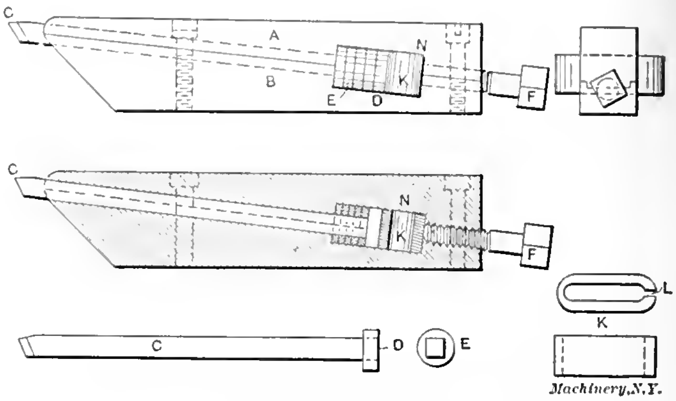
Flue-sheet Cutter or Counterbore

Two Harbors, Minn. AUSTIN G. JOHNSON.

PRECISION THREAD TOOL

Every toolmaker and machinist knows the difficulties often encountered in cutting screw threads of even ordinary accuracy, owing to the tendency of the thread tool to leave chatter marks, especially on large work where the steel is very soft. The goose-neck thread tool of old has gladdened more than one weary heart, only to sadden it again when the work reached the inspector, for I believe that while this tool will make a smooth and very beautiful appearing thread to the casual observer, it is impossible to make an accurate thread with it, or anything like a thread that a nut can be fitted to so that it will not speedily become loose if used a few times. This is caused by the springing of the tool into and out of the metal being cut, as well as sidewise, distorting the thread angles, and causing variations in the depth of the thread so that when a nut is fitted to this thread the high spots soon wear away. With all of its imperfections, however, the goose-neck tool is extensively used, as it will do fine looking work much quicker than the ordinary straight, rigid tool. The toolmaker, however, is often confronted with work which must not only look well, but must be done quickly and accurately, and then he is filled with a longing for a better tool with which to do the work.

I think it is safe to say that steel cannot be made, or at least has not yet been made, so that it is of exactly the same consistency all the way through from end to end. There are places near together where the metal is either softer or harder than the average, the difference being very slight, yet existent. Then there is the imperfect lathe, made as perfect as man is capable of making it, yet to the toolmaker there are observable plenty of signs of wabbling and winking, on the best makes of lathes—small it is true, but nevertheless there —that combine with the more or less imperfect steel to make the toolmakers hair grow white while he is still young.



Precision Thread Tool designed to allow the Cutter to spring away from the Hard Spots

In the effort to better conditions in my own practice, some time ago I designed and made the thread tool shown in the sketches herewith. I do not claim that it is so perfect that it will overcome *all* the troubles of those who make an effort to cut ideal threads, but I do claim that an approximately perfect thread can be made more expeditiously with it than with any tool of its class I know of, and the thread will be as smooth and pleasing to the eye as the very best work done with a goose-neck tool. The accompanying illustration shows the construction of the tool. The cutter-blade *C* is made of a piece of self-hardening steel, which is ground on the surface grinder as nearly square as possible, and then lapped to exactness. On its rear end is a collar *D* which is made of machine steel and shrunk on. The other end is carefully ground to the angle of the thread to be cut. To hold this cutter in the tool-post of the lathe, two pieces, *A* and *B*, of machine steel are milled, grooves being cut in both the top and bottom pieces as represented by the dotted lines, so that the cutter-blade will be held between them. They are also made to interlock as shown in the end view. These cutter grooves should be made so that the blade will fit perfectly, and yet allow it to move rather freely longitudinally. Four screws hold *A* and *B* together, two on each side of the blade, and at opposite ends. A rectangular slot *N* is cut through the tool transversely, one-half of this slot being in the part *A*, while the lower half is in the part *B*. All of the work should be accurately done, as it will pay in a tool of this class to make it as perfect as possible in order to get corresponding results. A hole is drilled and tapped in a line axially, with the cutter groove, for the set-screw *F*. In the slot *N*, there are five washers *E* which are strung on the cutter-bar before it is finally inserted in the holder. The purpose of these washers is to allow the cutter-bar to be advanced as it is ground off, from time to time. A rectangular spring *K* having a slot *L* in one end is placed in the slot *N* behind the head *D* of the cutter. A core made of whitewood and slightly smaller than the interior of the spring is inserted within it. The assembly now being complete it will be seen that the cutter-bar *C* is free to slide back in the groove in the holder so far as the spring *K* will allow it, the pressure of the spring against the cutter-bar being adjusted by the set-screw *F*.

As before mentioned, the old goose-neck tool is free to spring into as well as away from the work, and it is also free to spring sidewise. It will also spring while taking the finishing cut as well as when roughing, which is fatal to accurate results. From the extensive experience I have had with the tool herewith shown, it appears that to cut a

smooth thread, it is only necessary to allow the point to spring *away* from the harder spots in the steel and to prevent the cutting point from digging into the softer part after it has passed the hard. I usually take the roughing cut on small work with the set-screw *F*, slackened so that the slot *L* in the spring *K* is well opened, and when I am ready to finish, I turn the set-screw up until the whitewood core is gripped by the spring. For roughing large work the ordinary goose-neck tool may be used, but care must be taken not to take off too much, as work done with this tool is deceptive, and where accuracy is required it may dig in so deep that when an attempt is made to finish with this new tool it will be found that in places it will not touch the thread made by the goose-neck roughing tool. When properly made there is no chance for side movement of the cutter-bar *C*, in the holder *A-B*, and the resulting thread angles are as perfect as they are ground on the cutter and as the various imperfections of the lathe will allow.

Newark, N. J. G. J. MURDOCK.

JIG FOR DRILLING SLOTS

There are many details in machine construction that require an oblong slot. This work can be readily done with an ordinary slot milling machine when the width of the slot is great enough to permit the use of a stiff cutter; but a slot or other milling machine is not always available, in which case the jig described in the following will be found an excellent substitute. In fact, for doing such work as cutting spring cotter slots in the valves shown in Fig. 1, milling cutters are too weak to withstand more than a slight cutting pressure sideways, as the slots are only about 1/16 or 3/32 inch in width. A drill of this size, however, will cut very rapidly with a direct vertical pressure. In Fig. 2 a jig for drilling these slots is shown with the valve stem in position. The stem is held in place by the set-screw *C*. The two holes *A*, which are 3/16 inch apart, are first drilled in the stem, after which the jig is turned over and the hole *B*, which is central with the holes *A* is drilled, which produces a slot as shown at *A* in Fig. 1. As will be seen, there is very little metal to remove in order to obtain a smooth slot. This is accomplished with the drift shown in Fig. 3, the end of which is turned to a sliding fit for a 3/32 inch hole. This end acts as a guide or pilot to the cutting teeth. The number of teeth in this broach should be sufficient to allow a very slight amount of metal to be removed by each tooth. The drawing is shown on an enlarged scale in order that the construction may be better understood. The teeth on the sides of the broach are inclined in opposite directions in order to counterbalance the thrust endwise. Of course, if the teeth on both sides were inclined in the same direction the broach when driven through the slot would tend to bind against one end of the latter. As will be seen in Fig. 2, the valve stem is located in the jig by the adjustable screw *D*. Only part of the full area of the end of this screw comes into contact with the end of the stem to be drilled. This provides an opening through which any dirt or chips which may be in the hole when the stem is inserted, may pass out. This opening also allows a punch to be inserted for the purpose of driving the valve back when the holes have been drilled.

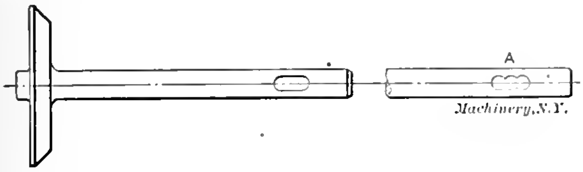


Fig. 1. Oblong Slot drilled in the Jig shown in Fig. 2

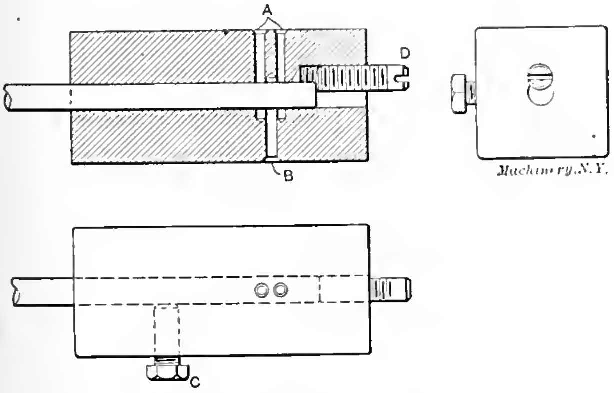

Fig. 2. Jig in which the Central Hole of an Oblong Slot is drilled from the Opposite Side

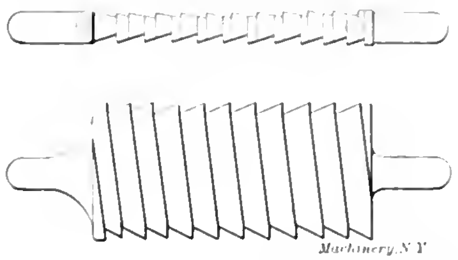

Fig. 3. Enlarged View of the Broach for Finishing the Slots

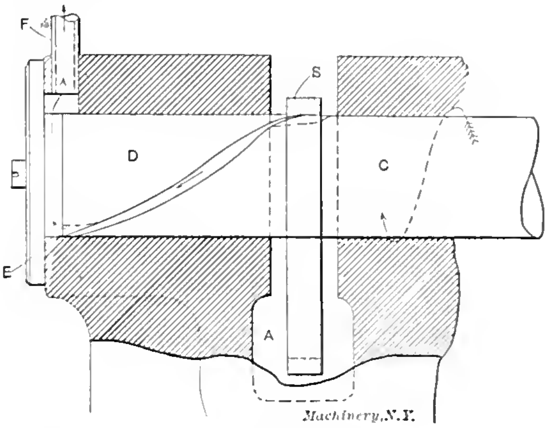
If a blind hole were used it would be quite difficult to remove the chips, with the result that the holes in the stem would be drilled in the wrong position. By referring to the sectional view of the jig it will be seen that the holes for guiding the drill are extended a little way into the opposite half; this is done in order that the drill may pass clear through the stem. CONTRIBUTOR.

FORCED LUBRICATION

An ingenious and simple method of continuous and forced lubrication, which has given complete satisfaction for the purpose intended, is shown by the line drawing. In many respects it is similar to the usual ring oiling bearing, but an important difference consists in utilizing a spiral groove for forcing oil to another bearing which could not be reached by a ring oiler, and for which a liberal supply of oil was necessary. Referring to the drawing, *A* is an oil reservoir; *B* a loose ring on the shaft *C*; *D* a spiral groove cut in the shaft; *E* a plate covering the end of the bearing; and *F* a pipe through which the oil is forced to the other bearing (not shown). The shaft revolves at a high speed, and the ring *B* carries oil from the reservoir to the shaft. Some of this oil is deposited in the groove *D*, and, owing to its inertia and the angle of the groove, the oil is forced along the groove into the chamber at the end of the shaft, and up the pipe *F* as shown by the arrows. When trying this in its initial stages, it was an easy matter to force the oil 3 feet above the shaft. OILER.

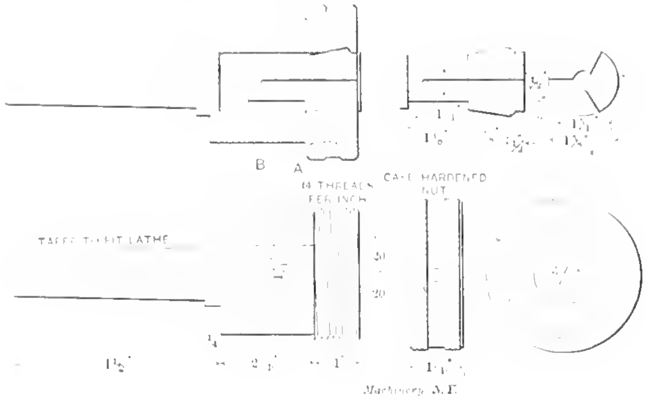


Ring Oiling Bearing arranged to force the Oil to another Bearing

IMPROVED LATHE CHUCK

Many of the standard bench lathe chucks on the market present the disadvantage of having a very short gripping surface; it is also difficult, at times, to release the work from the draw-in chuck without tapping on the hand-wheel. When the rear end of the collet has a larger hole than the front, the work is also constantly tossing about. The accompanying drawing shows the construction of a lathe chuck which is designed to remedy these troubles. This chuck was especially built to hold drill rods from 3/16 to 5/8 inch in diameter. The

body is made of tool steel. The taper shank should first be fitted to the lathe in which the chuck is to be used, so that the latter may be inserted in the spindle and finished. The nut A is made of machine steel and case-hardened. It may be turned with a spanner wrench, holes being provided as shown. Collets of the required size are made of tool steel and hardened. The rear end of the collets have the same size holes as the front, so as to prevent the work from being tossed about. A spring is inserted in the body of the chuck, which is held in position by a flanged collar *B*, which, in turn, is retained by dowel pins. When the collet is in position, it is forced against the collar and spring by nut *A*. When this nut is released the spring forces the collet out and thus releases the work, which can be removed without trouble. These collets should be tempered so that the center is as soft as possible to prevent their being easily broken. As will be seen by referring to the illustration, this chuck can be made in almost any shop without the use of special tools.



Chuck with Spring-actuated Collet

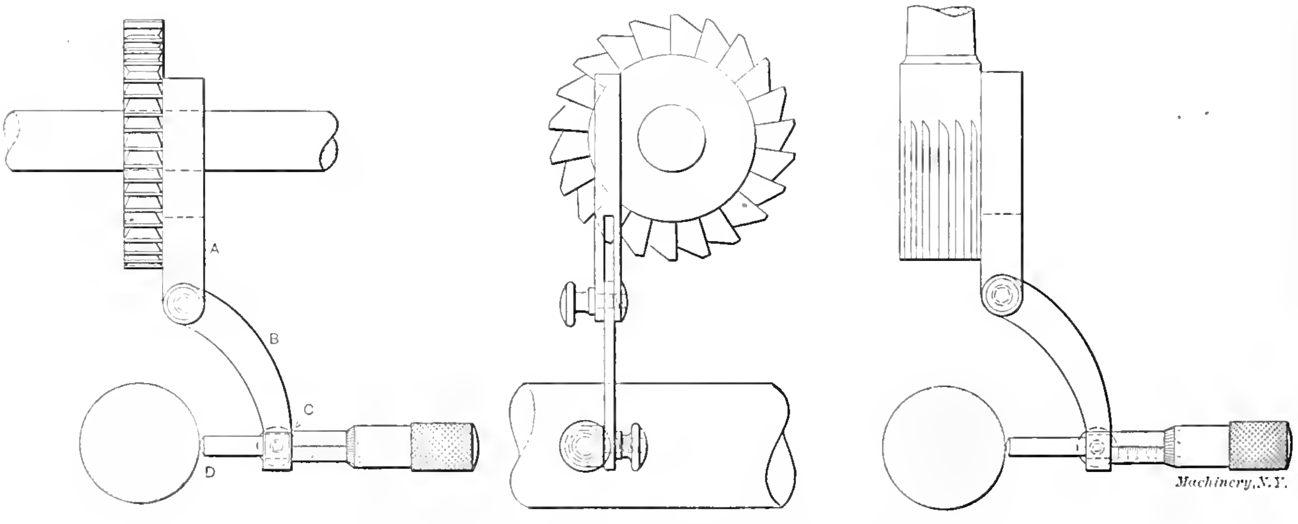
Washington, D. C. H. D. Chapman.

A GAGE FOR CENTERING WORK WITH MILLING CUTTERS

The accompanying drawing shows a handy tool for milling machine work, such as milling keyways and gears. One method of setting the work central with the cutter is to place a square on the table of the machine with the blade in contact with the work, and caliper between the upper end of the blade and the cutter first on one side and then on the other. The cutter is, of course, central when the caliper reads the same on both sides. The method of dial reading is also used.

I made this micrometer attachment for such work. Place the base *A* against the cutter as shown in the engraving. Move the arm *B*, which swivels at pivot *C*, so that the point *D* of the micrometer screw nearly touches the work; then adjust the micrometer until the point touches the work and take the reading. Use the tool on the other side of the cutter in the same way and adjust the work until the micrometer shows the same reading on each side. This tool is also handy for leveling work on grinders or planers, where accuracy is desired. H. D. Chapman.

Washington, D. C.

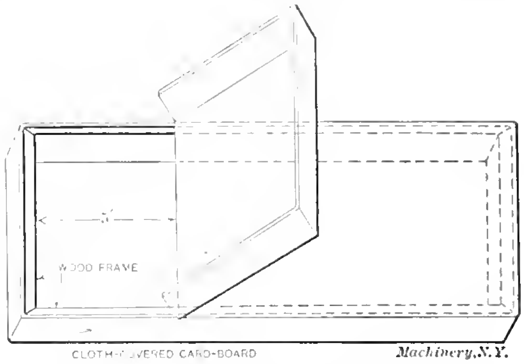


Micrometer Gage for Setting Work Central with Milling Cutters

SIZE OF WORKING DRAWINGS

In commenting on Mr. Breath's article advocating the use of several small sheets for detailing one part, Mr. Washburn in the May number of Machinery makes some very strong points against such practice.

We started some time ago to reduce our large sheets containing numerous details to individual sheets of small size. Three sizes were adopted: 14 x 18 inches; 9 x 14 inches; and 7 x 9 inches; and the size which gives the best results as to clearness of outline is used. Occasionally it has been necessary to put three views on separate sheets, in which case we paste the blue-prints together on one sheet for shop use. The views, however, were all detailed (in pencil) on one sheet and projected as usual, only becoming separate when traced. Repetition of dimensions is avoided by a note which reads: "For other dimensions see sheet number — and number —." This note is placed on each view with the proper numbers added. In this way we have met the objections mentioned by Mr. Washburn.



Portfolio in which the Drawings are Filed

We do not designate the size of the sheet by any symbol, but have assigned certain blocks of numbers—enough to last some years—to each size, which allows each size to be filed numerically, as the numbers are assigned serially and placed on corners of the tracing. In place of the envelope, which is liable to tear if frequently used, we used a portfolio which is illustrated in the engraving. These boxes each hold one hundred sheets and they are made in three sizes to fit the drawings.

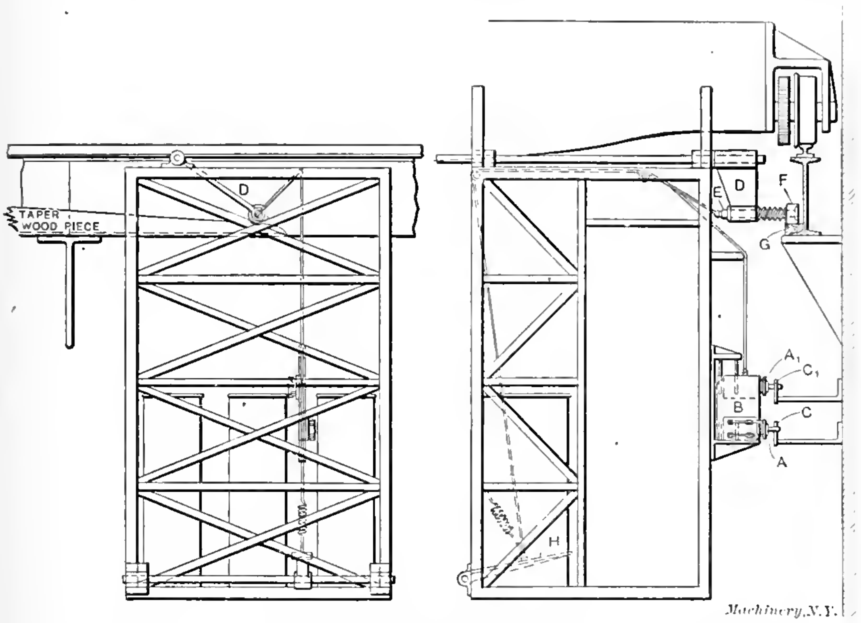
The box has a framework of metal or wood which prevents it from being crushed or broken, and it is covered with cloth-covered card-board. Any first-class box factory will make these portfolios at a reasonable figure, and they will last for years. Ralph W. Davis.

Rochester, N. Y.

SAFETY DEVICE FOR ELECTRIC CRANES

I ran across a safety device the other day for automatically stopping the bridge travel of the electric cranes, which seemed meritorious to me. At least, it possesses the virtue of originality. It was not the product of a mechanical engineer, nor did it have its conception in the brain of an electrical wizard. It is just a plain, simple, practical affair without the "frills and furbelows" of electric brakes, circuit breakers, etc. However, from what I know of the device, I am not sure but that I would trust to its operation in preference to any other with which I am familiar. It consists, primarily, of two positive, quick-breaking switches (one operating in either direction to cut out the power from the bridge travel); and an automatic device for applying the friction brake, to overcome the momentum of the crane and to bring it to a stop at any desired point.

Referring to the accompanying illustration, *A* and A_1 represent the cut-out switches which are fastened to a wooden piece *B*, about 8 inches wide by 12 inches long, located at the back of the operator's cage. Trips *C* and C_1 are arranged at the proper points along the wall to trip their respective switches as the crane passes them. An arm or lever *D* is attached to the extended end of the friction brake shaft. The outer end of this lever carries a stud *E* upon which is mounted a roller *F*. A tapered piece of hard wood *G* is secured to the I-beam at each end of the travel of the crane. The length and degree of taper of these pieces are regulated by local conditions. When the crane reaches the danger points, at which places the trips are located, *C* or C_1, as the case may be, knocks out its respective switch, and the roller *F* begins to ascend the incline of the piece *G*, in consequence of which the friction brake is gradually applied, and the crane is brought to a gentle stop.



A Safety Device for Automatically Stopping Electric Cranes by Breaking the Power Current and Applying the Brake

If it is necessary to pass the danger points, the operator presses the foot-lever *H*, which, through the medium of a small wire cable, raises the piece *B* carrying the switches, and allows the latter to pass over the trips. The same operation of the foot-lever withdraws the stud *E* through the arm *D*, and the roller *F* passes in front of the tapered piece *G*, instead of running up the incline. This leaves the crane in normal condition, free to be operated in either direction as though no safety device existed. While in the danger zones it is not necessary for the operator to keep the foot-lever depressed, as it may be released as soon as the trips *C* and C_1 are passed, for then the roller *F* cannot resume its normal position, but will slide along the face of the tapered piece *G* until the crane has been reversed and passes out of the danger zone. In leaving the danger zone, the spring on the stud *E* forces the roller *F* back into its normal position. The trips *C* and C_1 are hinged to move in one direction only, thus allowing the crane to pass out of the danger zones without interfering with the switches.

A telltale light is hung in the cage and lights a few feet in advance of where the trips operate so that the operator knows when to depress the foot-lever if he desires to enter the danger zones.

The distance in which a crane can be stopped and the consequent length of the danger zones, are, of course dependent upon such conditions as the size and weight of the crane, the traveling speed, and the efficiency of the friction brake; but to give an idea of what these may be, the crane upon which this device is in operation is one of 20,000 pounds capacity, with a span of about 45 feet, and running at full speed from one end of the building to the other is brought to a stop in from six to eight feet after the power is cut off.

Cincinnati, O. J. F. MIRRIELEES.

TOOL-ROOM CHECK SYSTEM

In the March issue of MACHINERY Mr. George D. Hadun has something to say in regard to tool-room check systems. In my wandering about I have found that most of the shops have the check system which Mr. Hadun abandoned; that is, the system in which each man has a number of checks in his own keeping and when a tool is wanted a check is given for it and placed where the tool is kept. The shop in which I am employed has the same system and we also find that it is very unsatisfactory. Very often the men are charged with tools they haven't seen, and, then again, others get possession of tools somehow without a check and refuse to turn them in—then, of course, there is trouble.

Mr. Charles Dodd, tool-room foreman of a well-known shop employing about 250 mechanics in one department, informs me that he has an addition to this system which has proved helpful. A number of checks stamped from one to thirty-one and of a different shape than the other checks, are kept in separate boxes in a drawer and used for each date of the month; they are used for the finer tools only, such as standard plugs, etc. When a man gets a standard plug, for instance, his check is placed on the pin where the tool is kept, and a check with the date of the month is also placed on the same pin, thus showing what day the tool was taken. At the end of the month if the tool is still out the man having it is looked up and if he still wishes to use the tool, he must first return it to the tool-room; another check is then put on the pin showing that the tool was taken again on the first of the month. By this method the tool-room foreman knows where the tools are on any date of the month, and how long they have been out. No trouble has been experienced with this part of the system thus far.

Mr. Dodd has in mind a system that is a little different from the ordinary, which I think is worthy of a trial. Each man has a number of checks in his own keeping, as before. A check of different shape, with the name and size of tool stamped on, is placed on a pin near each tool on the shelf or in the drawer. When a man calls for a tool, he gives his check, and, in return, receives in addition to the tool, the check with the name and size of tool on it; it is really an exchange of checks. This system would tend to prevent the men or boys who give out the tools, from placing the wrong check on the peg of some missing tool and holding the wrong man responsible for it, because the man who has the tool also has the check to show for it; furthermore the men sometimes forget what tools they have out on check, either by lending or misplacing them, and in such a case the check with the name and size of tool on, would be a reminder. [The system advocated in the foregoing, in which there is an exchange of checks, is in use and is, as far as we know, satisfactory.—Editor.]

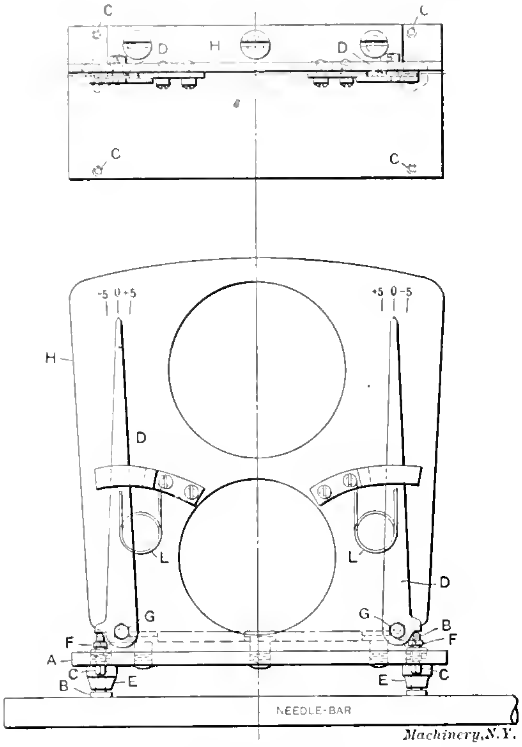
A neat way of arranging small emery wheels that are let

out on check is to have the pin on which they are kept in the drawer turned smaller at the top end to fit the hole in the check; when the wheel is taken off the peg the check is slipped on the end of the pin so that when the wheel is returned it cannot be put in place unless the check is first taken off.
A. J. De Lille.

Elgin, Ill.

A SPECIAL INDICATOR

In one type of shoe sewing machine there is a needle-bar which has besides its endwise motion a swinging motion sidewise through a small arc. For each stitch the bar makes a full advance, a slight return to loop the thread, a full advance and a full return; during this time it also makes one lateral motion. Aside from time, the chief requisite is exact alignment, or that the bar shall be at all times parallel with the base, which lies in a horizontal plane. The inspectors found in some machines that this bar did not swing parallel with the frame, and a special indicator was needed which would show at once such error.



Indicator for Testing the Parallelism of a Sewing Machine Needle-bar with the Frame

After sketches had been made of two or three designs, the indicator illustrated herewith was made. The steel base *A* rests on four feet *C*, which were hardened and then ground and lapped into the same plane. When the indicator is in use, these feet rest upon the frame of the machine. The hardened tool steel plungers *B*, which come into contact with the needle-bar, are flat on one end and spherical on the other, as shown. These plungers fit loosely into the bearings *E*, and are held from dropping out by the nuts *F* which are adjusted to allow sufficient rise and fall. The bearings *E* are of such a length as to give a slight clearance when the plungers are raised as high as they will be when the indicator is in use. Fulcrumed on the studs *G* are the pointers *D*, which have small hardened projecting arms which are in contact with the upper ends of the plungers *B*. The frame *H*, which is of sheet steel, is bent at a right angle along the bottom and screwed onto the base. Right and left coiled springs *L* act in opposition to the plungers and return the pointers to their extreme outward positions. A description of how these springs were made right and left without winding twice may be of interest. A short section of spring was first wound, and then cut into two pieces. The end of one of these sections was bent through it axially and grasped with pliers, while the other end was also held with pliers; the spring was then easily reversed by simply pulling the end through quickly. When the pointers were to be adjusted, the instrument was set on parallels, a height gage inserted under each of the plungers, successively, and the rounded ends of these stoned off until at the same setting each pointer stood at the zero mark. The figures + 5 0 — 5 indicate thousandths of an inch. When completed this tool proved very satisfactory.

Winchester, Mass.

RECORDING BOARD TO KEEP TRACK OF THE BELT LACER

A recording board for keeping track of the belt lacer is shown in the illustrations. We have a man who does nothing but attend to belts, and formerly there was a lot of time wasted in trying to find this man, so a board was provided which indicates the department in which the belt lacer is at work, and also tells him the number of the department in which he is wanted. This board has thirty holes at the top, as shown in Fig. 1, each having a number corresponding to a department. Below these holes there are additional holes containing six black pegs and fifteen red ones. When the belt lacer is wanted, one of the red pegs (which have numbers painted on them from 1 to 15) is put in the hole at the top, which has the correct department number. Then when the belt lacer looks at the board he knows in which department he is wanted; but before leaving he takes out the red peg and puts in a black one. By having the pegs numbered the lacer knows where to go first; the men also know just what department he is in by observing the number of the hole in which the black peg is inserted, so that he may be called in case of emergency. The board is kept in a central location, and it is a case of "First come, first served"; whereas by the old way the first man lucky enough to find the belt lacer would get his belt laced first.
F. Terry.

BENDING DIE FOR ARMATURE BAR CLIPS

The article in the January issue of Machinery entitled "Bending Die" was very interesting to me, and I thought possibly my way of doing the same work might be of interest to others. Some years ago I was called upon to design tools for blanking and forming armature bar clips. The pieces are first blanked as shown at *A*, Fig. 1, in a tandem punch and die, which is so simple that it need not be described. The first operaton of U-bending, as shown at *B*, Fig. 1, is done

by the forming or bending die illustrated in Fig. 2. This tool has replaced 37 formers of the old style. A space former *A* was made to suit the width of the space in the clips. The parts *B* are adjustable jaws which are moved by the screw *C*. These jaws are held in place by springs fastened to hooks *D*. These springs are used for the purpose of keeping the jaws in position after adjustment, and to cause them to release the work after bending has taken place. The block *E* is given an inward movement by two cams or punches with angular ends set in the punch-head which, in turn, is attached to the

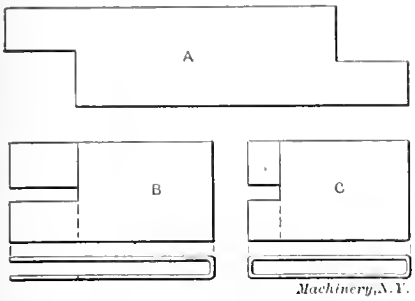

Fig. 1. The Blanked Clip and its Shape after the Two Bending Operations

press ram. As this ram moves downward, these cams come against the angular surfaces *H* and give the block *E* a forward movement toward *A* so that any stock placed between the parts *B* and *A* will be formed in a U-shape. Block *E* is returned to its original position by springs which are fastened to the pins *G* and the eye-bolts *I*.

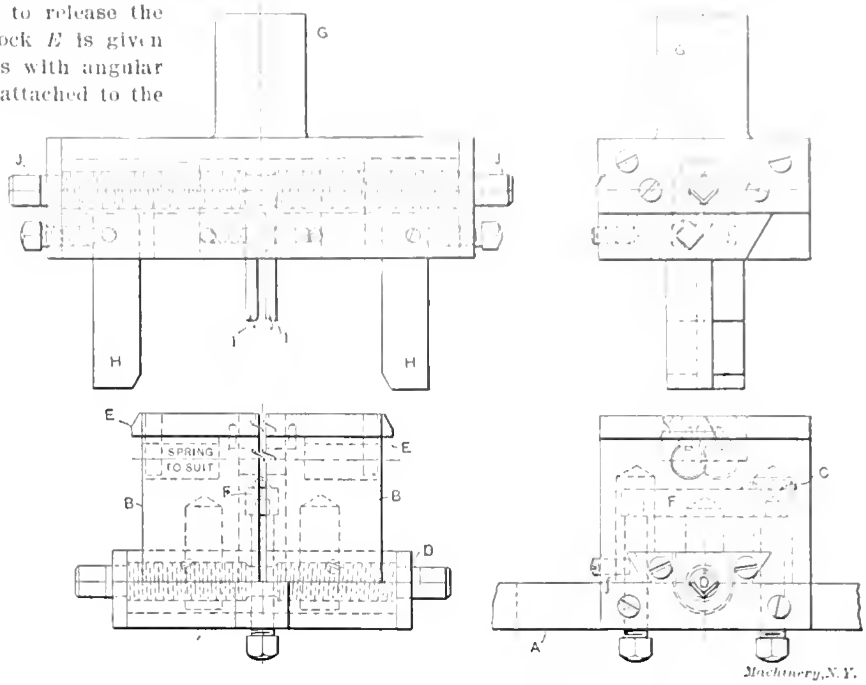

Fig. 3. Punch and Die for Finishing the Clip as shown at C in Fig 1

The clip is now ready for the second and last bending operation, which is done in the tool shown in Fig. 3. This tool, as is the one shown in Fig. 2, is adjustable for anything within its range and forms 37 different clips; but 57 could be

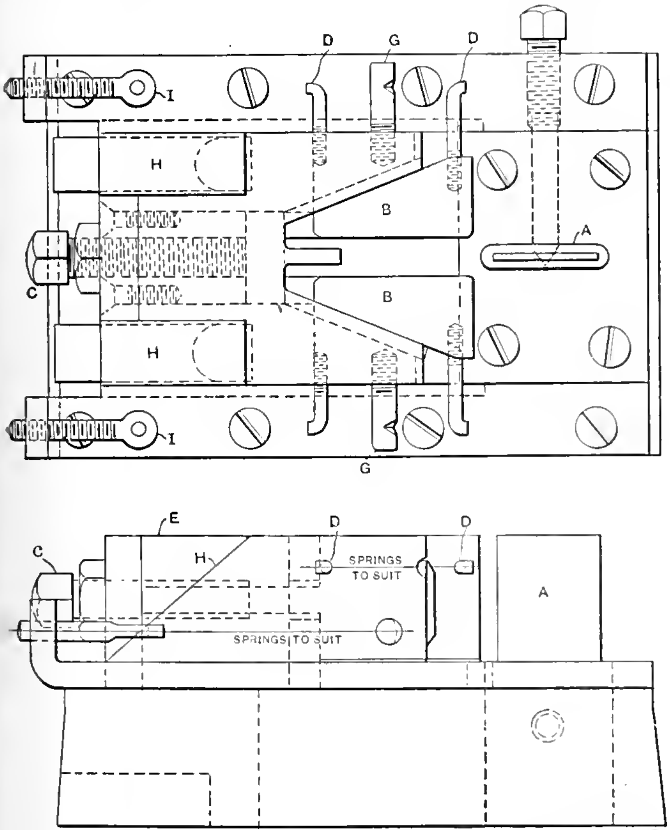

Fig. 2. Die for Forming the Clip as shown at B, Fig. 1

formed with it just as well. The tool is made entirely of steel and consists primarily of a base *A*, two blocks *B* which are adjusted by right- and left-hand screw *D*, two horizontal forming tools *E*, and a support *F* which is adjustable for clips of different heights. This adjustment was required in order to bring the space former (Fig. 4) upon which the clip is mounted during the bending operation at the right distance from the forming tools *E*. On this support *F* there is a small screw *C* which locates the former, thus bringing the work central. The punch *G* has two cams *H* and two formers *I*. These cams and formers are adjustable by the right- and left-hand screw *J*. To perform the last operation on the U-shaped piece, it is put on the space former (Fig. 4) which is then placed on top of the support *F* with the notched corner shown resting against the small screw *C*.

The formers *I* are then adjusted to the outside width of the clip. As the formers *H* are fastened to the same block they are, of course, adjusted at the same time. As the press ram descends, the cams *H* strike the formers *E* and cause them to move toward the center of the die. This movement bends the prongs of the clip to a horizontal position; as the ram continues its downward stroke the vertical formers *I*

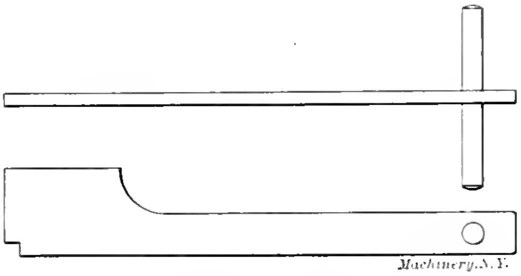

Fig. 4. Former upon which the Clip is Mounted during the Last Bending Operation

bend these prongs down and set them. This finishes the second and last operation forming the piece as shown at *C* in Fig. 1. These tools have been in daily use since they were first made.

Peterboro, Ont., Canada.

* * *

A kink which comes from Carr Brothers, of Syracuse, relates to the cutting off of thin tubing of copper, brass, etc., with the power hack-saw. This is usually a matter of some difficulty, owing to the tendency of the saw to dig into the thin walls of the soft metal. To overcome this tendency, an old saw blade is used for this work. The blade is first run over the face of the emery wheel, so as to grind the teeth almost down to the roots, leaving only very small notches. The saw thus treated is used in the regular way. It cuts very slowly when it first begins, but works at good speed and without digging in during the remainder of the operation.

HOW AND WHY

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST

Give details and name and address. The latter are for our own convenience and will not be published

FIGURING GEARING FOR WORM-WHEEL HOBBING MACHINE

J. B.—The engraving, Fig. 1, shows the gearing on a hobbing machine. Please explain to me how to figure and prove the change gears to cut a worm gear of, say, 50 teeth. A 48-tooth gear is sometimes used in place of the 96-tooth gear at *A*, when cutting a large number of teeth. Please explain how to allow for this.

A.—The way in which the machine is geared will depend on the assortment of change gears with which it is provided. If there is a sufficient variety of these, simple gearing may be employed, using an idler on the swinging arm to connect the gear on shaft *D* with gear *A*.

First find the revolutions of the hob for each revolution of the worm-wheel. This is found by dividing the number of teeth in the wheel by the number of threads in the hob, or worm, with which it is to run. For instance, if there are fifty teeth in the wheel and the worm is single threaded, the number of revolutions of the work to one of the hob will be $50 \div 1 = 50$. This may be called the *ratio* of the wheel. If the worm is double threaded, the ratio will be $50 \div 2 = 25$, and so on. With the gear connections you have shown for simple gearing, when *A* has 96 teeth, the gear on shaft *D* must have a number of teeth equal to 4 times the ratio; that is to say, if we have a worm-wheel with 50 teeth, driven by a double threaded worm, the ratio is 25, and the number of teeth in the gear at $D = 4 \times 25 = 100$. If a 48-tooth gear is used at *A* in place of the 96-tooth gear, the gear on *D* is found by multiplying the ratio by 2. If, for instance, the number of teeth in the wheel to be cut is 135, to mesh with a triple threaded worm, the ratio will be $135 \div 3 = 45$ and the number of teeth for gear *D* will be $2 \times 45 = 90$, when *A* has 48 teeth.

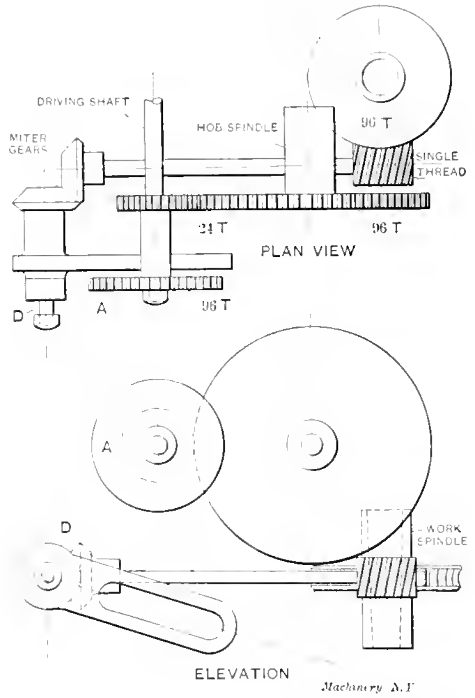

Fig. 1. Arrangement of Gearing in Hobbing Machine

A wider range of ratios can be provided for with a given number of change gears if *A* and *D* are connected by compound gearing, as shown in Fig. 2, where *A* and *C* are the driving gears and *B* and *D* the driven gears. The rule for finding the number of teeth for *B*, *C* and *D* when *A* has 96 teeth then becomes

$$\frac{\text{number of teeth in } B \times \text{number of teeth in } D}{\text{number of teeth in } C} = 4 \times \text{ratio.}$$

When *A* equals 48, this becomes

$$\frac{\text{number of teeth in } B \times \text{number of teeth in } D}{\text{number of teeth in } C} = 2 \times \text{ratio.}$$

Suppose, for instance, that we have a set of change gears going by 6's, that is to say, the numbers run 18, 24, 30, 36, 42, etc., from 18 to 120. Suppose the ratio of the worm gear to be cut is 50, and the number of teeth in gear *A* is 96; then we have:

$$\frac{\text{number of teeth in gear } B \times \text{number of teeth in gear } D}{\text{number of teeth in gear } C} = 4 \times 50 = 200.$$

By selecting the 60-tooth gear for *B*, a 120-tooth gear for *D*, and a 36-tooth gear for *C*, we have

$$\frac{60 \times 120}{36} = 4 \times 50.$$

Proving the calculations of the gearing for this machine is practically the same, whether simple or compound gearing is used. Consider that the whole mechanism is driven from the hob spindle; then the product of all the driven gears, divided by the product of all the driving gears, equals the number of teeth in the worm-wheel divided by the number of threads in the worm or hob. An idler gear between a driving and driven gear is not considered at all, as it has no effect on the motion other than to reverse it. Proving the first example by this method, we have

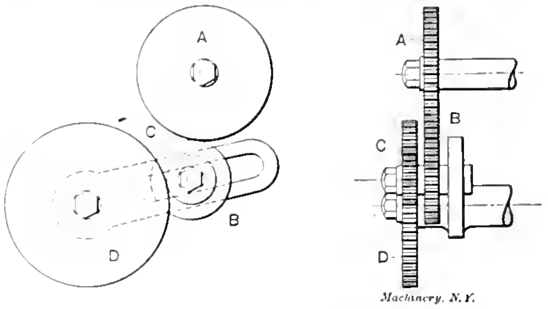

Fig. 2. Compound Gearing for Machine in Fig. 1

$$\frac{96}{1} \times \frac{1}{1} \times \frac{100}{96} \times \frac{24}{96} = \frac{50}{2} = 25.$$

The number of teeth in these driving and driven gears are given in their order from the work, through the mechanism, to the hob. The fraction $\frac{1}{1}$ represents the miter gears, which are of even ratio, but the number of whose teeth are not given. For the last example the proof is similar. Here we have

$$\frac{96}{1} \times \frac{1}{1} \times \frac{120}{36} \times \frac{60}{96} \times \frac{24}{96} = \frac{50}{1} = 50.$$

You can get further help in the matter of calculating gear ratios by studying Chapters IV and V of Shop Arithmetic for the Machinist, No. 18 of MACHINERY's Reference Series

* * *

The purchasing agent of a large electric railway company until lately bought metal for car journal bearings of a certain concern, paying twenty cents a pound. The metal gave satisfaction, but the price was considered too high. A sample was sent to a chemist for analysis and upon receipt of the report, the purchasing agent sent out for bids on a metal of the composition shown by the analysis. A reliable concern at once offered the same metal at six cents per pound. As the amount of metal used in the year is large the saving is considerable. This is an example of the materials that can be bought on specifications to advantage. The purchasing agent, armed with the knowledge of the desired materials' constituents, sends out the specifications and asks for bids. Those who bid, do so with a knowledge of the characteristics of the required materials, and that the material supplied will be rejected if it does not come up to the specifications. The plan has been followed for many years by the Pennsylvania Railroad Company with great satisfaction.

NEW MACHINERY AND TOOLS

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP

BLISS COMPOUND PNEUMATIC FORGING HAMMER

As may be surmised from an examination of the accompanying engravings, the pneumatic forging hammer shown herewith, built by the E. W. Bliss Co., 5 Adams St., Brooklyn, N. Y., closely resembles the construction of the ordinary steam hammer used for the same work. At first thought it seems improbable that the interposition of an air compressor between the boiler and the hammer would result in any actual saving in time, expense and labor. A study of the design and use of the tool, however, as given in the following paragraphs, will show that there is warrant for expecting a saving from this construction.

Fig. 1. An 800-pound Forging Hammer with Compound Cylinder, operated Pneumatically

Compound Air Distribution and Valve Mechanism

A most important improvement made possible by the use of air is the compounding of the cylinder so that the air is used expansively. Compounding has been tried many times with steam hammers, but has hitherto proved impracticable, on account of the tremendous condensation met with. By the time the hammer was ready to use the steam over again on the expansion stroke, there would be nothing left but water. With air, where there is no possibility of condensation, a high economy may be obtained by using the direct pressure for lifting the ram, and a second or expansion stroke for accelerating its downward movement. The arrangement of the cylinders and the valve mechanism for effecting this will be understood from a study of Figs. 2 and 3.

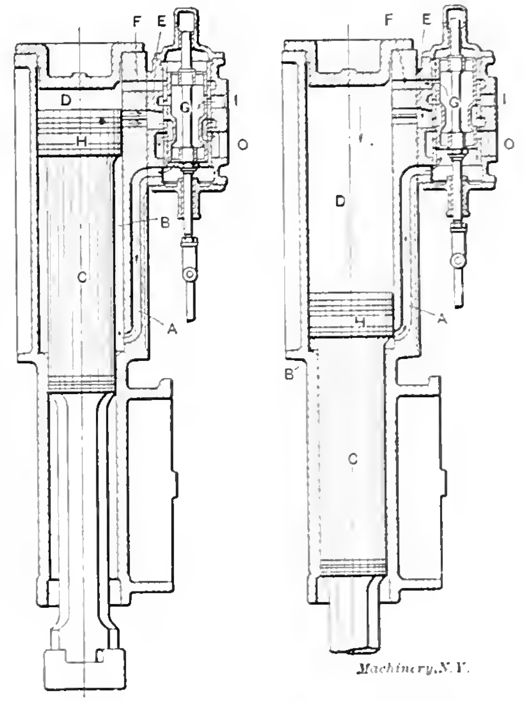
In Fig. 2 the hammer is shown raised to the upper limit of its stroke. The inlet is at *I*. From here the air follows the arrows through the port into the center of the valve *G*, and thence down through the lower port *A* into annular space *B*, and around the small diameter *C* of the piston, where it acts on the under side of head *H* to raise the ram. In raising the ram, the air in space *D* above the piston has been exhausted through ports *E*, following the arrows shown to exhaust *O*. Port *F* is closed by valve *G* in this position so that the upward movement of the piston and ram is limited by the cushion in space *D*.

On the down stroke the valve *G* is raised to the position shown in Fig. 3. Here the inlet *O* has been cut off the interior of valve *G* being connected with port *F* instead, which thus puts space *D* in communication with annular space *B* below head *H* of the piston. (Owing to the fact that the air in *D* in Fig. 2 is under compression, the evil effect of the clearance at this point is not so important as would otherwise be the case.) Port *E* is closed so there is no escape to the atmosphere, and the air at initial pressure in *B*, *A* and *G* is thus allowed to expand in the cylinder *D*, accelerating the downward movement of the ram and increasing the force of the blow without requiring any perceptible increase in air consumption. On lowering the valve again, to the position shown in Fig. 2, the space *D* is again connected with exhaust *O*, and space *B* with inlet *I*, raising the piston again to the position shown in the illustration.

Provision for Using Direct Pressure on Ram

By examining the side of the hammer frame in Fig. 1, it will be seen that the downward movement of the valve lever (and the consequent raising of the valve) is limited by a pin. This pin may be removed, increasing the valve travel. This increased valve travel allows space *D* to be directly connected with the compressed air supply on the downward stroke, space *B* meanwhile exhausting into the atmosphere. This provision permits the striking of a much heavier blow than is indicated by the normal rating of the hammer, thus increasing its capacity for exceptional work. This increase of capacity is naturally obtained at the expense of economical working, so it is not recommended for regular practice. It has the advantage, however, of giving the tool an exceptionally high "over-load" capacity.

The action of the valve when raised to the direct pressure position will be readily understood from Fig. 4, where it will be seen that the air at *B* escapes into *D* as before, but that in addition the inlet supply at *I* is connected by means of the annular passage around valve *G* with ports *E*, leading to space *D* above the piston.



Figs. 2 and 3. Position of Valves and Flow of Air in Compound Cylinder, with Ram held up and down, respectively

Fig. 5, which has reference letters corresponding to Figs. 2, 3 and 4, shows the arrangement of the valve mechanism for the largest size of double frame hammers, such as shown in Fig. 6. The reference letters correspond in all the engravings, and the principles of operation are the same for both cases.

Incidental Advantages of the Use of Air

Besides the advantage of using the air expansively as just described, there are a number of other advantages attaching to the use of air in place of steam. Long steam lines and a high rate of condensation are almost inevitable with the steam hammer. It is common practice to leave the drip valves open for the line, the cylinder and the exhaust, this being necessary to take care of the amount of water produced. The escape of steam through these openings amounts to more than a small percentage of the amount of steam usually employed. In this hammer no drips are necessary, as the air is relieved of its water in the receiver. Furthermore, long lines are unnecessary, as the compressor may be placed in the closest and most convenient position with relation to the boilers, irrespective of the position of the hammer and the furnace. It is also feasible to use a compressor of high commercial efficiency, using the steam in a far more efficient manner than in the crude mechanism of the ordinary steam hammer. The saving from these sources is considerable.

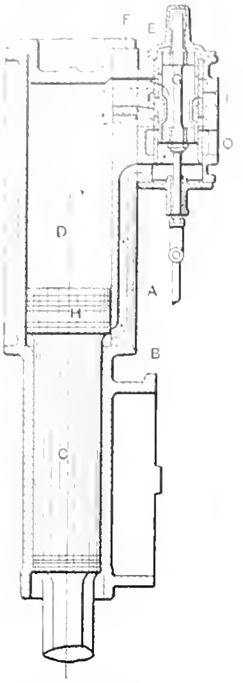


Fig. 4 Using Full Air Pressure on Down Stroke

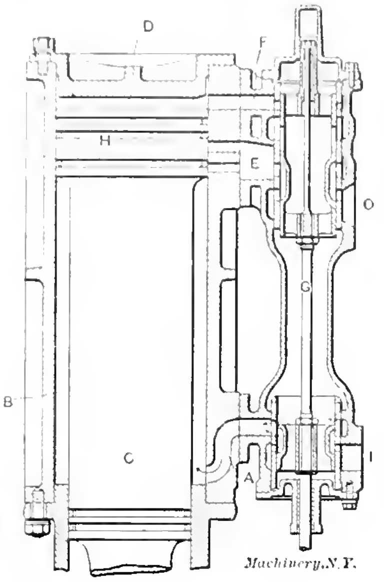

Fig. 5. Valve Arrangement used on the Large Sizes

The heavy condensation in the cylinders when using steam results in a constant flow of water through the stuffing boxes, down the piston, and onto the die faces. This makes it necessary to exercise great caution in striking the first blow on a piece of work, as striking the red hot forging loosens the scale. This makes a heavy blow dangerous, as the flying scale and metal are liable to injure the workman. For this reason the first blow given by the hammer man to a new spot on a forging is habitually light, so as to either compress the scale or knock it off. This blow is wasted so far as effectiveness in shaping the work is concerned, though it uses about as much steam as a heavier stroke. The absence of drip in the pneumatic hammer overcomes these difficulties, and the corresponding freedom from loose scale permits keeping the die faces clean, thus giving them much greater durability. The fact that there is but one line of piping, that for the air pressure, simplifies the matter of installation and maintenance. The exhaust takes place directly into the atmosphere, thus assisting in cooling and ventilating the building instead of heating and vitiating the atmosphere as in the case of a steam hammer.

Details of Mechanical Construction

While the hammer is made in the single frame design, shown for the 800-pound hammer in Fig. 1, for the larger sizes the double frame type shown in Fig. 6 is used. As will be seen in Figs. 2 to 5, these tools are of simple construction, with very few wearing surfaces. The small part of the cylinder forms a guide for the ram, which with the jaws for the die, are forged from a solid steel ingot. The shape of the section of the ram is nearly uniform throughout, while the cylindrical portion is almost entirely contained in the guiding cylinder when the blow is struck. Ordinary piston rings are employed in the guiding cylinder as well as on the main piston head, making the use of stuffing boxes unnecessary. The freedom from friction thus obtained is an important factor in increasing the efficiency of the machine.

The use of air in place of steam simplifies the mechanism in a number of ways. The absence of condensation, just mentioned, makes it possible to strike the first heavy blow without working the hammer. For this reason the automatic striking attachment usually found has been dispensed with. The valve is thus controlled by one hand-lever and the hammer is more simply operated. Proper manipulation of the single handle will give any weight of blow, light, heavy, exceeding heavy or holding down, as required. When the handle is raised, the ram rises and remains in its highest position.

The piston and dies are kept from rotating by wooden jaws, which bear against the flattened sides of the ram between the die head and the smaller diameter of the piston. These are kept automatically lubricated and have no other function than that of keeping the piston from twisting, so the service on them is not severe. A detail of interest will be noted in Figs. 2, 3 and 4, where it will be seen that the bearing surface by which the cylinder casting is bolted to the frame is provided with a tongue, engaging a corresponding groove in the frame. This takes the thrust and jar, relieving the bolts from shearing strain. The latter may, in fact, be quite loose without harm to the mechanism.

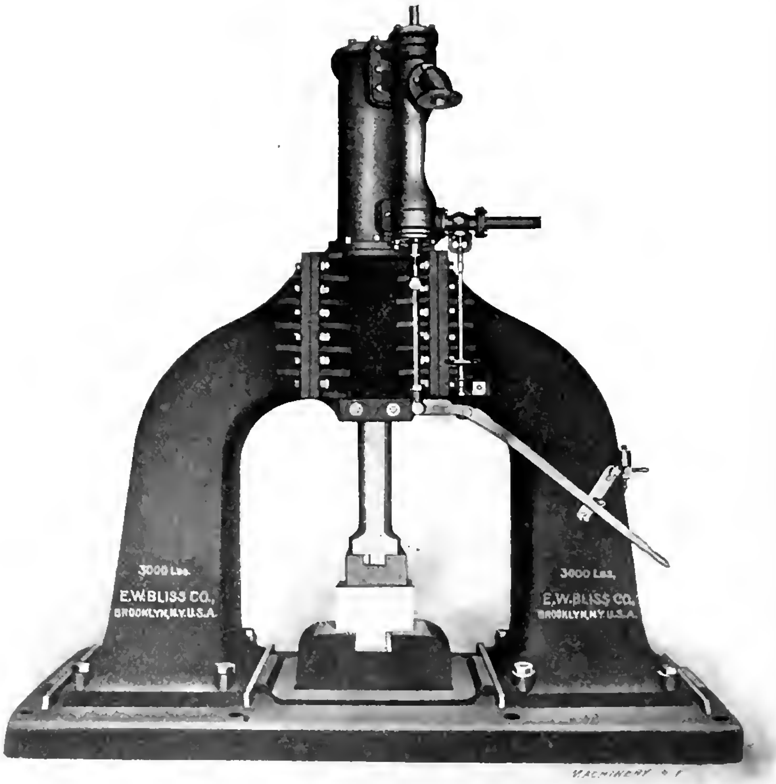

Fig. 6. Heavy Double-frame Pneumatic Forging Hammer

Sizes and Capacities

This pneumatic forging hammer is made in ten sizes, ranging from 150 pounds to 6,000 pounds. These figures give the

nominal size of the hammer, reckoned on the basis of the actual falling weight in pounds. The maximum blows per minute range from 120 for the smallest size to 30 for the largest size. These hammers are designed to use air at the usual shop practice of 80 pounds per square inch. Their consumption of free air in cubic feet per blow at this pressure ranges from 0.158 to 11.2 cubic feet per blow. The capacity of compressor recommended ranges correspondingly from 30 to 450 cubic feet of free air per minute.

An interesting application of the two smaller sized hammers (150 and 250 pounds) has been found, which is made possible by their operation with compressed air. This relates to the hammer for forging and dressing tools, such as are used in mines, quarries, etc. Such establishments are usually already provided with the necessary air pressure, so that the matter of providing a hammer is very simple as compared with installing one of the old style. These light hammers are mounted on trucks and may be moved from place to place whenever their service may be required.

Summary of Advantages

In brief, the advantages claimed for the use of air in this forging hammer are as follows: Greater economy through the use of the compound principle; increased capacity from the provision of direct action for taking heavy blows; no condensation and consequent economy in the use of steam—both in that escaping in the drip and that used when working out the hammer to free the cylinder of condensation; no long steam lines; location of compressor close to boiler and possibility of using a light economical form of engine and compressing mechanism, in place of the inefficient mechanism of the steam hammer; simplicity of construction and operation.

This tool is of English origin. The makers have had one of the smallest sizes, such as shown in Fig. 1, in use in their shops for many months, and their favorable experience with it has led to their purchase of the American rights for these tools. The 3,000 pound hammer shown in Fig. 6 was supplied to the Lackawanna Railroad Co., for general railway forging. In this work it has given complete satisfaction.

DAVIS CLUTCH

The clutch illustrated in the accompanying engravings is made by the Davis Clutch Co., 1232 East 3rd St., Cleveland, Ohio. It is the result of a desire of the makers to obtain a simple, durable and efficient construction embodying all the requirements necessary for meeting the exacting conditions under which such mechanisms are used.

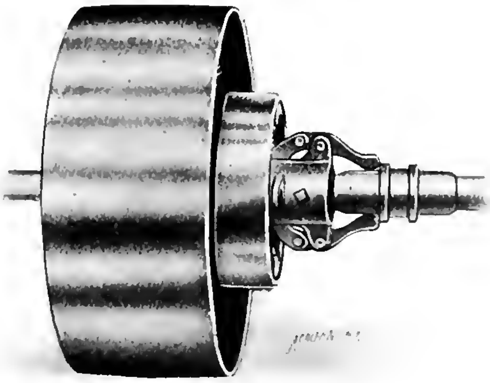

Fig. 1. The Davis Friction Clutch

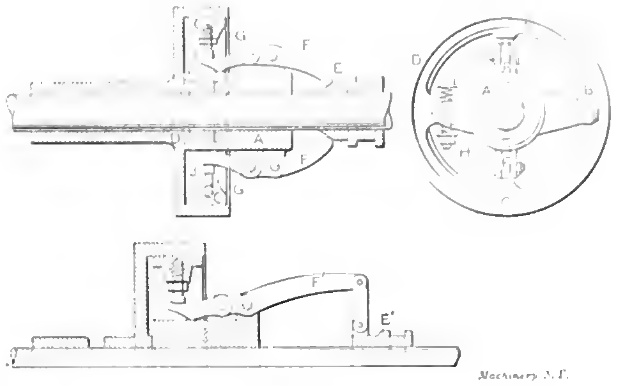
The construction of this clutch is plainly shown in Figs. 2 and 3. The body piece *A* is keyed to the shaft. On this are hinged at *B* two friction rings *C*, which extend all the way around the hub and are pressed by the levers shown against the inner flange of the friction rings or hub *D*. On this latter member is mounted the pulley or gear which it is desired to connect with or disconnect from the shaft.

A compound lever system is used. The thimble *E* in Fig. 2 spreads apart the outer end of levers *F*, and thus tips up the toe of lever *G*, which is fulcrumed on the hub of the body piece against adjusting screw *J* in the friction rings. As shown, these rings terminate at one end in two lips provided with through-bolt *H* and springs, which assures plenty of clearance when the levers are dropped and the clutch is thrown out. A variation in the lever mechanism for larger clutches is shown in the lower view of Fig. 2. Here levers F' are connected with sliding sleeve E' by means of links as shown, the rest of the mechanism being practically identical with that just described.



Machinery, N.Y.

Fig. 2. Construction of the Davis Clutch

The provision for adjustment is very simple, and practically unlimited in range. The adjustment of the clutch is effected by throwing it into engagement, and then tightening down set-screws *J* with the same force on each side, to the degree desired, locking them at that point with the jamb nuts. Equal bearing of the fingers and levers on both sides of the thimble *E* holds the latter rigidly in place, and prevents spring of the shaft. The clutch is carefully balanced, so that there is no vibration, with consequent danger of jarring the thimble out of position.

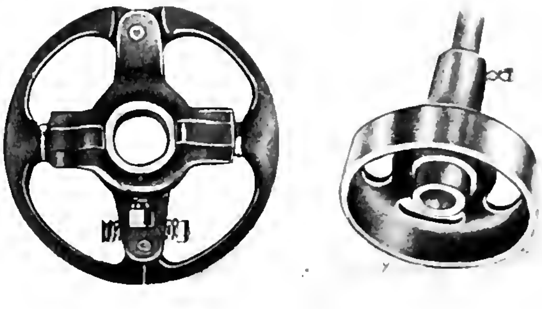


Fig. 3. The Clutch Disassembled

The matter of lubrication has been carefully attended to. Sleeve *D*, it will be seen, is of great length, being extended forward into a counterbore recessed into body piece *A*. From an oil chamber in the center of the sleeve (not shown) oil is distributed over the bearing through carefully located channels. It is recommended that the friction surfaces be lubricated with cup grease or vaseline; this improves their durability and action.

This clutch is very compact, and is easily adapted to special uses in machinery of all sorts. The length of the hub and diameter on *D* may be varied to suit the machine where it is to be used, and special forms may be given to this member to meet unusual requirements.

A test of a series of these clutches was recently made by an impartial investigator, Professor R. H. Fernald, of the Case School of Applied Science, Cleveland, Ohio. The purpose of this test was to enable the manufacturers to make conservative guarantees of the capacity of their productions when installed in the shops of their customers. They were made under the following conditions:

(1) The clutch must run perfectly free when no load is applied. (2) The load carried during each test must be entirely removed before releasing the clutch, and upon releasing, the clutch must run free, and the shaft must come speedily to rest. (3) With the clutch set as indicated in (1) and (2) the following ratings must be determined: (a) The load which the clutch, when suddenly thrown into action, will readily pick up and carry for a period of 15 minutes. (b)

The maximum load which the clutch will carry when the load is gradually applied. This maximum load is also to be carried for 15 minutes.

The five clutches submitted for test were tried out on the above basis. The principal dimensions and the results secured are presented below.

TABLE I.

Clutch Number	Diameter of Friction Surface, Inches	Outside Diameter of Clutch, Inches	Width of Friction Surface, Inches
6	$5\frac{5}{8}$	$6\frac{1}{8}$	$1\frac{5}{16}$
8	$7\frac{5}{8}$	$8\frac{1}{4}$	$1\frac{3}{4}$
10	$9\frac{7}{16}$	$10\frac{1}{16}$	$2\frac{1}{4}$
14	$13\frac{1}{4}$	$14\frac{1}{4}$	$2\frac{3}{4}$
18	$16\frac{3}{4}$	18	4

Under the conditions specified above, the following results were secured:

TABLE II.

Clutch No	6	8	10	14	18
Max. "pick-up" load, pounds.	21.5	50.5	70.5	254.0	354.0
Revolutions per minute for maximum "pick-up" load	91.4	111.7	122.8	119.3	133.8
Horse-power transmitted for maximum "pick up" load at r. p. m. indicated	1.96	5.64	8.66	30.3	47.3
Maximum load carried	35.5	58.0	81.5	254.0	354.0
Revolutions per minute for maximum load carried	86.5	111.0	129.8	119.3	133.8
Horse-power transmitted for maximum load carried, at r. p. m. indicated	3.07	6.40	10.57	30.3	47.3

Rating the clutches on the basis of 100 revolutions per minute, the horse-power transmitted was as follows:

TABLE III.

Clutch No	6	8	10	14	18
Horse-power transmitted for maximum "pick-up" load	2.15	5.05	7.05	25.4	35.4
Horse-power transmitted for maximum load carried	3.55	5.80	8.15	25.4	35.4

These clutches are made in sizes to deliver from 3 to 60 horse-power, at 100 revolutions per minute. Besides the difference in the lever mechanism shown in Fig. 2, the clutches are furnished in two styles, depending on whether they are to be used for counter-shaft or main line use. In the former case two levers are used, each friction ring having a single bearing point on the lever, as here illustrated. For line shaft use, four sets of levers are used, each ring having two bearings.

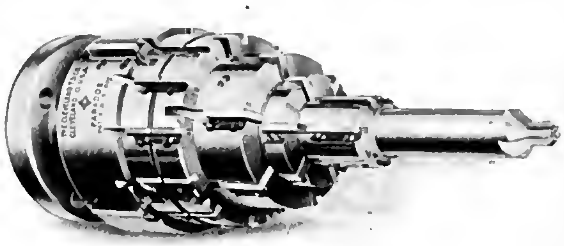
The tests given above are worthy of record as giving authentic results for commercial clutches under laboratory conditions.

CLEVELAND MULTIPLE REAMING AND FACING TOOL

The accompanying engraving shows a remarkable inserted tooth multiple reamer, recently built by the Cleveland Twist Drill Co., of Cleveland, O. It was built for a well-known cream separator company, and was designed for rough reaming and facing eight diameters, completely finishing all the holes in the casting on which it is to be used.

The body is made of a cylindrical casting carrying the outer blades, into which is fitted a second and smaller body of machine steel, turned and slotted to receive the next three sets. This body in turn holds the counter-sink, which is made of hardened tool steel. The tool is 21 inches long, and $6\frac{1}{2}$ inches in diameter, weighing nearly 100 pounds. The counter-sink, five reamers and the formed facing tool for facing and rounding the top ring, require in all 34 inserted blades. Twelve of these are of the double combination cutting type, making, with the four counter-sink lips, a total of 50 cutting edges. The tool, in use, is bolted on the boring head of a large horizontal boring machine.

The prime advantage of this construction is that the cost of the whole tool is considerably less than that of the set of individual ones necessary to perform the various operations. Another obvious advantage results from performing a number of operations at one time, thus saving labor and time. The high speed steel blades used reduce the necessary regrinding to a very small amount. The adjustable blade feature in this, as in other similar designs, is an important feature in the economy of the device. A solid, built-up reamer of the same character would scarcely pay in service for the large initial expense, since when one of the reamers is worn below size, the usefulness of the tool is destroyed. These blades, on the other hand, can be adjusted whenever required, and may be replaced with new blades at small cost when worn out.

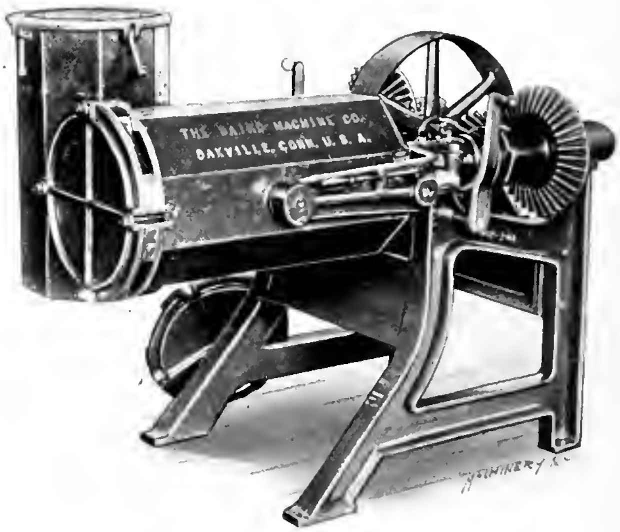


A Multiple Reaming and Facing Tool with Thirty-four Inserted Blades and Fifty Cutting Edges

BAIRD DOUBLE HORIZONTAL TILTED TUMBLING BARRELS

The tumbling barrel shown herewith is designed especially for rolling small metal articles with steel balls. This operation may be employed for burnishing such work before plating, or polishing it afterwards. It has been largely used on such articles as electrical fittings, typewriter, adding machine, and similar parts, chains, collar buttons and other jewelry, fancy hardware, etc.

The machine is double, as may be seen. The barrels are of cast iron, lined with maple. This lining is very durable, and when worn out, may be easily replaced, thus preserving the iron barrel indefinitely. The barrels are carried on forks on the ends of the spindles, being pivoted near their centers. A slight push on the locking pin allows the barrel to be swung from the horizontal operating position to the upright position for inspection, or to be dropped to the reverse position for dumping. The cover bolts may be quickly loosened and thrown back, permitting the cover to be removed. The operation of emptying out the work is thus one of moments only.



Tumbling Barrels of Convenient Construction, especially adapted to Polishing Work with Steel Balls

The advantages of this construction are obvious. There are no loose parts, the cover bolts being hinged to the barrel itself, and the nuts have only to be loosened and not taken off, so there are no parts to be lost. Each barrel is independently driven by a clutch engaging the driving gearing, so

that one of them can be emptying and refilling while the other is in motion. The barrels are water-tight, each being provided with a rubber gasket.

This machine is made in but one size, having a barrel 10½ inches inside diameter by 24 inches long, geared 2 to 1, with a driving pulley intended to run at about 60 revolutions per minute. This machine has a net weight of 1,300 pounds. Two other sizes will be made to order, or any other requirements on the part of the customer will be specially looked out for.

RIBLET TRANSVERSE CURRENT WATER HEATER

The apparatus shown herewith is called by its builder (the Riblet Heater Co., of Erie, Pa.) the "transverse current water heater." It may be used as an ordinary feed water heater, using the exhaust of a steam engine, but it has been especially adapted to the heating of water for shop, laundry, hotel or other purposes from the exhaust of the gas engine. It is believed to be the first commercially successful device for this latter purpose that has been placed on the market. As is well known, only a comparatively small percentage of the heat of the gas used in generating power in the gas engine, is changed into work. The balance is wasted through the exhaust and the water jacket. The exhaust has a temperature of from 600 to 1,000 degrees, and this heater is designed to save all of this heat that can possibly be saved. It has been found that with an engine using 15 cubic feet of gas per hour, nearly two-thirds of the total heat is thus made available. It has been calculated and found from experience that, allowing for loss from radiation, etc., one of these heaters will raise the temperature of nearly 70 gallons of water from 40 to 200 degrees per hour, for each horse-power developed by the engine.

Fig. 1. Water Heater adapted for Use with Gas Engine Exhaust, as well as with Steam

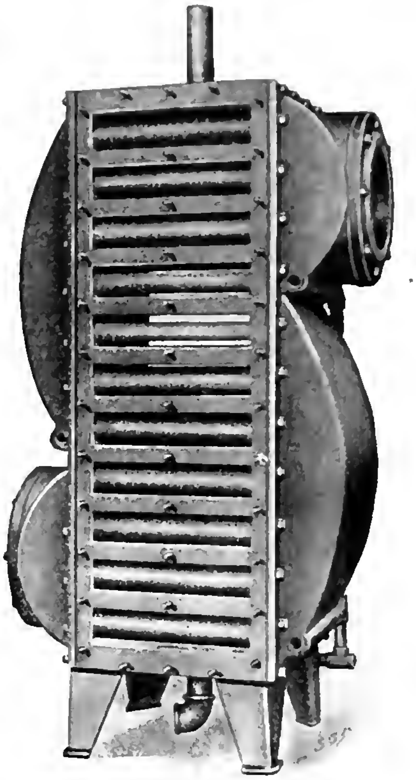


Fig. 2. Casings removed, showing Reverse Courses of Water and Exhaust

In construction the heater, as may be seen in Figs. 1 and 2, consists of a series of flat rectangular passages, of sufficient number to give the required heating surface. These are so arranged in connection with the inlet and outlet openings at the end that the exhaust enters the heater at the bottom, passing through a sufficient number of these passages or ports to avoid back pressure, and then turns backward again, passing through from side to side of the heater from three to five times before reaching the exhaust outlet which is located at the top.

The water enters the heater at the top, passes over the first port, back over the second, over the third, back over the fourth, etc., from top to bottom. This back and forth movement is controlled by the circulation plates. The water thus goes through but one passage at a time, traveling downward across, and in the opposite direction to, the exhaust. In this way, the hottest water, just as it leaves the heater at the bottom, passes through the section heated by the hottest exhaust. When more convenient for installation this order can be reversed without interfering in any way with the circulation. The entire heating surface is thus made effective, and as the water is constantly agitated, the maximum amount of heat is absorbed.

As a feed water heater operated by exhaust steam, this device has the advantage of being made entirely of cast iron, which does not readily corrode, and is not readily affected by electrolysis or acids. As the result of this precaution the life of the heater is, of course, greatly prolonged. There are no tubes to collect scale, no internal joints to leak, and the water does not come in contact with the exhaust.

This heater has been thoroughly tested out for some months in connection with both steam and gas engines, the results in both classes of service being satisfactory to the makers and users.

"NU-CLINCH" BELT AND ROPE DRIVE SURFACERS

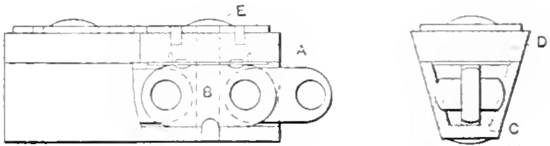
The Improved Surface Co., North Tonawanda N. Y., has placed on the market a line of belt and rope dressings which are designated respectively as the "Nu-clinch cleaner," "Nu-clinch filler," "Nu-clinch preserver" and "Flexite surfacer." The first two are intended for general belt use, the preserver is used on old worn-out belts, while the flexite surfacer is intended as a dressing for rope drives.

These compounds are composed of lubricating liquids of great penetration, which enter into the pores of belt or rope, reducing their internal friction, at the same time that they prevent them from slipping on the pulley or sheave. The material spreads throughout the belt and does not gum up, keeping the surface open and unglazed.

These products are given a careful chemical inspection before leaving the factory, together with the mechanical tests necessary to insure that they will produce the results for which they are sold. Each lot is thus tested. Samples will be sent free on request. They are put up for sale in 14- and 35-pound packages and barrel lots.

PEERLESS V-BELT

We describe and illustrate herewith a belt made by the Peerless V-Belt Co., 215-219 So. Clinton St., Chicago, Ill., which possesses many advantages over both the chain and the leather belt. It is designed to give a maximum of capacity and durability in the same product. Its construction will be understood from Fig. 1, where it will be seen to be composed of a central core of blocks *A* and side links *B* forming a steel chain, surrounded by a raw-hide and friction paper casing *C* and *D*. The cross-section of the belt is of V shape, to fit the grooves in the pulleys over which it runs.



Machinery,N.Y.

Fig. 1. Construction of the V-Belt

The lower or raw-hide casing *C* is a continuous strip, covering the bottom and the two sides of the chain. This material gives a friction surface of great efficiency, the coefficient of friction of raw-hide on cast iron being very high. The upper part of the casing is of friction paper, there being one section to each link of the chain. It is pivoted at an angle so as to continue the friction surface up the sides. Each section is fastened to the link by a rivet *E* passing through it.

The pulleys used are provided with grooved faces, cut to an included angle of 28 degrees, which has been found the most suitable for this work. At this angle the friction is very efficient, and still the chain does not become wedged into the grooves so that power is lost in pulling it out after it has gone round the pulley. To preserve the wedge-like tightening of the chain in the groove, the bottom of the later must be deep enough so that the belt will not touch it under any conditions, thus destroying the wedging effect and reducing the friction. It is not necessary in installing this belt chain to purchase new grooved pulleys in place of the old straight faced ones. Special V-groove rims will be furnished by the makers, so constructed that they may be placed on any ordinary flat faced pulley.

It was stated that capacity and durability were two prime points of the excellence aimed at in the construction of this belt. As to capacity, it is stated that raw-hide has a higher coefficient of friction than leather. The weight of the belt, where the center distance is reasonably large, causes the chain to wedge firmly into the groove, giving it a high transmitting capacity. The raw-hide itself is not subject to tension, only to the compression and transmitting strain. Under these conditions it is very lasting and may be subject to continued dampness without being impaired by it. Durability is also obtained by the careful fitting and hardening of the chain. The sides of the link and the forged connecting blocks are pack hardened to as high a degree as practicable. The rivet passing between the side links keeps these far enough apart to allow the free action of the block when the chain is bent around the pulley.

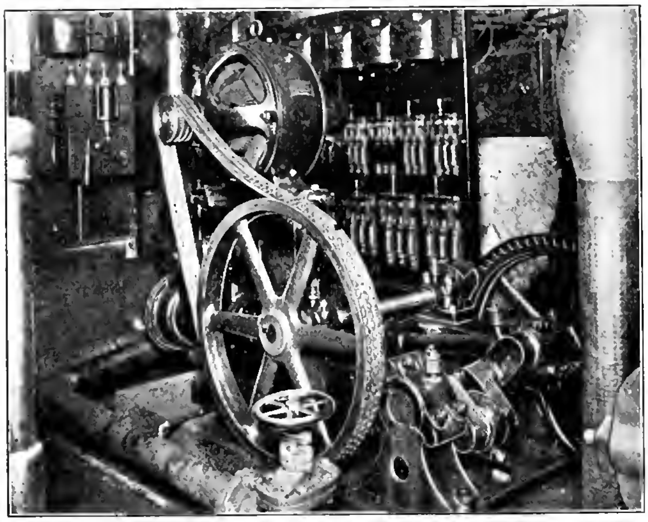


Fig. 2. The Peerless V-Belt, with Steel Chain Core and Raw Hide Friction Surfaces

The high efficiency obtained by the wedging action in the grooves of the pulley should give, from theoretical considerations, fully four times the capacity of a flat leather belt for the same width. This has been verified in practice. The following comparisons are based on the safe assumption that a flat belt 1 inch wide requires about 800 feet per minute of contact for each horse-power transmitted. The V-belt is made in two sizes, one ⅞ inch across the top and the other 1¼ inch. The ⅞-inch size will transmit 1 H. P. for every 200 feet per minute of contact. The larger belt requires only about 130 feet per minute per horse-power. This holds true even for short center distances, scarcely longer than those used for chains. For extremely short center distances, slightly larger velocities are required per horse-power.

The advantage of this belt over the ordinary flat belt lies in its strength and carrying capacity. As compared with the chain drive it has the advantage of being perfectly noiseless. It can also be used at much higher speeds. On small pulleys it may be used easily up to 3,000 feet per minute, while on pulleys of ample size it may travel at speeds as high as 5,000 feet per minute. When once put on, it requires very little attention. An occasional lubrication of the chain three or four times per year is all that is necessary. Any ordinary mineral lubricant is used, a drop or two being poured between each block as it passes over the sheave. The raw-hide absorbs a good deal of this and as it is in constant contact with the joints of the chain, it serves as a reservoir, supplying the lubricant for a long time.

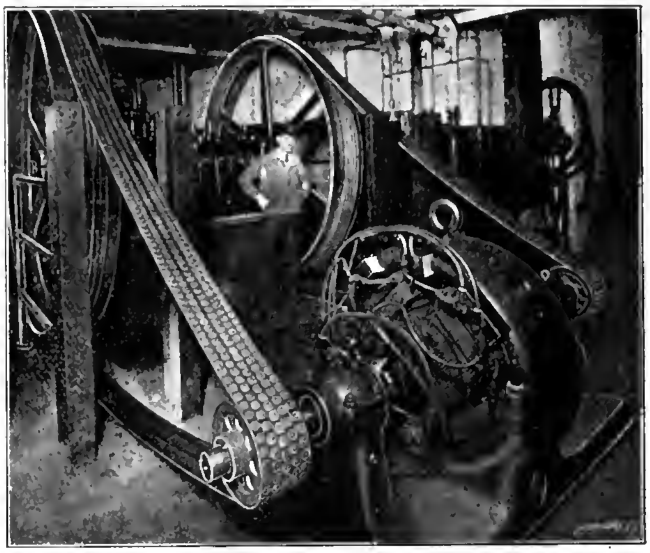

Fig. 3. Driving a Pump for High-pressure Electric Service

Two interesting applications of this belt are shown in the accompanying half-tone engravings. In Fig. 2 a 15 H. P. motor is direct connected to a duplex pump at a center distance of 36 inches. The pump was formerly used with a gear drive, which caused annoyance to the tenants from noise and vibration. The V-belt installation has worked noiselessly and furnished ample power. Fig. 3 shows a 50 H. P. motor driving an elevator pump, working at 900 pounds pressure. The ratio of pulley diameters is about 1 to 10. Formerly two 12-inch flat belts were used, pressed down by idlers weighted to 230 pounds each. An auxiliary pump was required to keep up the pressure during rush hours. With the V-belt and without idlers, slippage has been eliminated and the one pump does the work. A saving of 6 per cent on the power used has been effected.

IMPROVEMENTS IN THE TILTED TURRET SCREW MACHINE

In the department of New Machinery and Tools of the August, 1907, issue of MACHINERY, we described the original design of the tilted turret lathe built by the Wood Turret Machine Co., of Terre Haute, Ind. The construction which

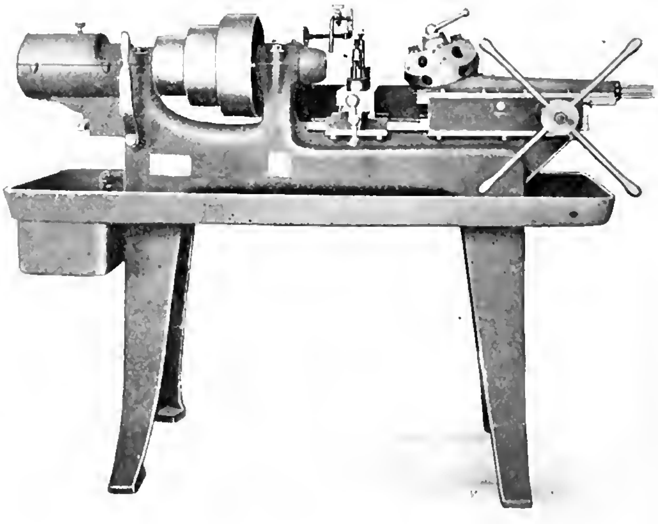

Fig. 1. New Design of the Tilted Turret Lathe

gives this machine its name, as described at that time and as plainly shown in the accompanying view in Fig. 1, is the setting of the axis of the turret at a considerable angle from the vertical position. While this had previously been done on the heaviest class of such machinery, its application to a small turret lathe was new, and it was applied in such a way as to offer distinct advantages not previously obtained.

In the first place, the tilting of the turret obviously allows the use of tools of large diameter. It allows such tools to swing over the rear of the turret slide, while still permitting a low and rigid design of the turret. The angle to which the turret is tilted is 15 degrees, so that tools are swung up at an angle of 30 degrees from the horizontal in the rear position. An exclusive feature of this turret is the continuation of each hole through the stationary turret stud and out through the further side of the turret, below the tool hole on that side. It is thus possible to pass bars of stock of great length through the hollow tools, without requiring excessive overhang. The tilting of the turret also brings the pressure of the thrust directly on the slide, which is brought up almost on a line with the center of the spindle. This relieves the center post from strain, and increases the rigidity and cutting power of the tool.

Fig. 2. Automatic Roller Feed Mechanism removed from the Machine, showing Compact Construction

The New Roller Feed Mechanism

The design of this machine shown in Fig. 1 has among its other improvements a continuous automatic bar feed in place of the old-style wire feed previously used. The compact and simple construction of this mechanism, shown in Figs. 2, 3 and 4, has made its use possible on this comparatively small machine. Fig. 2 shows the mechanism removed from the spindle. Fig. 3 shows a cross-section of the device in place on the machine, while Fig. 4 shows it disassembled, with the working parts in full view. When the lever A, see Fig. 3, is pushed to the left, wedge B is forced between two brake arms C. These arms are pivoted at D so that their upper ends are caused to close around scroll E and grip it firmly, stopping its revolution. As the spindle and casing of the mechanism continue to revolve, gears F and F', meshing with scroll E, set in motion gears G and G' and rollers H and H' which roll the stock in or out according to the direction in which the spindle is revolving.

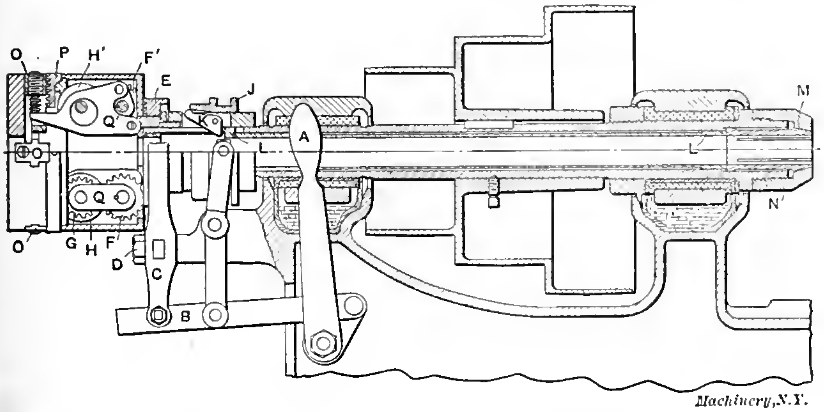

Fig. 3. Details of Chuck and Roller Feed Mechanism

As shown in Figs. 3 and 4, provision is made for adjusting the rolls to the diameter of the stock simultaneously with the adjustment of the supporting jaws at the rear end of the spindle. These latter, shown at O, are simultaneously adjusted in or out by means of a scroll P. Two of the jaws O are provided with slots and spring pressure devices for operating the pivoted jaws Q and Q' in which rollers H and H' are mounted. There is thus but one adjustment for changing the supporting jaws and rolls to suit different diameters of work. Suitable provision is also made for taking square hexagon, and other shaped stock through this mechanism as well as round stock.

Lever A, besides operating the roller feed, opens and closes the split chuck at the front of the spindle, opening it before the feed is thrown into action when the lever is moved to the left, and closing it after the stopping of the feed when the lever is thrown to the right. The mechanism for doing this will be understood from Fig. 3. In throwing lever A to the right, clutch collar J acts on chuck fingers K, which in turn force tube L against collet M. The latter seats in the tapered nose of hood N, thus holding the collet down on stock. The control of the chuck and of the feeding by the same lever gives rapidity of action and at the same time eliminates the destructive wear which would occur when trying to roll stock into the machine while the collet is gripped down upon it.

Fig. 3 shows the self-oiling arrangement used on the spindle bearings in this machine. Each bearing, as shown, has a groove in it through which is laid a wick with its ends dipping into the reservoir below. The thrust bearing, as shown, is at the front end of the spindle.

Construction of the Turret, Turret Slide and Saddle

Fig. 5 shows a detail view of the turret slide mechanism, illustrating the tilted turret construction very plainly. As explained, this permits the use of large box tools and die heads, while the double set of holes and the stationary stud allow the passage of long work clear through the turret, even with all the faces occupied. The turret being hexagonal in form, permits tools to be bolted to the face, thus giving a more rigid support to the tool, and leaving the turret hole free for the passage of large work.

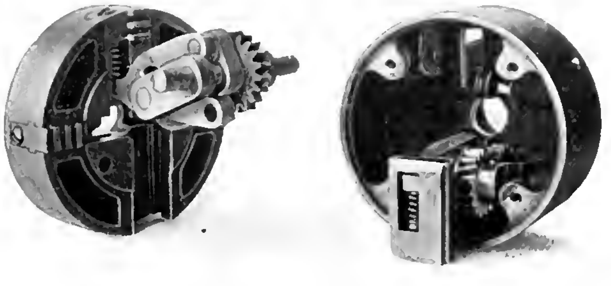

Fig. 4. Feed Mechanism Dismantled, showing Construction

The bearings of the cross-slide rest and of the turret slide and the saddle, are furnished with taper gibs passing the whole length on each side. This gives a crosswise adjustment to the turret. The saddle is held to the bed at the outer edges by flat gibs throughout its entire length. It is held down onto a supplementary taper base which is interposed between it and the top of the bed. By adjusting this taper base the center lines of the turret holes can be adjusted to the exact height of the center of the spindle.

The turret slide is shown removed from the saddle in Fig. 7. This, in conjunction with Fig. 6, gives a good idea of the arrangement of the indexing and stop mechanisms. At A is a latch pin which may be pulled out to cause the indexing finger B to clear the star wheel C. This simple provision sets the machine instantaneously for non-indexing work, as required by one-operation jobs made in large quantities. D is the locking pin which passes through the slide into the turret. The locking pin lever E is acted on by the eccentric cam F on the backward motion of the slide on the saddle. This pulls the bolt clear of its hole in the turret so that there is no dragging on the bottom bearing. The pin is held clear until the turret is revolved to the next hole, when it automatically drops into place and locks the turret.

In Fig. 5 is shown the turret and slide with the accompanying mechanism. Near the turret is seen the center bolt by means of which it is tightened down on the slide. The hole

through this bolt for the passage of the work is plainly seen. It will be noticed that this bolt is provided with a double taper bearing, seated in the turret. This may be adjusted to give the turret free movement at all times and still hold it firmly. With the backward movement of the slide the indexing finger *B* engages star *C* on the inner side. This through a geared connection shown more plainly in Fig. 7 swings the turret for one-sixth of a turn. The ratchet is fast to crown gear *C*, which engages a bevel gear screwed and doweled to the base of the turret.

As stated, a stop is provided for each hole in the turret, these stops being shifted automatically as the turret revolves.

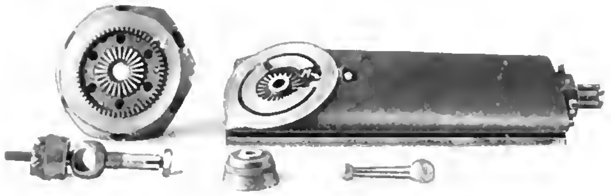

Fig. 5 Turret Slide removed from Turret, showing Construction of Stud Revolving Mechanism, etc.

They are contained in a drum as shown in Fig. 7, mounted on a long shaft connected by bevel gear *M*, see Fig. 5, through an intermediate, with bevel gear teeth *L* cut in the base of the turret. The automatic stops are adjustable for each tool without disturbing the others.

A self-oiling counter-shaft is furnished with each machine. The two friction pulleys in the counter-shaft are of single piece construction. Oil reservoirs are cored completely around the bearings, and the space is filled with cotton and oil. The hanger shaft bearings are supplied by oil boxes below them. Each of them is oiled in a way similar to that shown for the spindle bearings in Fig. 3.

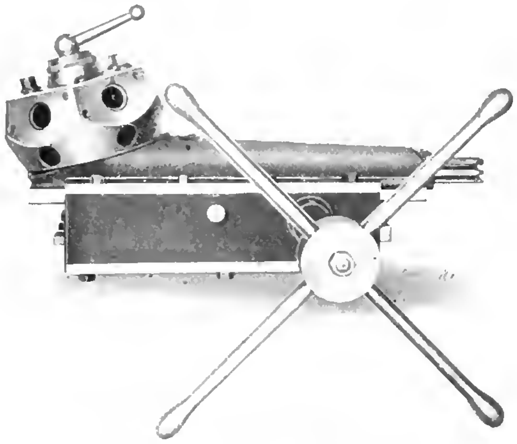

Fig 6. The Turret, Turret Slide, and Saddle

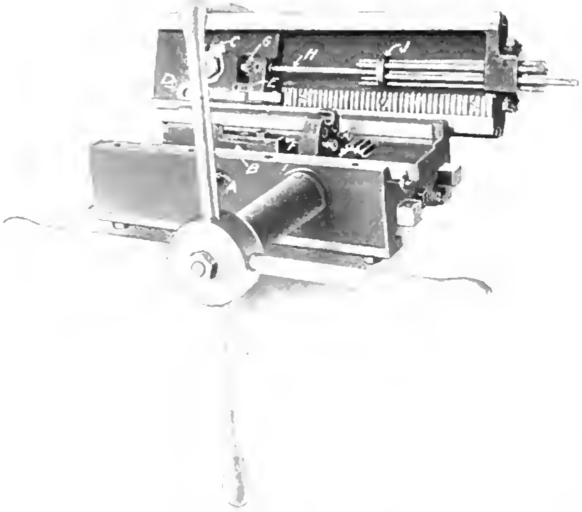

Fig 7 Slide removed from Saddle, showing Indexing Mechanism and Adjustable Stops

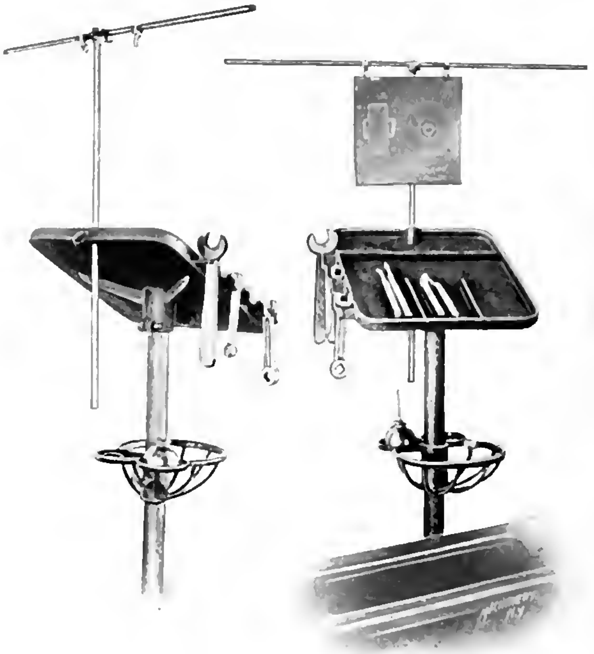
These machines may be seen in operation by a visit to one of the demonstration shops of Hill, Clarke & Co., Inc., of Boston and Chicago, or their branch offices at New York, Philadelphia, and Cleveland.

WELLS TOOL TRAY AND STAND FOR LATHES

The accompanying illustration shows a lathe tool stand or holder, made by F. E. Wells & Son Co., Greenfield, Mass.



A Convenient Tool Holder and Stand for the Lathe Operator

This device, which can be fastened to any lathe, is provided with places for oil cans, a basket for waste, a tray for lathe tools, chucks, centers, etc., and a rack for wrenches. There is also fastened to the back of the tray, as shown, an adjustable device for holding blue prints up to 26 by 30 inches. The whole tray is adjustable for height and can be swiveled to any angle, as can also the waste basket and oil can holder.

The attaching of this device is exceedingly simple. There are no holes to drill or tap, as a clamp is provided which is tightened to the lower side of the bed with a monkey-wrench, this being the only tool required for attaching the device. The provision of a suitable place for holding lathe tools, wrenches, oil cans and waste within easy reach of the operator, should result in permitting better concentration on the work in hand, and less loss of time and energy. The blue-print holder has been found especially useful in the way of keeping the work continually in front of the operator. It saves the print, as well, from getting torn or soiled from contact with boxes and castings on the work-bench. The illustration shows the tray and stand as seen from the front and back.

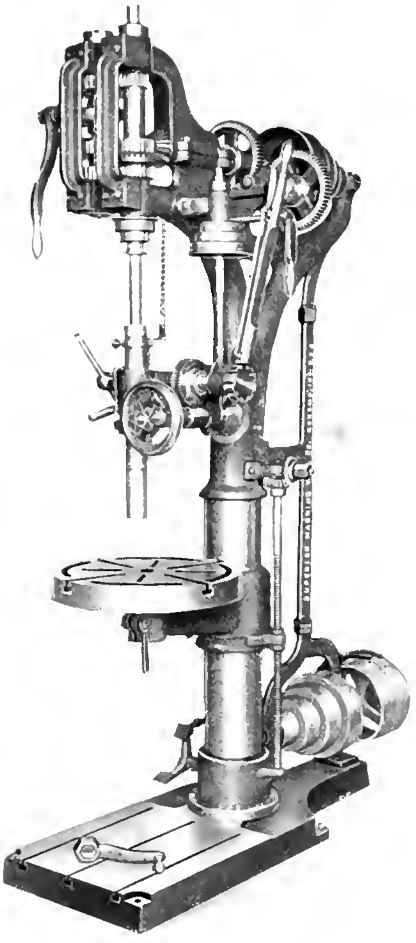


Fig. 1. Superior Machine Co.'s Drill Press with Tapping Attachment

THE SUPERIOR MACHINE TOOL CO.'S TAPPING ATTACHMENT FOR DRILL PRESS

The drill press made by the Superior Machine Tool Co., of Kokomo, Ind., was illustrated in the department of New Machinery and Tools of the April, 1907, issue of MACHINERY. This machine was substantially the same as the one here shown, except for the power feed, back gears and tapping attachment, which have since been added. The latter is of unusual interest as it differs radically from the usual construction.

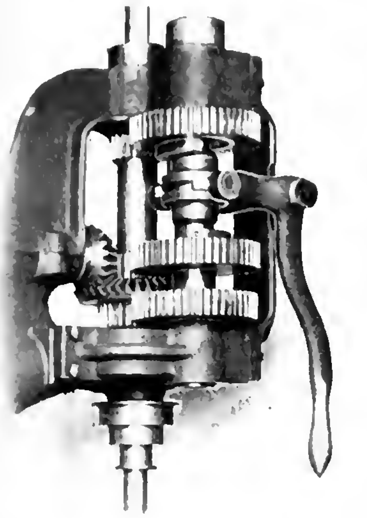

Fig. 2. Tapping Attachment for the Drill Press, designed to prevent Cramping the Spindle

One of the difficulties met with in applying a tapping attachment to the drill press is that of driving a spindle satisfactorily through the short key usually provided on the reversing clutch. This difficulty is met with in the usual construction, in which the clutch mechanism is mounted directly on the spindle. When the load of the tapping operation comes on to the spindle, the strain binds the key so strongly into the keyway of the clutch that if the load is great, it is difficult for the spindle to follow the tap.

With this attachment this difficulty has been overcome. The key and keyway have been greatly lengthened, passing through the full length of the long sleeve shown above the bevel gear. The friction clutches are mounted on a shaft parallel with the spindle. The upper driving shaft is connected by the usual bevel gearing with an idler gear, concentric to the spindle. This meshes with the driving gear on the supplementary clutch shaft (best seen in Fig. 2). On this clutch shaft are loosely mounted two gears, one meshing directly with a mate on the pinion sleeve, the other meshing through an idler. Either of these gears may be connected with the reversing shaft by friction clutches operated by the lever shown. This furnishes means for reversing the spindle for the tapping operation. The key in the sleeve on the spindle extends its full length. On the 23-inch drill this length is 14 inches.

As may be seen, the attachment may be added with practically no alteration in the regular design of drill press.

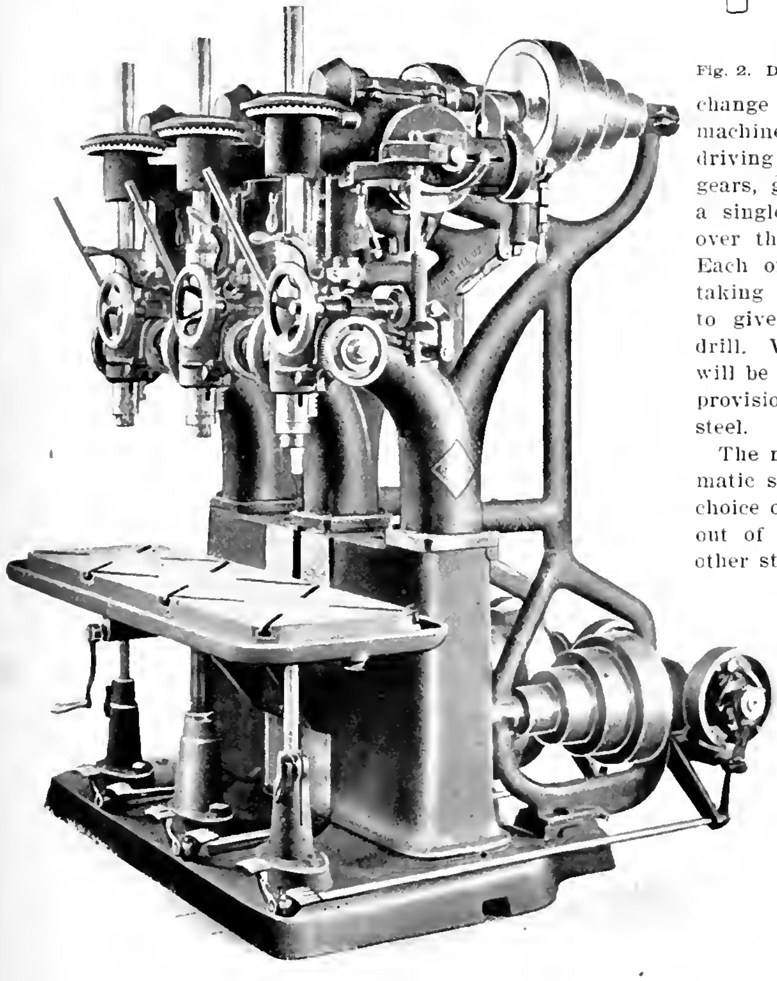

Fig. 1. Gang Drill with Improved Counter-shaft Drive and Feed Mechanism

BARNES $22\frac{1}{2}$-INCH DRILL

The accompanying illustrations show a gang drill built by W. F. & John Barnes Co., 231 Ruby St., Rockford, Ill. This drill is intended for heavy manufacturing service, being equipped with back-gearing, power feed, automatic stop and positive change feed gearing. The counter-shaft at the rear of the machine is driven by a single belt. It is connected with the driving cones of each machine by a friction clutch and bevel gears, giving separate control for each spindle. The use of a single belt drive effects a considerable saving in belting over the usual method of having individual counter-shafts. Each of the main shaft bearings may be adjusted without taking the counter-shaft apart. This drive is proportioned to give the same capacity as the makers' regular 34-inch drill. When desired, however, special three-step cone pulleys will be provided, which will carry a $4\frac{3}{4}$-inch belt. With this provision the machine will drive a $2\frac{1}{2}$-inch drill in solid steel.

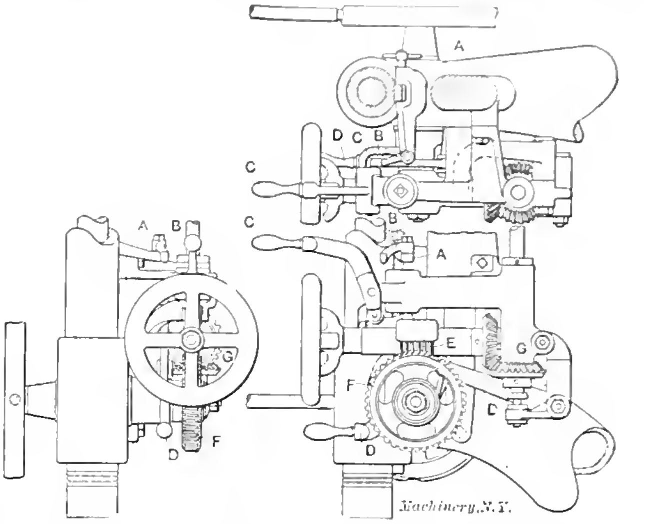

Fig. 2. Detail of Feed Mechanism, showing Double Automatic Stop Motion

The makers call particular attention to the feed and automatic stop mechanism shown in Fig. 2. The operator has a choice of two automatic stops. One of these throws the work out of mesh with the gear on the pinion shaft, while the other stops the main feed by throwing out the miter gear connection with the vertical feed shaft. The automatic stop dog is shown at *A*, clamped to the feed rack on the sleeve. It is provided with a tappet *B*, which may be swung so as to engage either lever *C* or lever *D*. In the top view in Fig. 2 it is in the latter position, its position for engagement with *C* being indicated by dotted lines. Lever *C* controls the engagement of worm *E* with wheel *F*, while *D* operates the throw-out mechanism on bevel gears *G*. The throwing out of the work gearing leaves the spindle free for action by the use of the hand or lever feed at the left side of the spindle. This will be appreciated in such work as requires facing or similar operations at the end of a drilling or boring job. The second throwout is the one more commonly used, but it does not leave the spindle free for motion, as worm *E* and gear *F* are still engaged after the feed is tripped.

The provision for back-gearing and the positive geared feeds will be readily seen in Fig. 1. The whole construction gives

evidence of possessing the power and rigidity required for the heavy manufacturing work the machine is intended to handle.

SELLERS CAR-WHEEL LATHE

A test to demonstrate the extraordinary power and speed of a new car wheel lathe was made in the works of William Sellers & Co., Inc., Philadelphia, May 15, before a large company of railway officials, mechanical engineers and others interested in improved railway machine tool design. Four pairs of steel tired wheels were turned, three pairs being nominally 36-inch coach wheels, and one pair 33-inch engine wheels. The accompanying log of the performance is a record that impressively shows the great advance made possible in tire turning by the new high-speed steels, when a machine is provided capable of utilizing them to the limit of capacity and an operator is available who can handle the machine with skill and energy.

Fig. 1. Sellers Car-wheel Lathe with Tool Turrets

The average official time for turning each pair of 36-inch wheels including the time required for placing the wheels in the lathe and removing them to the floor, or "from floor to floor," was 19.11 minutes. The time in the table is expressed in minutes and decimals, 19.47 minutes being 19 minutes and 28 seconds, and so on. The replacing of a burned tool required 27 seconds, which deducted from the total time leaves 72 minutes 1 second required for four pairs of wheels, floor to floor. This time does not include that required for changing the lathe for the last pair of wheels, which was just six minutes. On ordinary practice the operator would not change from outside to inside journal wheels pair by pair but would group the wheels so as to turn all of a kind or size in a lot. The steel used for roughing and finishing tools was "Novo Superior." The operator was Mr. William Anthony of the P. & R. Ry., Reading, Pa., shops.

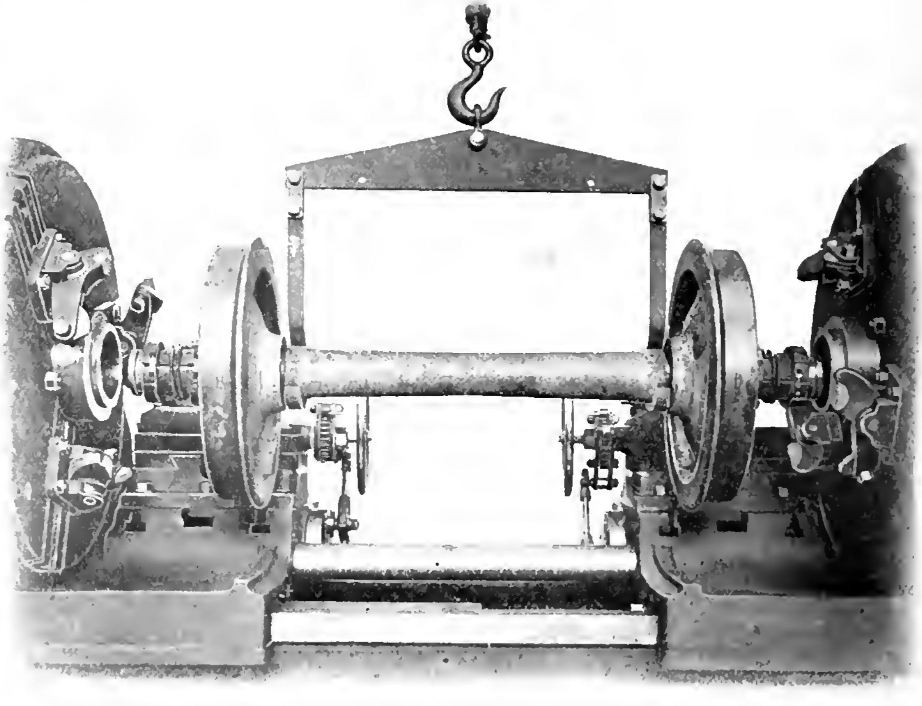

Fig 2. Turned Wheels being lifted out of Lathe. Note Faceplate Drivers, Bushings on Journals and Tracks cast on Headstock Extension to match Shop Track

Characteristics of Lathe

The lathe which is shown on the operator's side in Fig. 1 is designed to turn all kinds of steel-tired car wheels from 28 to 42 inches diameter, whether of plate or spoke center type. The machine as a whole and the bed especially are of massive construction as will be inferred from the weight which is 72,000 pounds. The headstocks have extensions on which the tool rests are mounted. The left-hand head-stock is fixed on the bed and the right-hand head-stock is traversed by power, an independent motor being provided for this purpose. The connection of the motor to the gearing is through a clutch that is adjusted to slip in case a solid obstruction is met by the head-stock in its traverse. The traversing motor is capable of exerting a pressure of 55,000 pounds through the head-stock against the wheels, and this power is utilized to sink the driving dogs into the tires when setting the wheels in place.

In its characteristics the machine is quite similar to the tool turret driving wheel lathe, illustrated and described in the June, 1908, number of MACHINERY. On this car wheel lathe, however, the tool turrets are square, having provision for four tools, and the indexing and locking mechanism are

simplified. The face-plate driver also differs, it being necessary to provide means by which the wheel can be driven by gripping the outer edges of the tires only. Another essential difference is the means for centering and supporting the axles of coach wheels and other car wheels having outside journals. Three-part taper bushings held assembled by two turns of a weak coiled spring are used, these bushings being slipped over the journals before rolling the wheels into place. The bushings enter the taper mouthed spindles in the head-stock and thus center the wheels by the journals. A coiled spring in the movable head-stock forces its spindle forward and "weighs the load," keeping a constant pressure on the bushings and journals, and holding them firmly against the pressure of any cut that the machine is capable of taking. For engine truck wheels having the journals between the wheels, pointed centers and bushings are provided to fit the taper holes in the spindles. The center points support the axle centers in the usual manner of common shaft turning.

TEST OF SELLERS CAR-WHEEL LATHE

	Wheels 1	Wheels 2	Wheels 3	Tank Wheels 4
Diameter of wheel, rough, inches	$35\frac{1}{8}$	$34\frac{15}{16}$	$35\frac{1}{4}$	33
Floor to chuck, minutes....	1.05	1.66	1.18	1.2
Rough turn	17.8	16.02	18.17	13.55
Rough flange.............				
Finish flange and tread...				
Finish chamfer, minutes.				
Machine to floor, minutes ..	0.62	0.77	0.65	0.4
Total time, minutes.......	19.47	18.45	19.40	15.15
Average cutting speed in feet per minute..........	15–16	16	14	19

The lathe equipped as shown in Fig. 1 has an overhead trolley track composed of two channel section beams rigidly secured to the upright springing from the fixed head-stock. The opposite ends are supported on friction wheels fixed to the upright springing from the movable head-stock, this arrangement being necessary on account of the traverse of the movable head-stock. The trolley carries an air cylinder and tackle for lifting and lowering the wheels; no crosswise movement of the trolley is provided or needed. Short tracks are cast on the feet of the tool carriages as shown in Fig. 2, which match the shop rails, thus providing support on which the wheels are easily rolled under the trolley, and out again when turned. During turning of the wheels the trolley tackle is not disengaged from the axle, but is simply lowered so as not to be in contact with the axle.

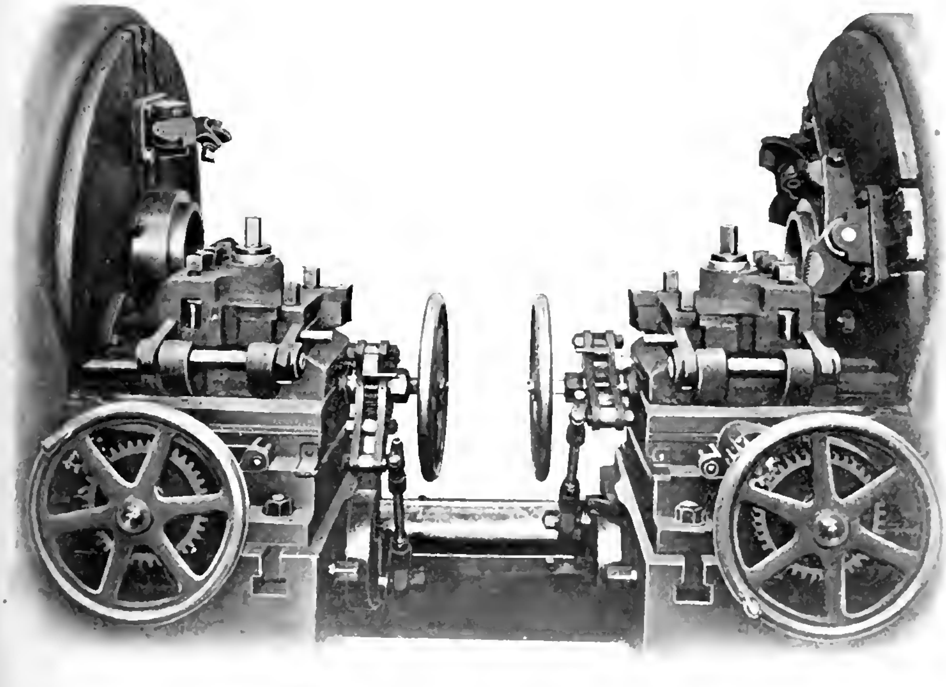

Fig. 3. Turret Tool Heads and Carriages, Sellers Car-wheel Lathe

Turret Tool Heads

The turret tool heads shown on an enlarged scale in Fig. 3 are noteworthy because of simplicity of design and effectiveness of action, aside from the fact that turret tool heads are provided on a lathe of this character. The need of means for easily and quickly changing from roughing to flanging to finishing tools has been apparent to those who have watched the operation of a modern wheel lathe equipped with the common four-bolt type of tool-post, when the lathe is pushed to the limit of its capacity. The labor of changing tools is exhausting, and the time required retards the production of turned tires. The present car wheel turret tool head is not as highly developed as the driving wheel lathe turret tool head previously described. The operator has to lock and clamp the turret by independent movements, whereas in this one all these functions are performed with one lever. The locking mechanism of the car wheel lathe turrets comprises two cams for each turret mounted on a short shaft supported in the bearings forming a part of the tool head support. The cams bear against the side of the square turret near the corners, thus locking it at the points furthest removed from its center of rotation. The cams are worked by a crank and the turret is turned by a wrench engaged with square bolt heads on the turret at or near each corner. The center bolt clamps the turret rigidly in place. The roughing tool is made of bar steck and is placed in a through slot, where it is clamped by four screws. The finishing tools are short sections and are mounted on ledges cast on the sides of the turret, where they are held in position by filister head screws.

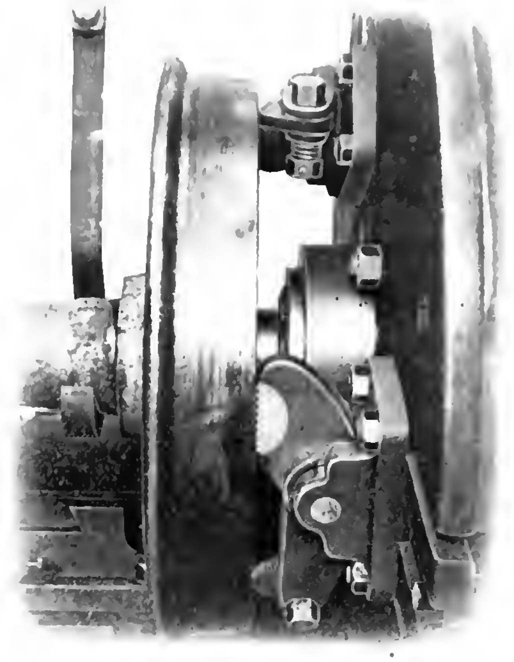

Fig. 4. Faceplate Driver engaged with Tire

Automatic Toggling Drivers

Three toggling drivers of the form shown in Fig. 4 are mounted on each face-plate, and drive by the engagement of serrated semicircular blocks forced into the edges of the tires. The drivers are mounted loosely on a pin near the center of the lever, and heavy trunnions support the thrust, the pins only acting to hold the levers in place. At the opposite ends of the levers are cams with teeth. When the

when it is brought into position the traversing motor forces the toothed blocks in the face-plate drivers into the tires, thus making initial engagement. The cams are then forced against the tires by wrenches fitting the hexagon head pins on which the cams are mounted. The cams force the steel blocks in the opposite ends of the drivers still further into the tire, and should the wheel slip, the cams roll on the tire forcing the serrations deeper and deeper into the tires, and effectually stop further slipping. Practically no evidence of slipping is noticeable, the first engagement being sufficient to drive. Each block has eight or nine serrations, and the depth the teeth sink is only about 1/32 inch.

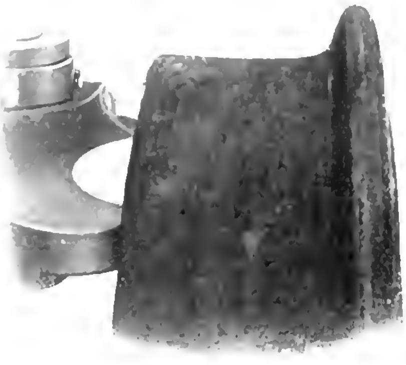

Fig. 5. Worn Tire as taken out of Service

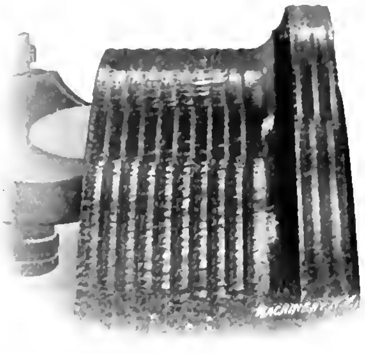

Fig. 6. Roughing Cut on Tread and Flange Completed

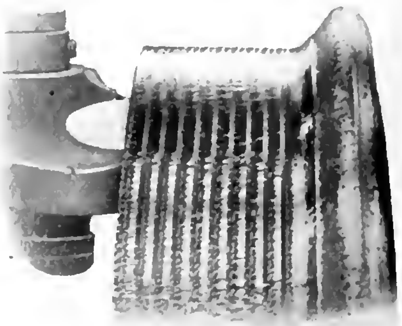

Fig. 7. Flange Roughly Formed

Controlling Apparatus

The lathe is driven by an adjustable speed motor of 25-30 horse-power, and is controlled by an automatic solenoid switch panel. The push button pilot switches are located in a position convenient to the operator. By the use of these switches he is able to start and stop the machine and reduce to an extremely low speed without stopping when required for passing hard spots. After the hard spots have been passed the lathe will resume the speed at which it was running by merely releasing the slow down switch. The perfect control of the cutting speed thus obtained has a marked effect on the productive capacity. Were it not possible to run the lathe at the slow speed necessary when cutting hard spots, the production, of course, would be much less than that possible when the maximum speed is used except when hard spots are being cut out.

Fig. 8 Flange and Tread Finished

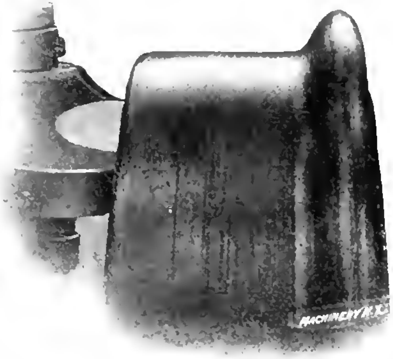

Fig. 9. Tread Tapered and Corner Chamfered; Tire Finished

Order of Operations

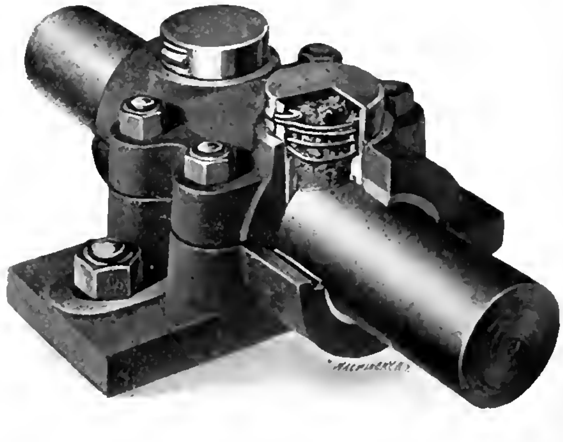
Figs. 5, 6, 7, 8 and 9 show the various stages from the worn to the finished tire. In Fig. 6 the roughing has been completed. The roughing tool has passed over the tread and flange with a feed of 3/8 inch and depth of cut of about 1/2 inch. In Fig. 7 the rough flanging tool has been brought into position and the corner of the tire roughed to shape. In Fig. 8 the finishing flanging tool has turned the flange and tread to shape, and in Fig. 9 the tread has been tapered off and the outer corner chamfered at one operation. Notwithstanding the speed at which the wheels were turned in the test, the appearance of the finished wheels was good and tests of diameters and contours left nothing to be criticised.

VAN DOREN AUTOMATIC SHAFT LUBRICATOR

The shaft bearing shown in the accompanying engraving is fitted with a Van Doren automatic lubricator, using grease as the lubricating medium. The method of lubrication insures the constant feeding of the material to the shaft at just the right rate to agree with the requirements, this being done automatically so long as the supply holds out; the device is thus very economical in the use of the grease. The C. J. Van Doren Co., 5 West Madison St., Chicago, Ill., is the manufacturer.

As shown in the engraving, this oiler comprises a metal shell or barrel fitted into the bearing cap, a cap covering its upper end, a spring, and a wooden gland. The distinctive feature of the apparatus is this wooden gland, which is forced by the spring down onto the shaft, conforming exactly to its contour. As shown, it is hollow and filled with grease, which lies on the shaft. A ring of felt packing in a circular groove cut in the bottom of the gland furnishes a smooth bearing surface and prevents the generation of any surplus friction on the wood, keeping the shaft wiped clean as well, and allowing only enough grease to escape to give proper lubrication. The spring holds the gland in contact with the shaft, the thrust being taken in slots in the barrel serving also as a locking device for the cap. The bearing should be drilled so that the barrel will fit snugly in the hole, where it is held in place by staking or calking the edge with an offset center punch. On ordinary bearings up to 4 inches in diameter and 12 inches long, two lubricators are necessary. For larger sizes and for extra heavy work more may be required.

The gland allows just enough grease to be taken away to make a proper coating for the shaft, and no more. It keeps the surplus always taken up. If for any reason the bearing should begin to heat slightly above the normal, the lubricant lying directly on the shaft has a tendency to run more freely,



A Lubricator for Supplying Grease in the Exact Quantity required

and so supply the extra amount needed until the bearing is restored to its normal condition. It might be expected that this melting of the grease from the heating of the bearing would occur suddenly, and would continue until all of it had been carried off. Such a provision would make the principle of the device impracticable. In use, however, it is found that the rise of temperature and the consequent softening of the grease is held under absolute check.

The advantages claimed for these bearings are numerous. They are inexpensive, easily applied and economical in the use of the lubricant, giving practically perfect lubrication at a nominal cost. Their cleanliness is also a strong point in their favor. It is unnecessary to provide drip pans, guards, or similar devices for keeping the machine and surrounding floor and ceiling clean, the lubricant being supplied so slowly that trouble on this score is obviated. The use of grease as compared with oil is objected to by some mechanics, but it is stated that lubricants of this character are now made having a coefficient of friction as low as those of the oils.

The economy derived from the use of this grease cup relates not only to the small supply of lubricant used as compared with the usual method of flushing with an oil can, but is important on the score of labor cost as well. One man can tend to a great many more bearings than is possible where liquid lubrication is employed. There is also said to be considerable economy in repairs and re-babbitting, due to hot boxes and similar causes. The makers of this device stand ready to send it on trial to responsible parties having use for such devices in their work.

MULTIPLE SPINDLE DRILL WITH VARIABLE SPEED DRIVE

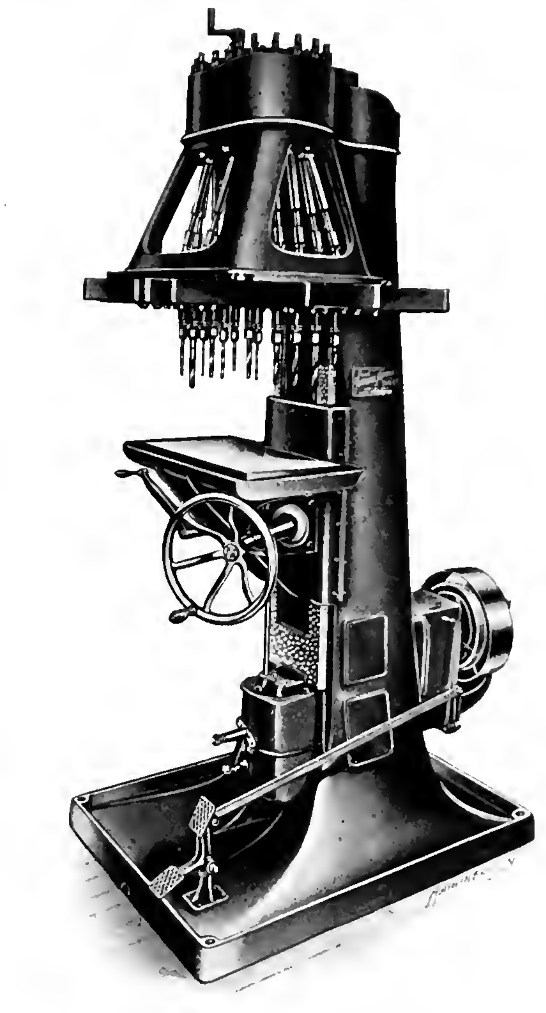
The weakness in the construction of the usual type of adjustable multiple spindle drill press is the fixed driving ratio between the different spindles, which require all to be run at the same rate, irrespective of whether a large or small hole is being drilled. The machine illustrated herewith, built by the National Automatic Tool Co., Ice Avenue and St. Clair Street, Dayton, O., is designed to overcome this difficulty. Each drill and tool may be revolved at its proper cutting speed. This is effected while still preserving the wide range of action, rigidity of construction and the close center distances which are expected on a machine of this type. The practical result obtained is an increased output on work having holes of different diameters.

Maximum Output

The power is delivered by a friction pulley through a change speed box and bevel gears to the main vertical shaft in the column. Five cone gears on this main vertical shaft in the head, by means of three separate series of compounds and idler gears, deliver the power to each independent spindle gear. These cone gears are thrown into commission by means of three sliding keys located in the shaft. One key engages the lowest gear, the next key the other two gears and the third, the remaining two gears. Thus three of them can be in commission at the same time, and deliver their respective speeds to the spindle driving gear. The combinations possible are 500, 750, 2,000; 500, 750, 1,500; 500, 1,000, 1,500; and 500, 1,000, 2,000 revolutions per minute respectively for the spindle driving gears. In addition to these triple combinations, any one of two speeds of those above given can be obtained on the spindle driving gear. Thus if only one size drill is being used, none of the other cone, compound and idler gears revolve if the sliding keys in the shaft are disengaged. These changes, together with the three in the speed boxes and those in the feed box will give any combination needed.

The spindle driving gears are keyed to their respective driving shafts by means of a bronze gear fork, through one end of which a spindle shaft runs and to the other end of which a screw is connected. The spindle driving gear is thus quickly raised or lowered for three different speeds or three neutral positions. By this means such spindles as are not in use can be placed in the neutral position and remain idle, thus saving wear on all the spindle parts. The screws are operated from the top of the machine, and indicators on each show exact position of the spindle driving gear within the head. With the initial speed in the change gear box fixed, any desired spindle speed can be obtained independently by the raising or lowering of the respective spindle gear within the head. One-sixteenth, ⅛, ¼, ⅜ and ½-inch drills can be run side by side, each at its proper cutting speed and maximum feed.

Ball races are placed between all the main driving, compound and idler gears in the head. Ring oilers are used in the speed boxes. Ball thrust bearings are provided at the top of the vertical shaft bearing in the column. All the gears are cut from the solid, and those in the head, feed box and speed box, and on the vertical shaft within the head, run in an oil bath. An oil pump keeps a continuous circulation of oil within the column on the change gear box. The bushings in the idler and compound gears in the head are hardened and ground and run on hardened and ground studs. The adjustable rails are made of cast steel, and are sufficiently rigid to prevent deflection of the drills even under the stiffest feeds. The spindles are of tool steel and run in hardened and ground bushings. Adjustment for different lengths of drills is provided within the spindle.



A Multiple Spindle Drill, in which the Speed of Individual Spindles can be varied

Attention is called to the unique construction of the universal joint. The cube and its four connecting pieces are made from a solid block of metal, thus obviating the use of screws for connecting the cube and the driving sides. All the wearing surfaces are hardened.

The work-table has a large oil groove and is so constructed that T-slots can be cut in it. It has a large bearing on the column, is counter-weighted and has both hand and power feed. There is a 16½-inch vertical adjustment between the end of the largest drill and the top of the table.

Speed Box

Three rates of feed are provided in the feed box, giving 1½, 3 and 4½ inches of movement per minute respectively. An automatic knock-out for the table feed is provided. An

pump and a large reservoir for the lubrication of the cutting edges of the drills is provided on this machine. This multiple drill is made in a number of different sizes, with a squared head carrying up to 12 spindles, and a rectangular head carrying up to 20 spindles.

LODGE & SHIPLEY LATHE WITH AUTOMATIC FEED STOPS

A patent head, quick-change gear engine lathe, as manufactured by the Lodge & Shipley Machine Tool Co., of Cincinnati, Ohio, is shown in Fig. 1. This lathe, as seen in the engraving, is equipped for machining malleable iron hubs for automobiles, two of which are shown on the floor beneath the machine. The particular feature, aside from the automatically revolving turret, which adapts this machine to work of this kind, is the arrangement of automatic stops which control the longitudinal movement of the carriage and the movement of the cross slide. The stops for controlling the length of the carriage travel, are seen mounted on the left end of a bar on which they are free to slide, which extends along the front of the bed. By varying the positions of these stops, which telescope into one another as shown, shoulders of any desired length can be obtained, for as the lever attached to the left end of the apron comes against one of these stops, the bar upon which it is mounted is given a slight longitudinal movement to the left thus throwing a clutch which disconnects the lead screw from its driving gears. A more complete description of the way in which these stops control the movement of the carriage travel will be found by referring to the article descriptive of the Lodge & Shipley crank-shaft lathe in the New Machinery and Tools department of the June number. The diameter gage, which is shown to the right of the cross slide in Fig. 2, consists of a slotted drum carrying adjustable stops that control the cross travel of the compound rest and stop the tool at any desired point. By turning this drum, different stops are brought into alignment with the tappet in the cross slide and in this way the stop is quickly set for different diameters.

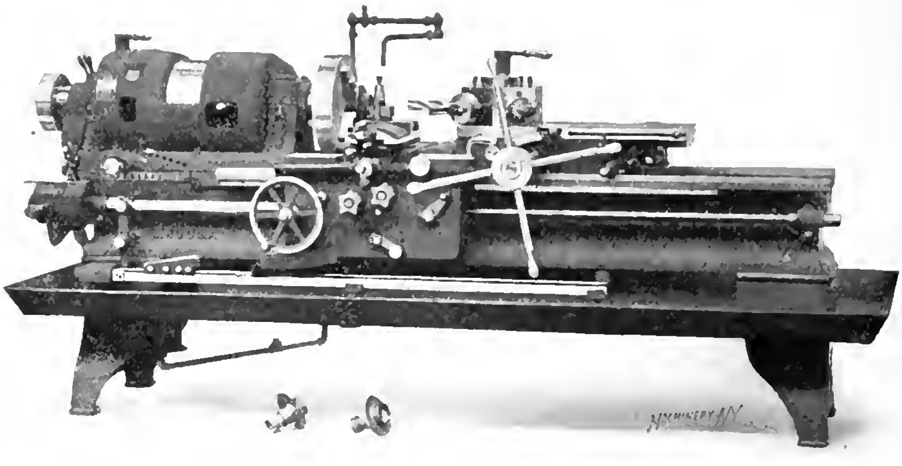


Fig. 1. Lodge & Shipley Lathe equipped with Automatic Stops for Controlling the Longitudinal and Cross Movements of the Turning Tools

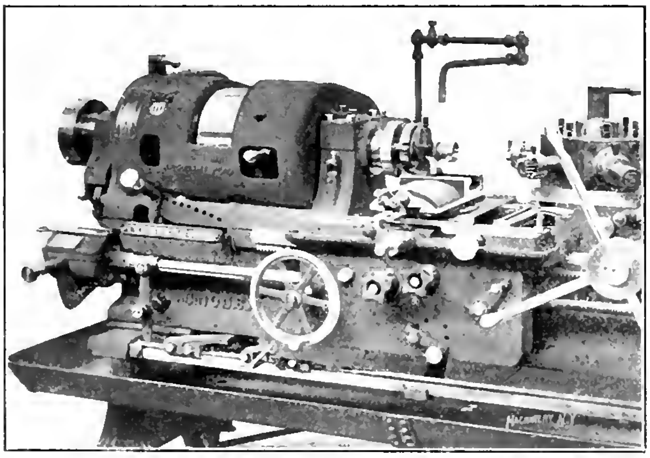

Fig. 2. View showing the Stops more in Detail

By way of illustrating the usefulness of this combination of automatic stops, a brief description of the various steps in machining automobile hubs, for both the front and rear wheels, will be given. The front hubs shown in Fig. 1, are $5\frac{1}{8}$ inches in length, $5\frac{1}{2}$ inches in diameter across the flange and $2\frac{1}{2}$ inches in diameter on the small end which is threaded. The rear hubs are similar, the main difference being that they are faced on both ends, finished more completely on the outside and have a ball race at one end only.

For the first operation on the front hub, the lathe is provided with special reamers, boring jigs and a 15-inch combination chuck. The hub is held with the flange against the chuck jaws, as shown in Fig. 1. The turret operations comprise boring a straight hole through the hub with a four-lip drill, boring the seat of the ball cup and reaming the seat of this cup. While the tools of the turret are in operation, the compound rest tool faces the end. This completes the first operation, and prior to the second, the holes in the flanges are drilled.

In Fig. 2, the method of holding and driving the work, and the equipment for the second operation is shown. The hubs are first mounted upon an expanding straight mandrel, which is inserted in the lathe spindle. The drive is from a pin which fits into a drilled hole in the flange. A seat for the ball cup is first bored and reamed, the correct depth being positively obtained. While the turret tools are performing this operation, the tool on the compound rest is facing the flange, its inward movement, of course, being controlled by the automatic stop referred to. The barrel of the hub is also turned, and the various diameters are positively obtained by means of the diameter gage. Cutting the thread completes the machine work for the front hub.

During the first operation on the rear hub, it is held in the chuck with its flange against the jaws, practically the same as shown in Fig. 1. The turret tools first bore and ream the seat for the ball cup and also face a seat for the dust washer. Simultaneously with these operations, the compound rest tool faces the brake pan on the flange and turns the flange diameter, all diameters and lengths being obtained from the positive stops. After the flange is drilled as in the first case, the hub is mounted upon a straight arbor, which is located in the hole of the lathe spindle, for the second operation. The work is additionally supported by a bar carried in one of the turret holes which makes coarser feeds and faster cutting possible and also gives truer work. All of the remaining operations are then performed by the tool in the compound rest.

IMPROVEMENTS IN WATSON-STILLMAN HYDRAULIC JACKS

One of the regular line of lifting jacks built by the Watson-Stillman Co., 192 Fulton St., New York City, has been provided with truck wheels and a handle to facilitate moving it from place to place. The wheels touch the floor only when the jack is tilted so they are not in the way during lifting operations. It can also be used in an angular position or flat on its side, without interference. This jack is made in eleven sizes, from 20 to 50 tons capacity, with lifts of from 12 to 18 inches, filling all the ordinary requirements of general shop work.

This firm has for some time built a jack in which the pump is separate from the ram, being connected thereto by flexible copper piping. This construction is convenient where it is difficult to work the lever of the usual apparatus, from lack of room or insufficient footing. This tool also requires much smaller head room than when the pump is included in the same mechanism. This jack has been re-designed and built from new patterns. An added improvement is furnished,

if desired, in the shape of a gage, which is not needed for ordinary lifting, but is useful in adapting the jack to testing purposes. When so equipped it may be used between two fixed platens for making compression tests, testing the tightness of forced fits, etc. The gage will be furnished to read in pounds per square inch, or in tons load upon the jack, or both as required. These jacks are furnished in fifty three sizes, ranging from 2 to 1,200 tons capacity. The rams of the various sizes have movements of from 4 to 8 inches.

MOORE & WHITE AUTOMOBILE CLUTCH

In Fig. 1 is shown a half-tone, and in Fig. 2 line drawing details, of an improved friction clutch of the multiple disk variety made by the Moore & White Co., 15th St. and Lehigh Ave., Philadelphia, Pa. While intended particularly for automobile work, this clutch should have a wide application for other similar uses. As designed for automobile use and as shown herewith, the clutch is contained within the balance wheel *A* of the motor; the inner cover *B* fastened to this balance wheel forms with it an oil reservoir in which the disks *C* are constantly immersed, thus being absolutely self-oiling and free from danger of destructive wear.

The disks *C* follow the usual construction of clutches of this type in being keyed alternately to the balance wheel *A* and to the driving spider *D*. The latter is keyed to the driven shaft, which is supported in the wheel on ball bearings *E*. The engaging device and the means for maintaining the pressure are extremely simple and powerful. The clutch is normally in its engaged condition, the disks being forced together by springs *J*, under a pressure determined by the adjustment of the ring *K*. For disengaging the clutch, sliding sleeve *H*, through the action of levers *G*, releases the pressure of spring *J*, so that the alternate disks revolve loosely on each other, and no motion is transmitted from the balance wheel to the driven shaft. An adjustable abutment for levers *G* is provided at *F*. As the rings wear, this is screwed up to keep the parts in their proper relative positions.

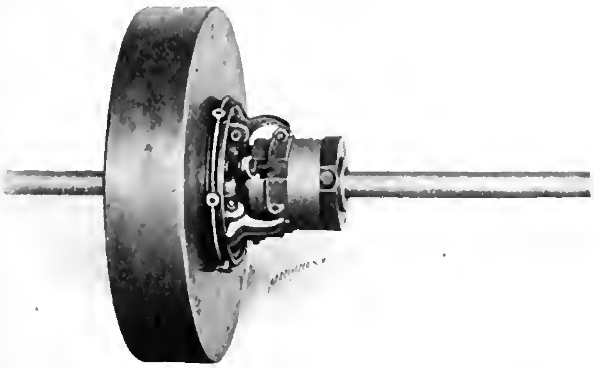

Fig. 1. A Multiple Disk Clutch especially adapted for Automobile Work

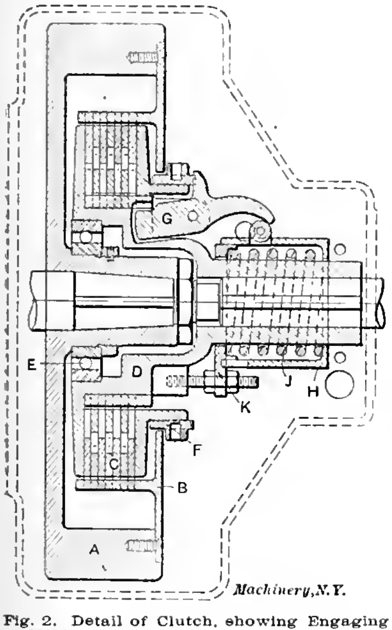

Fig. 2. Detail of Clutch, showing Engaging Mechanism and Provision for Oil Bath

BROWN & SHARPE STOCKING GEAR CUTTER

The formed cutter shown herewith is intended for stocking and roughing out the teeth of gears. It is of unusual construction, as may be seen, in that it is made up of alternating plain and stepped teeth. This construction has the advantage that it closely conforms to the shape of the finished tooth space, thus leaving little to be removed by the finished cutter; and at the same time breaks up the chip so that high speeds and feeds can be used without subjecting the cutter to great strains or heating. It is superior in this respect to both the plain formed cutter and to the design in which all the teeth are stepped

A Stocking Cutter with Alternating Plain and Stepped Teeth for Breaking the Chip, made of either Tool or High-speed Steel

The cutter shown is an unusually large one, being 13 inches in diameter and being intended for cutting teeth of 1 diametral pitch. In spite of its size, the way in which the chips are produced enables heavy cuts to be taken without undue strain on the teeth or the driving clutches.

MOORE & WHITE VARIABLE SPEED DRIVE

An interesting variation of the taper cone pulley type of speed changing mechanism, built by the Moore & White Co., 15th St. and Lehigh Ave., Philadelphia, Pa., is shown herewith. Instead of running the belts directly on the tapering surface of the cones, short supplementary belts are provided, built up of tapered segments, which furnish true cylindrical surfaces for the connecting belt to run on. The speed is changed by means of a belt shifter which receives its movement from a screw actuated by any suitable means, though usually by a chain and sprocket wheel from the operator's position. The belt shifter, thus operated, moves the supplementary belts and the connecting belt toward the large or small end of the driving cone, thus increasing or diminishing the speed of the driven cone. This device was originally brought out for use in paper mill machinery, where very fine gradations of speed have to be obtained while transmitting great horse-power; it has now been developed in smaller sizes for use in machine tool drives. A very convenient and compact form of the device is shown in Fig. 1. This takes up little more space than the ordinary counter-shaft. A still more compact arrangement, suitable for attachment to the wall, is shown in Fig. 2.

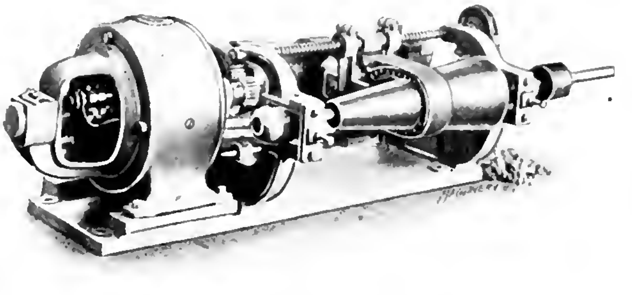

Fig. 1 Variable Speed Counter-shaft of the Taper Cone Type, giving Cylindrical Belt Contact

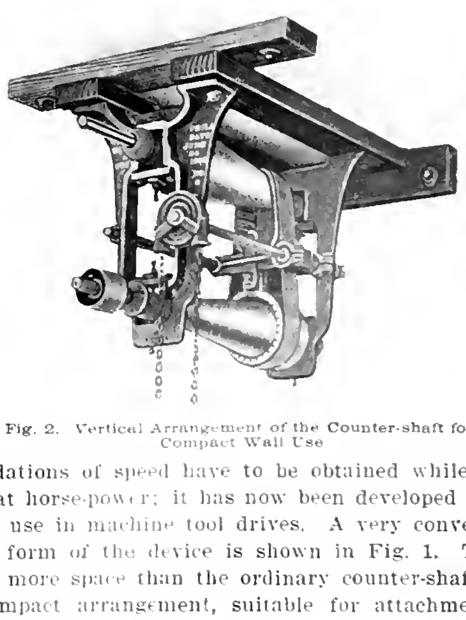

Fig. 2. Vertical Arrangement of the Counter-shaft for Compact Wall Use

RYERSON INTERNAL COMBUSTION RIVETER

One of the most interesting of the many machines and appliances shown at the June conventions of the American Railway Master Mechanics' and Master Car Builders' associations at Atlantic City was an internal combustion portable riveter made and sold by Joseph T. Ryerson & Son, Chicago. The principle of action of this riveter, which is applicable to many other machines in which the work is done by rectilinear motion, including punches, shears, bulldozers, etc., eliminates the power plant necessary for compressed air, hydraulic, or steam riveting installations, the power plant of each riveter being self-contained. An explosive mixture of air and any gas commonly used to operate gas engines is pumped into the work cylinder, thus forcing the dies against the hot rivets, and when a predetermined pressure has been reached the charge is automatically fired and the rivet set. The only outside power required is that necessary for operating the charging pump and firing the charge. This may be supplied, if required by the conditions of the work, from a storage battery.

Ryerson Internal Combustion Riveter for Steel Cars, Structural Work, etc.

The riveter in general appearance resembles the ordinary C-frame riveter in common use. It has a toggle action by which the pressure on the rivet dies is increased as the end of the stroke is neared. The piston is directly connected to the toggle action, and on top of the cylinder is mounted a small electric motor and direct-connected pump for charging the mixture of air and gas into the explosion chamber. On the side of the cylinder is the operating lever, and mounted on the same spindle is a pressure controlling handle by which the pump pressure is predetermined. The dial is numbered, each number representing an atmosphere or 15 pounds (nearly). If the indicator is set at, say, seven atmospheres, the charge will automatically explode when the pump has charged the cylinder to a pressure of about 105 pounds. The rise of pressure forces the dies firmly against the rivet so that the full power of the explosion is exerted in setting the rivet. As the charge is fired, the pump motor is cut out so that consumption of electric power is confined to the time actually required to charge and fire.

The piston is automatically returned by means of a coiled spring in the hub of the toggle links. The operation of charging, firing and releasing requires about one second on light work. On heavy work the time is longer, it then being necessary to hold the dies on the rivet for a short period. The dies are held against the rivet by simply waiting the desired time before moving the lever operating the exhaust valve. However, on steam-tight work, where the dies must be held for some time in order to let the rivet cool and thus grip the sheets with the utmost firmness, a hydraulic cylinder is interposed between the gas cylinder and the die, by which the pressure can be held indefinitely. This auxiliary cylinder for steam boiler work is necessary because of the fact that gases cool rapidly and reduce the pressure. The gas piston on the riveter shown which is designed for riveting steel cars, structural work, etc., is air cushioned, there being ports drilled in the cylinder head of the piston which are closed by the piston in its travel, and thus air is entrapped to act as a cushion to reduce the shock of the explosion and prevent knocking out the head in case the charge should be fired with nothing between the dies.

The machine is operated by a single lever the same as an air machine, and can be worked in any position. It is simple in construction and operation, and the upsetting action on the rivet is much quicker than in compressed air, steam or hydraulic machines. It is claimed that the necessity of uniform heating of rivets is obviated as the operator has absolute control of the pressure and may readily gage it to suit the heat of each rivet. The riveter will drive any commercial size rivet and requires approximately one gallon of gasoline for four thousand ¾-inch rivets.

MILLING ATTACHMENT FOR THE ACME MULTIPLE SPINDLE SCREW MACHINE

A simple, compact and time-saving device for finishing duplicate parts requiring milling or slotting, has recently been designed for use on the Acme multiple spindle automatic screw machine, manufactured by the National-Acme Manufacturing Co., Cleveland, Ohio. This is one of a number of attachments recently designed for this machine for eliminating the rehandling of parts for the purpose of drilling, milling, slotting or countersinking them.

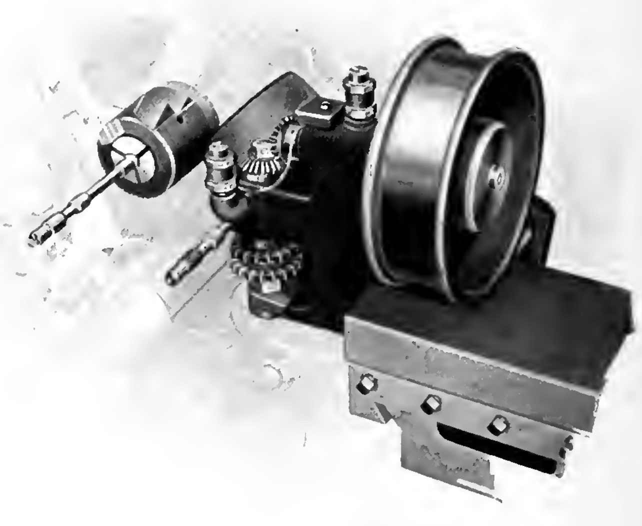

Fig. 1. An Attachment which enables Work to be milled in the Automatic Screw Machine, thus eliminating a Second Machining Operation

This attachment, which is shown in Fig. 1, is fastened to the top of the slide which carries the cutting-off tool. The engraving shows it arranged for milling the flat part on the piece shown in Fig. 3. This cold rolled steel piece is being made in the factory of the Cadillac Motor Car Co., of Detroit, at the rate of 53 pieces per hour. This number also represents the maximum output when the pieces are not milled. By the previous method of making these parts, less than one-

third as many per hour were produced, and milling the flats constituted a second operation. It will thus be seen that the entire cost of rehandling is saved by the use of this attachment. The way in which it is attached to a regular machine, and its general construction, will be seen by referring to the engravings. For milling the piece shown in Fig. 3 two milling cutters are set the required distance apart on the vertical arbor which is driven by bevel gears, which connect with a horizontal shaft carrying the driving pulley. This pulley receives its power through a belt from a "Simpul" countershaft. The feed of the cutters is controlled by the cutting-off cam, and the increased movement necessary is obtained by an auxiliary lever, which is seen to the left of the attachment in Fig. 2. This lever connects with the top cross slide which is dove-tailed to the slide beneath it. This second slide is also dove-tailed to the slide upon which it rests, and by its longitudinal movement, the cutters are adjusted to the proper location.

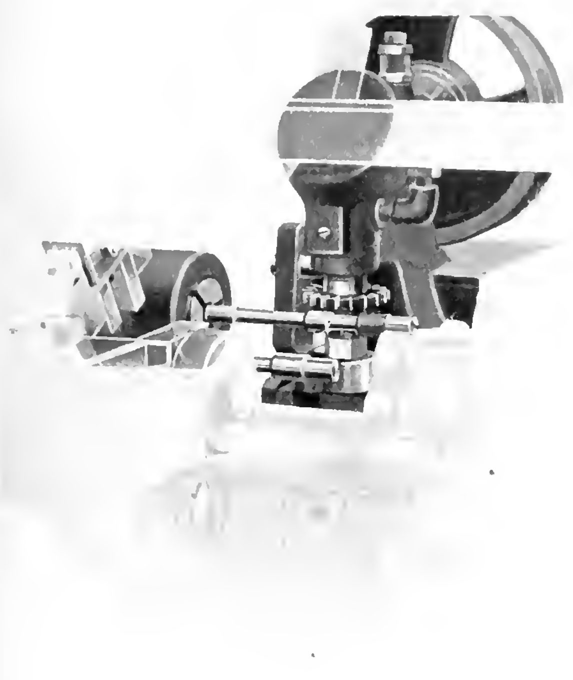

Fig. 2. Another View of the Milling Attachment

Fig. 3. An Example of the Kind of Work to which the Attachment is adapted

The milling operation upon the work takes place while it is in the third position, and at the same time that the thread is being cut. While this operation is taking place, the forming and box milling tools are at work in the first position. In attaching this device to a regular machine, it is only necessary to drill and tap two holes in the top of the cutting-off slide upon which the attachment rests. It is possible to drive this attachment without employing a special countershaft, by directly connecting it to the die spindle gears in the main tool slide, by a telescoping shaft, knuckle-joints and bevel gears. This makes it possible to drive the machine with a single belt or motor without any special over-head arrangement for the attachment.

MUMFORD WIRE BELT LACING DEVICE

Wire lacing for belts has of late years become the standard method of belt fastening in large establishments. The operation consists essentially of threading a coil of wire into the edge of each belt, flattening these coils down, interlocking them on the two edges and inserting a raw-hide pivot or pin to complete the hinged joint. About the only objection to this process in the ordinary shop is the expense of the apparatus required for coiling and inserting the wire. Mr. Harry T. Mumford of 258 West 22d St., New York City has invented and is placing on the market a device of great simplicity for performing this operation; it is so inexpensive that the smallest shops can afford to use it. This device is shown in use in Fig. 1.

A nickel and polished pattern plate is the essential feature of the invention. Into this the edge of the belt to be laced is placed, being held there by inserting two thumb tacks through holes in the upper lip, as shown. With the awl which is furnished with the outfit, the operator then pierces holes through the belt at the bottom of the slots formed in the turned up lip of the pattern plate. After all the holes have been pierced, a steel wire is threaded through them in helical form, over the wire mandrel which lies inside the lip of the plate, as shown. Fig. 1 shows this threading of the wire partly completed. After threading, the belt is removed from the plate and the mandrel removed from the belt. Then the wire lacing is squeezed in the vise flat and even with the belt, or pounded down flat on the bench. The ends of the wire are caught in and clinched to prevent them from loosening.

Fig. 1. An Inexpensive Tool for Inserting Wire Belt Lacing

The pattern plate is next reversed, and the other end to be joined is inserted in place. The slots on this other end of the plate are reversed, so that one of the wire coils will be right hand and the other left. This is necessary to permit them to interlock. The same operation of threading and pounding down is repeated with this end of the belt. The two ends may now be brought together with the coils interlaced, when a raw-hide pin or pivot is inserted, thus locking the joint, but leaving it hinged and flexible so as to be adapted for use on the smallest pulleys.

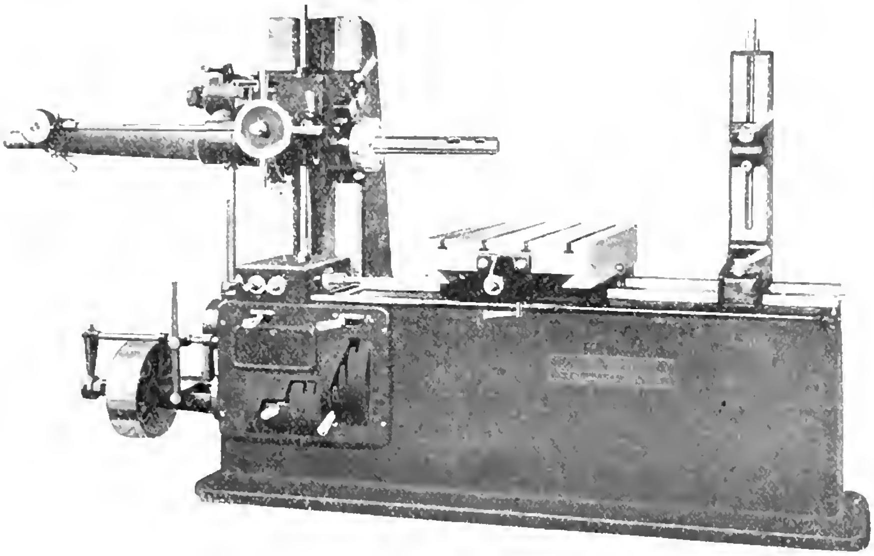
Fig. 2. The Rest of the Equipment Furnished with the Belt Lacing Device shown in Fig. 1

The outfit provided includes besides the pattern plate, awl and mandrel just described, a set of raw-hide pivots, a supply of wire lacing, extra awl points, thumb tacks, etc. This extra material is shown in Fig. 2. The plate may either be held in the vise, an attachment being provided for that purpose, or it may be held to the bench by means of buttons, also furnished with the outfit. It should be noted that by laying the belt crosswise in the lip, the side of the plate may be used as a gage for squaring up the ends, thus materially assisting in producing a serviceable and efficient joint.

CLEVELAND HORIZONTAL BORING, MILLING AND DRILLING MACHINE

The horizontal boring, milling and drilling machine shown herewith is built by the Cleveland Machine Tool Works, Cleveland, O. As may be seen, it is of the type in which the boring head is vertically adjustable on a stationary column, while the work is mounted on a table provided with cross and longitudinal movements. The main features of this particular design are its simplicity, the provision of gear boxes for the feeds and speeds, and its convenience of operation.

In regard to the matter of ease of operation it will be seen at once that all the various handles required for controlling the movements of the machine are within easy reach from the operator's position. The machine is driven by the constant speed pulley shown, which is provided with a friction clutch operated by the vertical lever. From here the power is taken to a speed change mechanism operated by the right hand one of the two gear box handles. Six speeds are provided at this point. This number is doubled by back gears in the head, giving 12 spindle speeds in all, in geometrical progression, ranging from 10 to 140 revolutions per minute of the spindle. The gear ratio from the vertical driving-shaft to the spindle is 7 : 4, with a back gear ratio of 12 : 1 for the slower speeds. The back gears are thrown in or out by a conveniently mounted lever on the head. Another adjacent lever stops, starts and reverses the spindle.



Cleveland Horizontal Boring, Milling and Drilling Machine

There are 16 feeds, applicable either to the vertical traverse of the head, the horizontal traverse of the work-table, or the longitudinal feeding of the boring bar. These vary in geometrical progression from 0.005 to 0.3 inch per revolution of the spindle. Eight of these are available for each position of the spindle back gear. Four changes are obtained by manipulating the handle of the right-hand gear box at the base of the machine, this number being doubled by the handle above it. All the feeds can be changed in direction by means of the reversing lever, and all the changes of feeds and speeds can be made without interference, while the machine is running.

The spindle is supported in solid taper bronze bearings with adjustments for wear. It has a face-plate to receive milling cutters, facing heads, etc., for heavy work. The fact that it can be stopped, started or reversed instantly makes the machine very convenient for facing, tap milling and similar operations. The spindle and back gear drive are located between the spindle bearings, bringing the power directly to the work with little strain to the mechanism. The spindle bar is 2½ inches in diameter, is provided with a No. 5 Morse taper hole and has a 22-inch traverse. It has a power feed in either direction, and can be securely clamped for face milling operations. The feed pilot wheel, by the shifting of the knob shown in its center, operates both the fine hand feed and the quick traverse for the boring bar.

The outboard support can be securely clamped to the bed and may be readily removed for overhanging work. It is aligned with the boring bar by means of scales and verniers reading to 0.001 inch. These scales also read directly to 1/64 and 1/100 inch, thus assisting in laying out bored holes to proper center distances. The box bed is very deep, with ribbing so designed as to make an expensive foundation unnecessary. Two chutes are provided for carrying away the chips. The platen has four ⅝-inch T-slots with a working surface of 20 by 36 inches, and a traverse of 24 inches. The platen and the carriage adjustments are made by means of micrometer dials.

The following additional dimensions will assist in giving an idea of the capacity of the machine. The maximum vertical adjustment of the head on the column is 20 inches, and the vernier adjustment is 18 inches. The greatest distance from the face-plate to the outboard support is 4 feet 6 inches. The floor space occupied over all is 11 feet 6 inches by 6 feet. The machine weighs about 6,000 pounds.

If required by the customer, special attachments for special work will be furnished with this machine. Among those for which provision is made are a revolving table, auxiliary table, special boring bars, and star feed facing head.

AUTOGENOUS WELDING EQUIPMENT FOR LIGHT WORK

In the October, 1908, issue of MACHINERY, we described the equipment provided by the Autogenous Welding Equipment Co., 92 Hayden Ave., Springfield, Mass., for operations such as welding, etc., requiring very high heat, using for that purpose the oxy-acetylene flame. In addition to the apparatus there described, this firm has recently placed on the market an inexpensive outfit adapted to the general run of work met with in the ordinary garage or small machine shop. While the apparatus previously shown is particularly suitable for jobbing work and manufacturing, that shown in Fig. 1 is adapted to general repair work in smaller establishments.

The apparatus includes one torch equipment, having an assortment of tips, which makes it possible to carry on a large variety of work. A gas generator is not included. It

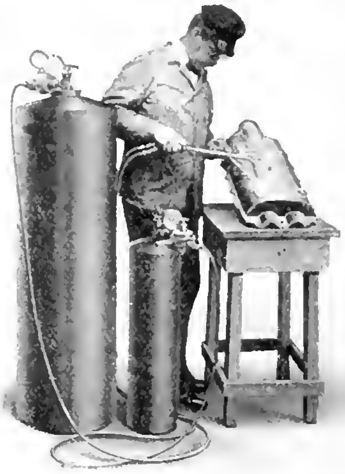


Fig. 1. Simple and Inexpensive Equipment for Autogenous Welding in Small Plants

would not be feasible for the majority of small plants to install a generator, this being rendered doubly difficult by the insurance regulations, which require it to be located outside of the building; for this reason the gas for this apparatus is supplied in cylinders of 125 cubic feet capacity. This gives a sufficient supply for performing a large number of jobs, and a full cylinder will be shipped to the customer immediately on receipt of the bill of lading for the empty one. The gas itself is furnished at a lower cost than is possible even when supplied for lighting purposes. An oxygen cylinder is also supplied with the equipment.

This outfit makes it possible to repair such expensive parts as cast iron cylinders, aluminum crank and gear cases, malleable axle housings, etc. While the operations are somewhat out of the range of the experience of the ordinary machine operator, complete instructions are furnished which will insure success in the hands of reasonably intelligent workmen.

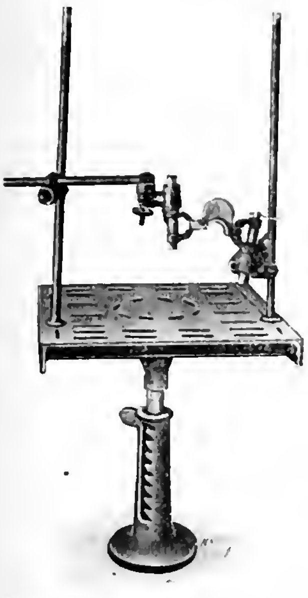

Fig. 2. Universal Table and Fixtures for Holding Parts for Autogenous Welding, Brazing, etc.

In Fig. 2 is shown a table which has been found especially adapted to the general line of work in small shops and garages. It has a substantial top, 30 inches square, with T-slots so arranged that the broken parts may be easily lined up and bolted into position. The table is carried on a ball and socket joint, so as to permit it to be tilted through a wide range of angles and fastened at that point. At any angular position the table can be revolved freely to bring the work to a position convenient for the operator. The pedestal is telescopic, so that the table can be raised and lowered as may be required. The edges are provided with flanges permitting the work to be clamped in a vertical position if desired. The top of the table is machined to permit accurate lining up of the work, and the underside is well ribbed, giving the necessary rigidity.

The universal clamping fixture for use in connection with this table, shown in place in the illustration, consists of a set of two universal vises, which can be held rigidly in any position by means of arms and clamps, so that broken parts of a wide range of shapes and sizes can be held together in the position required for welding or brazing. The provision of suitable clamping appliances is a matter of great importance in this work, as it has been found by experience that more time is consumed in setting up the work properly than in the actual welding or brazing, where suitable appliances are not provided.

ADDITIONS TO THE STARRETT LINE OF SMALL TOOLS

The L. S. Starrett Co., of Athol, Mass., has added a number of new instruments to its line of small tools. These additions are respectively, tool-makers' calipers and dividers, a universal bevel protractor with vernier scale, and sight attachments for the level.

The calipers and dividers, shown in Fig. 1, are particularly neat instruments, made from round stock with legs drawn down, giving the metal a hard and stiff quality. The fulcrum stud is hardened, the bows are of extra strength, the screw and nut are carefully fitted, and all the parts are finely finished. These tools are made with the solid nut only, in five sizes—2, 3, 4, 5 and 6-inch respectively.

An improvement in the well-known Starrett universal bevel protractor consists in the provision of a vernier scale which permits readings to be taken directly to as fine as 1/12 of a degree, or 5 minutes. Two verniers are used, so placed in relation to the graduated half of the circle as to make the protractor readable by vernier in any position. The protractor stock is 4 inches long, and is provided with either a 7 or a 12-inch blade, ½ inch wide. This is clamped by an eccentric stud against the edge of the disk. It may be slipped back and forth its full length and turned at any angle about its circle and firmly clamped where desired. The figures on the vernier are placed close to the lines, thus making it easy to read the tool when taking measurements. An attachment is provided for furnishing a reference edge at right angles to the regular blade. This, in connection with the beam of the protractor, will be found convenient in grinding short or long tapers to any angle or pitch.

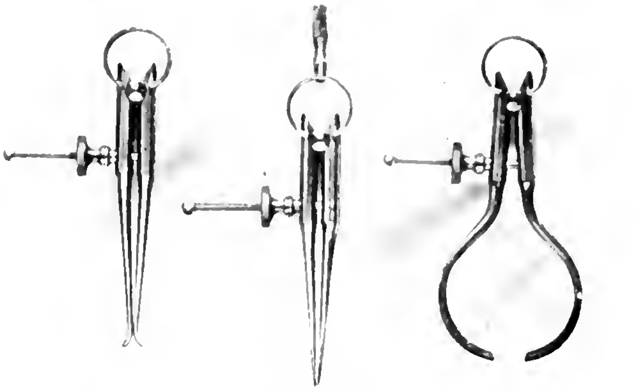

Fig. 1. A Neat Set of Outside and Inside Calipers, and Dividers for Toolmakers' Use

The attachments shown in Fig. 2 are designed to be used in connection with the makers' iron levels. They easily slip on or off the top side of the instrument, and are held in place by set screws. They are provided with sight holes as shown, the one at the left having a cross wire which is accurately lined and set parallel with the level. This attachment will be found convenient, as it permits the use of the ordinary iron level for leveling a plot of ground from a fixed point at long range. They are made to fit the 6, 9, 12, 18 and 24-inch, No. 132 levels.

Fig. 2. Sighting Attachments for Use with Spirit Level

BENNETT HANDY GREASE CUP

The Bay State Stamping Co., of Worcester, Mass., has recently designed the grease cup shown herewith. It is particularly intended for automobile use, but should find a wide application wherever grease cups are used, particularly on high-speed machinery subject to jar or vibration.

The cup itself is formed of sheet metal, with a hexagon the full diameter of the barrel, so that it may be screwed down close to the bearing and give a greater space for the grease without increasing the over-all height. The threaded cup is screwed down permanently, so that it will not jar off. It is provided with a thumb screw passing through the center, actuating a spring piston head, which binds on the inside of the cup to prevent it from turning. By screwing this down, the grease is forced into the bearing. The spring construction of this head makes a close joint, so that the grease, even if melted, is prevented from leaking out. This construction provides a neat, durable, and simply constructed cup for use on small or large bearings. It takes up little space, and may be quickly and easily operated.

A Simple Grease Cup

NEW DESIGN OF PEERLESS MULTIPLE SPINDLE AUTOMATIC SCREW MACHINE

In the department of New Machinery and Tools of the December, 1908, issue of MACHINERY, we illustrated and described a multiple spindle automatic lathe, or screw machine, built by the Peerless Automatic Machine Co., of Cleveland, O. This firm has recently developed a variation of the design shown at that time, possessing features which fit it to a more general line of work. These changes relate principally to the provision of a constant speed drive with geared changes for the spindle and feed mechanisms, the use of a knee-type tool-holder, and the provision of a supplementary swinging tool-holder, applicable to either the third or fourth spindle positions.

As the above changes have been made without altering the general construction, the machine will not be described throughout. It needs merely to be said that it is a multiple spindle machine of the type in which the work spindles revolve, and are indexed from one tool position to another successively, the tools being fed by the longitudinal movement of the holder in which they are carried. Two independent cross-slides are provided. The threading mechanism is of the differential type, in which the tap or die is backed off by being run in the same direction as the spindle but at a higher rate of speed. All the movements of the machine are controlled by the longitudinal feed drum shown beneath the tool-slide in Figs. 1 and 2, and by the various members keyed to the cam shaft at the rear of the machine in Fig. 2, this being geared with the longitudinal cam. The oil pump is connected by sprocket wheels and chain with the driving pulley, so that oil is always supplied to the cutting tools as long as the spindles are in motion.

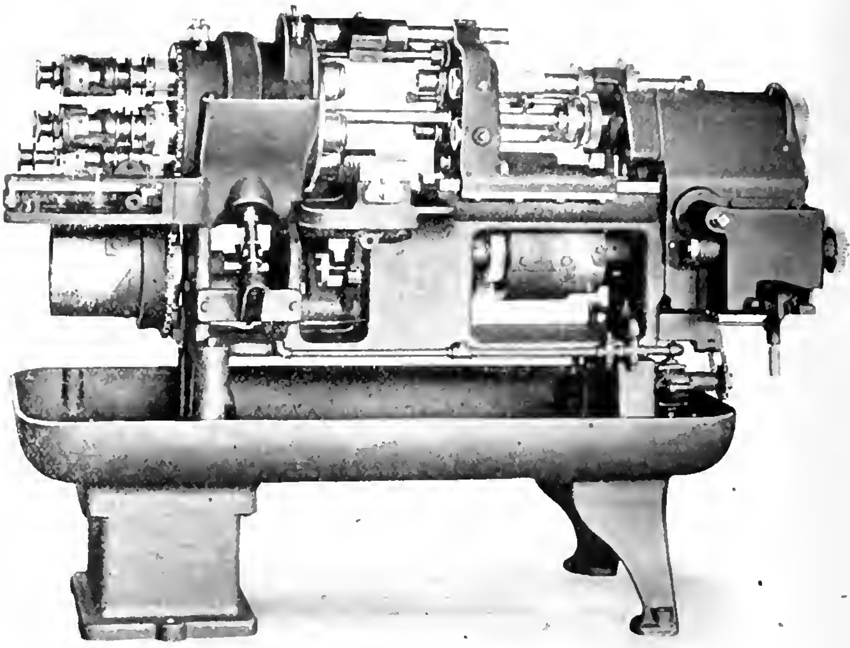

Fig. 1. Gear-driven Peerless Multiple Spindle Screw Machine

The arrangement of the single pulley, constant speed drive is most plainly shown in Fig. 3. The high-speed driving pulley operates the entire mechanism of the machine. It may be connected directly with a clutched pulley on the line-shaft or with tight and loose pulley counter-shaft if desired. It is connected through reducing gearing with the constant speed shaft at the same height with it on the left. Change gears, as shown, connect this shaft with the spindle driving shaft operating the stock spindles. The change gears provided give a wide range of speeds suitable for the different stock diameters and feeds. The cam mechanism is driven in one of two ways—either rapidly at constant speed from a direct connection with the constant speed pulley, or through change gearing at a slower speed. The former is used for the idle and changing stock feeding movements, and the latter for the feeding of the tool. The connection with the constant speed pulley, when the spindle head is being indexed, etc., insures that the machine shall always perform its idle movements at the maximum practicable speed, irrespective of the spindle speeds. The change from idle to operating feed is made by dogs, adjustably mounted on the circular plate at the end of the cam-shaft shown in Fig. 3.

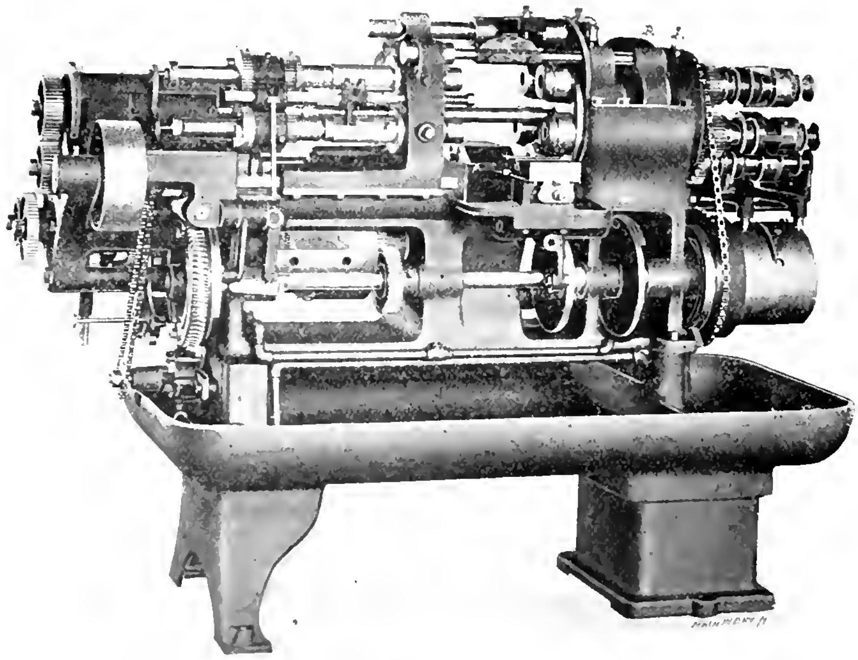

Fig. 2. Rear View of Machine, showing Oscillating Tool Holder

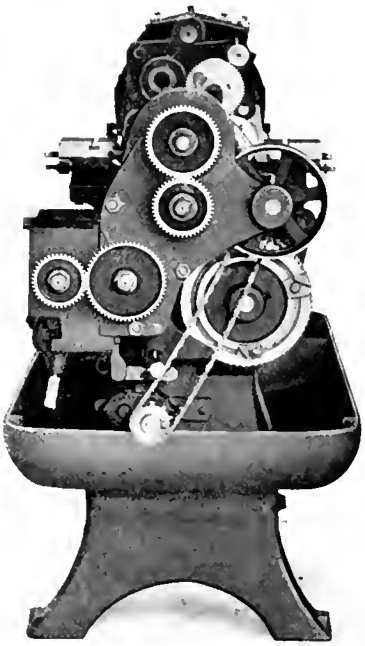

Fig. 3. End View, showing Speed and Feed Change Gears

For the feeding movements the cam mechanism is driven from the spindle driving shaft through the quick change gear box shown at the right in Fig. 1. This gives five changes of feed. By changing about the two gears shown on shafts in horizontal alignment with each other at the left of Fig. 3, five more feeds are obtained. By using an extra set of similar gears furnished with the machine, ten more feeds may be

obtained in the same manner, giving a total of 20 changes, ranging from 0.003 to 0.024 inch feed per revolution of the spindle. These feeds always bear a definite relation to the spindle speed, since they are driven from the spindle driving shaft.

The cam mechanism can be instantly disengaged and locked into disengagement by pushing inward the knob shown below the feed box in Fig. 2. This may be done during either the active or the idle movements of the machine. The cams can thus be hand operated by means of a crank handle attached to the squared end of the shaft projecting from the feed box, shown in Fig. 1. To set the cam mechanism into action again the knob is pulled outward, thus starting the feed. It is impossible to start the fast feed when the tools are in their operating position, or to start the slow-feed when they are in their idle position, so that there is never any danger of disaster on that account.

The auxiliary tool-holder, seen best in Figs. 1 and 2, is journalled on a bar held in the spindle bearing cap, and sliding in a seat on the upper side of the longitudinal tool-slide. This operates, as previously mentioned, on either the third or fourth spindle position. It is oscillated into the work by the cam shown in Fig. 3, adjustably carried by a rod fastened to and moving with the longitudinal tool-slide. A spring returns the auxiliary holder to its normal position.

All the moving parts of this machine are guarded wherever necessary. These guards are shown removed in the engravings, to permit a more complete view of the mechanism.

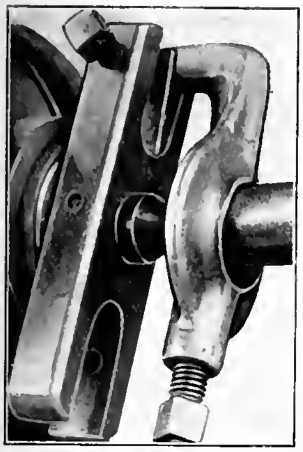

Fig. 1. Type of Dog Commonly Used

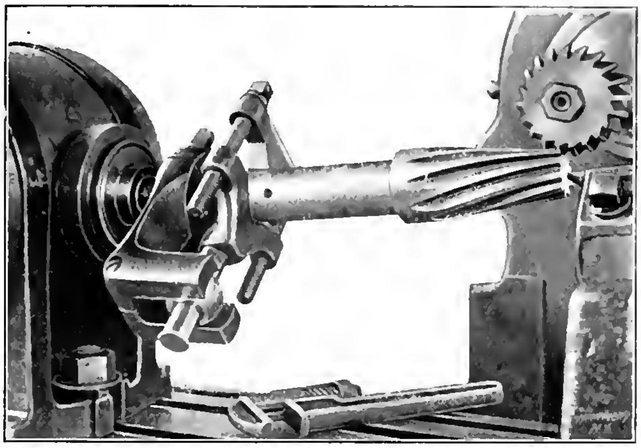

Fig. 2. A Dog which permits Indexing and Spiral Cutting on Taper Work

HILL MILLING MACHINE DOG

The common lathe dog ordinarily used in the milling machine is very unsatisfactory for indexing work on taper milling, as every mechanic knows, when the taper is obtained by raising the tail-stock center. Under these conditions the tail of the dog slides in and out of the driver slot, so that it either develops lost motion, or clamps in the driver, springing the work and throwing a severe strain on the centers. It is quite common to use a shim as shown in Fig. 1 to take up the varying looseness between the point of the screw and the shifting tail of the dog. The liability of this shim to drop out under ordinary conditions, and the practical certainty of its doing so when milling taper spirals, makes the device an uncertain one at the very best.

In Fig. 2 is shown a special milling machine dog made by the M. B. Hill Mfg. Co. of Worcester, Mass., which obviates in a very satisfactory way the difficulties just described. As may be seen, the device consists of a driver, clamped to the nose of the dividing head spindle or to the live center, depending on the construction of the head, and provided with grooved jaws in which slides the ball shown. The tail of the dog passes through this ball, moving up and down in it as the angle of the work varies, the ball at the same time moving in or out as required. The ball and the tail of the dog are hardened, ground and lapped to a close fit. The grooved jaws of the driver are split and provided with an adjusting screw for maintaining the proper fit of the groove on the ball.

It will be seen that the set-screw in the driver used in Fig. 1, which causes all the difficulty in work of this kind, is dispensed with. After the dog is placed in position on the centers, no further attention is required. It is held rigidly in the driver, while still permitting movement in any direction as required by the work. Its action is automatic, so that unskilled labor may be employed in operations of the kind to which it is adapted.

Not only does this device give a positive drive for taper work, which is lacking under the old conditions, but it mitigates the indexing errors due to the sliding of the tapered tail of the dog in or out of the slot, when set up as shown in Fig. 1. This accuracy of indexing permits the milling of rectangular tapers by the simple raising and lowering of the head center, a feature which is peculiar to this make of dog and driver.

POSITIVE BLADE STOP FOR LANG TOOL-HOLDER

The tool-holder made by the G. R Lang Co. of Meadville, Pa., illustrated in the department of New Machinery and Tools of last month's issue of Machinery, has been improved by the provision of a positive stop or abutment for preventing the blades from backing into the hole, even under the heaviest possible cuts. The change consists simply in drilling a row of pockets, which furnish successive seats for a commercial hardened steel ball. The ball is placed in that one of these pockets which agrees with the length of the blade in use. The blade is pushed back against it and is thus provided with a positive stop. In tests it has been found that a blade so held cannot be shifted from its position even when the clamp bolt is lost and the holder is placed in a vise with the weight of a heavy man on the handle. This device is now applied to all tool-holders of the style described, made by this company.

* * *

NEW MACHINERY AND TOOLS NOTES

Centering and Laying-out Tool: Max Jaeger, 109 No. Terrace Ave., Mt. Vernon, N. Y. This device may be used on circular work for finding the center, and laying out the positions of holes and surfaces therefrom.

Steel Tool Rack: Davis Mfg. Co., Milwaukee, Wis. This piece of shop furniture is made entirely of steel. It is provided with two shelves, a drawer and a bin for waste, etc. A tool-chest can be conveniently mounted on the top.

Socket Wrench: Frank Mossberg Co., Attleboro, Mass. This wrench is provided with a folding handle which permits storing the tool in a very small place. Removable sockets permit its use on a wide range of nuts and bolt-heads.

⅜-Inch Riveting Machine: Harvey Hubbell, Inc., Bridgeport, Conn. This riveting machine is of the maker's well-known rotary type, similar in principle to his smaller size, but designed for use up to and including 7/16-inch diameter.

20-Inch Roughing Lathe: Schumacher & Boye, Cincinnati, O. This lathe is of simple and rigid construction, provided with a two-step cone for a 6-inch double belt and double back gears. The feeds are gear-driven through a quick change gear box of the Emmes type.

Down Feed Attachment for Shaper: Queen City Machine Tool Co., Cincinnati, O. This attachment is operated by a worm-wheel and ratchet mechanism, controlled by dogs adjustably mounted in a slot in the holding-down gib, for the ram. The mechanism is very compact and simple.

Friction Clutch: Edgemont Machine Co., Dayton, O. This clutch is of the type in which a split rim is expanded by a lever movement against the inside of the pulley rim. An improved construction gives flexibility to the friction ring without decreasing its holding power.

Payzant Block Lettering Pen: Keuffel & Esser Co., Hoboken, N. J. This pen is made in a variety of sizes, any one of which gives a line of definite width, no matter in what direction the pen is moving. A reservoir is provided to permit the use of the pen for a long time without refilling.

Combination Depth Gage and Square: Wm. J. Gillard, 3617 Chicago Ave., Minneapolis, Minn. This tool consists of a pair of telescoping scales and a clamp, so arranged that the scales may be used either as a depth gage or as a square, set to any desired dimensions within the range of the tool.

Horizontal Spring Testing Machine: Thomas Carlin's Sons Co., Pittsburg, Pa. This tool applies the pressure by means of a horizontal pneumatic cylinder mounted on a framework of convenient construction for handling the springs. It may be profitably used also as a bull-dozer for light work.

Turret Lathe: Meriden Machine Co., Meriden, Conn. This turret lathe has a 20-inch swing, and is provided with friction head and back gears. The turret slide is adjustable vertically and longitudinally for centering the tool. An automatic chuck is provided, and an overhead brace is employed for stiffening the turret stud.

No. 1 Gear-Driven Plain Miller: Hendey Machine Co., Torrington, Conn. This milling machine is gear-driven, with a double back-gear connection. The feeds, as well, are positive and gear-driven. The mechanism is a modification of the well-known Norton gear box. Fifteen spindle speeds are obtained and twenty-one changes of feed.

Gang Drill with Tapping Mechanism: Rockford Drilling Machine Co., Rockford, Ill. This gang drill is composed essentially of three of the maker's regular drill presses, provided with tapping attachments. A single belt drive is used for the three, and the frames are connected by stiff cross bracing. A special fast feed is provided for reaming.

Rotary Hot Swaging Machine: Langelier Mfg. Co., Providence, R. I. This tool is similar to the makers' well-known rotary cold swaging machine, with the addition of a pneumatic holding device for the work, and the provision of an air blast for blowing the scale away from the dies. An oil pump gives continuous lubrication to the working parts.

Lemley Friction Clutch: W. A. Jones Foundry & Machine Co., 800 Noble St., Chicago, Ill. This is a clutch of the type in which a radial flange is compressed between two rings of wood, the compression being obtained by means of a powerful toggle mechanism, easily operated. The adjustment is simple. The clutch is made in both the pulley and cut-off coupling styles.

Helical Wire Coiling Machine: F. B. Shuster Co., New Haven, Conn. This machine is of the three-roll type, adjustable to produce helical coils out of wire ⅛ to ⅜ inch in diameter, in coils of 4 to 30 inches in diameter, and in lengths up to 16 feet. The pipe mandrel by which the helix is supported revolves in such a way as to reduce the friction usually required for driving the coils.

Radius Milling Machines: Newton Machine Tool Works, Inc., 24th and Vine Sts., Philadelphia, Pa. These machines are made in both vertical and horizontal styles, for milling radii up to 100 inches, and arcs up to 68 inches in length. While adapted to a general line of radius milling, they were originally developed for steam turbine work, on which they have been found very effective.

Gang Punch with Spacing Table: Long & Allstatter Co., Hamilton, O. This gang punch will use eight 13/16-inch punches and dies simultaneously. These may be spaced to any convenient lay-out, and each may be rendered individually operative and inoperative as required. The spacing table permits the longitudinal indexing of the work accurately to the dimensions given on the lay-out.

20-Inch Drilling Machine with Positive Feed and Double Spindle Attachment: Mechanics Machine Co., Rockford, Ill. This drill press is provided with a double spindle attachment, positive feed and built-in tapping attachment. In the double attachment the two spindles may be adjusted through a wide range of center distances, being held in a circular slot and driven by a gear mounted in the end of the main spindle.

Improved Drafting Machine: Universal Drafting Machine Co., Cleveland, O. This well-known instrument has been redesigned in its details, while retaining the same principles employed in the older models. The principal change relates to the provision of ball bearing joints. A number of improvements have also been made in the supporting mechanism, adapting the tool for use on boards of the largest size, under a wide range of conditions.

High-Duty Face Mill: Cincinnati Milling Machine Co., Cincinnati, Ohio. This face mill has a body and a backing ring of machine steel, carrying cutters made of ½ by 1¼-inch stock, fastened by a flattened taper pin in front of the cutting edge. The height of the latter is adjusted by small screws at the back of the head. This cutter has been found by the makers to produce results on face milling work hitherto unattainable for tools of the same size.

Multiple Starters for Large Direct Current Motors: Westinghouse Co.'s Pub. Dept., Pittsburg, Pa. These starters are much more effective and safe for large motors than those of the rheostat type used for the smaller sizes. The motor is started by the closing of series of switches, interlocked so as to prevent their closure except in the proper order. All the precautions necessary have been taken to prevent danger from overloads under all possible conditions.

Machine for Finish Grinding the Teeth of Gears: Gear Grinding Machine Co., Detroit, Mich. This machine employs a formed emery wheel for shaping the teeth of gears. While especially devised for finishing gears after hardening, it has been found profitable to use it in place of a finish cutter on soft gears, and also for giving the proper shape to cast gear teeth. An automatic truing device is provided which keeps the wheel constantly formed to the correct outline.

Six-Foot Radial Drilling Machine: Newton Machine Tool Works, Inc., 24th and Vine Sts., Philadelphia, Pa. This tool resembles the makers' older design in its general lines, but has been greatly strengthened and stiffened throughout, presenting an unusually powerful appearance. The machine has been re-designed from data collected in the past two years from a number of prominent shops. It is designed to produce results superior to anything hitherto obtained in the way of output.

Elapsed Time Recorder: International Time Recording Co., Flat Iron Building, New York City. This instrument is of remarkably ingenious construction, being employed for stamping on a ticket the date and hour at the beginning of a job, and at its completion, stamping the time of completion and the elapsed time—in other words, the time it has taken to do the work. It will do this over a period of several days, taking into account only the hours when the shop has been running and leaving half-holidays and Sundays out of consideration. Its use should thus greatly facilitate cost-keeping calculations.

Fourteen-Inch Engine Lathe with Gear Box: W. P. Davis Machine Co., Rochester, N. Y. This lathe is equipped with a quick-change gear box, giving 30 possible changes ranging from 3 to 30 threads per inch. Special or fractional threads may be cut by changing gears at the end. The tail-stock is offset to allow the compound rest to be swung parallel with the bed, and it is provided with a set-over for turning tapers. The carriage has a deep bridge, and the cross-feed screw collar is graduated to read to thousandths of an inch. With a six-foot bed the lathe swings 37 inches between centers and 9½ inches over the carriage. The cone diameters range from 4⅛ to 9 inches, and the back gear ratio is 10 to 1. The net weight of the lathe is 1,600 pounds.

Liquid Sealed Annealing Box: Raymond H. Kinnear, 2 Rector St., New York City. This annealing box is of unique construction, in that it is rendered air-tight without requiring a luting of clay or similar material. The form of the box and its cover provide a trough, which is sealed with molten lead, effectually preventing the entrance of the air and the consequent oxidization of the work. When the box has cooled, the cover is readily withdrawn. The outward passage of gas generated in the interior is not restrained by this construction. The lead remains in the groove and is always ready for subsequent heats. A small quantity of graphite floating on the top prevents its oxidization.

Accelerating Cut Planer: Powell Tool Co., Worcester, Mass. This tool of which mention was made in the article entitled "Improvements in High-Speed Steel," in the April, 1909, issue of Machinery, employs the novel principle of starting the work against the tool at about the ordinary rate of speed, and then accelerating it to a cutting speed much higher than ordinarily found possible. The economy from this operation lies in the fact that the limiting cutting speed on a planer is usually determined by the impact of the tool on the stock at the beginning of the cut, consequently the rate may be increased after this dangerous impact has passed. While there has been a recent tendency to increase the reverse of the planer table, it is evident that this increase of the rate on the cutting stroke means much more in the way of increase of output.

A POPULAR RESOLUTION

At the recent convention of the National Machine Tool Builders' Association, held in Milwaukee, some wag brought down the house by having Secretary Montanus read the following resolution:

Whereas: The designs of machine tools are rapidly changing and improving, and,

Whereas: The manufacturer who uses tools of obsolete design is doing himself and his employes a very great wrong, and,

Whereas: There does not seem to be any method so far developed to convince the user of obsolete machine tools of the wrong he is doing himself and the community; therefore, be it

Resolved: That this association, through its members, urge upon the legislatures of the various States to pass laws making the use of a machine tool for a period longer than ten years a crime punishable with suitable penalties.

A. R. M. M. AND M. C. B. ASSOCIATIONS CONVENTIONS

The forty-second annual convention of the American Railway Master Mechanics' and the forty-third annual convention of the Master Car Builders' associations were held at Atlantic City, N. J., June 16-23 inclusive. Following the custom of alternating the conventions in the matter of priority, the Master Mechanics' Association convention was held June 16, 17 and 18, and the Master Car Builders' Association convention followed on June 21, 22, and 23. Simultaneously with these conventions was the exhibition of railway supplies and apparatus, machine tools, etc., under the auspices of the Railway Supply Manufacturers' Association on Young's New Pier. This is one of the most important exhibits annually held in the United States, in point of capital represented, comparing favorably with many national expositions that are widely advertised.

The general technical program of the Master Mechanics' Association was made up as usual consisting largely of reports made by committees interspersed with individual papers, as follows:

June 16.—Discussion of reports on: "Mechanical Stokers"; "Revision of Standards"; "Motor Cars."

Topical discussion: 1. "Is the additional cost of flexible stay-bolts justifiable?" opened by H. D. Brown, Erie R. R. 2. "Is the usual front row of crown bolts in a locomotive boiler beneficial or otherwise?" opened by C. A. Seley, Rock Island Lines.

Discussion of individual paper on "Bank vs. Level Firing," by E. D. Nelson, Pennsylvania R. R.

June 17.—Discussion of reports on: "Castle Nuts"; "Safety Valve"; "Superheaters."

Discussion of individual paper, "Locomotive Performance under Saturated and Superheated Steam," by Prof. W. F. M. Goss, University of Illinois.

Topical discussion: 1. "Vanadium steel—Have the advantages claimed and shown in laboratory tests been substantiated in practice, particularly as regards the strengthening of locomotive parts?" opened by W. C. A. Henry. 2. "Are bypass valves necessary on piston valve locomotives?" opened by H. T. Bentley, Chicago & Northwestern Ry.

Discussion of reports on: "Widening Gages on Curves"; "Steel Tires."

June 18.—Discussion of reports on: "Tender Trucks"; "Fuel Economies"; "Lubricating Material Economies."

Individual paper: "The Transfer of Heat," by Prof. Charles E. Lucke, Columbia University.

Topical discussion: 1. "Is previous railway experience of advantage to locomotive firemen? If so, how may this be handled in a practical manner?" opened by D. R. MacBain, N. Y. C. R. R. 2. "Brick arches and water tubes, their value and influence on fuel economy," opened by J. F. Walsh, Chesapeake & Ohio Ry.

The meeting was conducted by President H. H. Vaughan, assistant to the vice-president of the Canadian Pacific Ry.

The following officers were elected:

President, G. W. Wildin, N. Y. N. H. & H. R. R.
First vice-president, C. E. Fuller, Union Pacific Ry.
Second vice-president, H. T. Bentley, C. & N. W. Ry.
Third vice-president, D. F. Crawford, Pennsylvania Lines.
Treasurer, Angus Sinclair, *Railway and Locomotive Engineering.*
Executive Committee: C. A. Seley, C., R. I. & P. (two years); D. R. MacBain, N. Y. C. & H. R. R. R. (two years); F. M. Whyte, N. Y. C. & H. R. R. R. (one year).

The program of the Master Car Builders' Association convention was made up in the usual manner consisting of topical discussions and individual papers as follows:

June 21.—Discussion of reports on: "Revision of Standards and Recommended Practice."

Topical discussion: 1. "Wheel defects—Is a brake burn due to prolonged brake application properly an owner's defect? How is it to be distinguished from the defect known as shelled out?" opened by H. D. Taylor, P. & R. Ry. 2. "Application of suitable lugs to steel or steel underframe cars for jacking up car bodies, and application of suitable push pole pockets to avoid damage to cars," opened by Thomas Paxton, El Paso & S. W. Ry.

Discussion of reports on: Train Brake and Signal Equipment"; "Brake Shoe Tests."

June 22.—Discussion of reports: "Tests of M. C. B. Coupler"; "Revision of Rules for Loading Long Materials"; "Rules of Interchange," including report of arbitration committee on "Revision of Freight and Passenger Car Rules"; also reports of committees on "Freight Car Repair Bills and Air-Brake Hose"; "Cast Iron Wheels"; "Splicing Sills"; "Tank Cars"; "Safety Appliances"; "Side Bearings and Center Plates."

June 23—Discussion of reports: "Freight Car Trucks", "Painting Steel Cars"; "Side and End Door Fixtures", "Train Pipe and Connections for Steam Heat"; "Classes of Cars"; "Salt Water Drippings from Refrigerator Cars"; "Revision of Constitution and By-Laws"; "Subjects."

Topical discussions: 1 "Wheel mounting pressures for various sizes of cast iron and steel wheels," opened by W. T. Gorrell, P. & R. Ry. 2. "Cleaning triple valves and brake cylinders on freight cars to meet Interstate Commerce Commission requirements," opened by T. L. Burton, C. R. R. of N. J.

The meeting was conducted by President R. F. McKenna, master car builder of the Delaware, Lackawanna and Western R. R. The following officers were elected:

President, F. H. Clark, C. B. & Q. R. R.
First vice-president, T. H. Curtis, L. & N. R. R.
Second vice-president, LeGrand Parish, L. S. & M. S. Ry.
Third vice-president, A. Stewart, Southern Ry.
Treasurer, John Kirby, Adrian, Mich.
Executive Committee: D. F. Crawford, Pennsylvania Lines; F. W. Brazier, N. Y. C. & H. R. R. R.; C. A. Schroyer, C. & N. W. Ry.; J. D. Harris, B. & O. R. R.; C. E. Fuller, U. P. R. R. (hold over); H. D. Taylor, P. & R. Ry.

The Mechanical Exhibits

The exhibit of machine and railway appliances comprised a seemingly larger proportion of machine tools and accessories for the machine shop than any previous exhibit, there being about fifty concerns represented out of a total of 228 exhibiters, who manufacture machine tools, machinists' hand tools and other accessories that are used in metal working. The exhibits were arranged on Young's New Pier in the same general order as in past years. Machinery Hall on the east side of the pier near the entrance was mostly filled with machine tools and would have been entirely filled had the management given the concerns space in this section where they properly belonged. A passenger car vestibule, steel car, and a few other examples of rolling stock equipment were clearly out of place and should have been grouped in another part of the exhibit with related exhibits.

The matter of proper segregation of exhibits is important. In the business districts of large cities, the tendency is for competitive lines to gather in the same localities, and the same idea should be followed in managing exhibits of machinery and tools. Lathes, planers, shapers, grinding machines, boring, drilling and milling machines, upright and radial drills, boring mills, automatic screw machines, nut tappers, plain grinding, cylinder boring machines, twist and flat drills, reamers, and all metal-working tools necessary for locomotive building and repair work should be grouped in one section so far as possible. Blacksmith shop tools and boiler shop tools should form a section intermediate with the purely machine tools section and the sections in which the rolling stock equipment and appliances are shown. In this section should be shown flue welders, flue rattlers, furnaces, riveters, pneumatic tools, etc.

Many of the machine tools were in operation and when all were working together the scene was animated, indeed. The tests of the power of radial drills using flat twisted high speed drills, attracted a great deal of attention, and some startling results were obtained in heavy high speed drilling. High speed shapers also received their share of attention and many remarked that the modern shaper is a very healthy competitor of the planer. The turning, boring, grinding, and threading operations did not lack for attention, but whether it was bestowed by railway officials intelligently or not, future sales only will show.

Exhibitors of Metal-working Machines and Accessories

Ajax Mfg. Co., Cleveland, Ohio. Improved bolt head upsetting and forging machine; high speed bulldozer and bending machine; reclaiming rolls for re-rolling scrap; hot sawing and burring machine.

American Blower Co., Detroit, Mich. Blowers for forges and furnaces; heating and ventilating apparatus, mechanical draft apparatus; vertical enclosed, self-oiling steam engines; Sirocco blowers.

American Specialty Co., Chicago, Ill. "Use-Em-Up" drill sockets and sleeves; Collis high-speed flat and flat twisted drills, universal adjustable blade reamers.

American Tool Works Co., Cincinnati, Ohio. Engine lathe, 24-inch by 12 foot, driven by Northern direct-connected motor;

multi-speed planer 36 inches x 36 inches by 10 feet, driven by direct-connected Westinghouse motor; 25-inch crank shaper with speed box, driven by direct-connected General Electric motor, 5-foot triple-geared high speed plain radial drill, driven by direct-connected Crocker-Wheeler motor; 2-foot high speed ball bearing radial drill with tapping attachment, driven by direct-connected Lincoln motor; Willey motor-driven water tool grinder with 2-inch x 16-inch wheel.

American Vanadium Co., Pittsburg, Pa. Vanadium ores, alloys, and steels, both wrought and cast, comprising saws, tires, axles, crank-shafts, locomotive frames, etc.

Armstrong-Blum Mfg. Co., Chicago, Ill. Power hack saw machine, portable grinder for lathes and planers, lever punch and shear.

Armstrong Bros. Tool Co., Chicago, Ill. Tool holders, ratchet drills, vises, C-clamps, knurling tools and other machine shop specialties.

Besly & Co., Charles H., Chicago, Ill. Besly spiral disk grinder, spiral circles, taps, oil and babbitt.

Boker & Co., Hermann, New York. "Novo Superior" steel and other high-speed steels, including "Intra" steel.

Brown & Sharpe Mfg. Co., Providence, R. I. Plain milling machine, vertical milling machine, and attachments for milling machines. Machines in operation.

Bullard Machine Tool Co., Bridgeport, Conn. Vertical turret lathe, in operation.

Carborundum Co., Niagara Falls, New York. Carborundum wheels, sharpening stones, rubbing bricks, carborundum paper and cloth and other abrasive products.

Celfor Tool Co., Chicago, Ill. High speed drills, reamers, counter-sinks, three-lipped drills, chucks, etc. These drills were in use on several drilling machines in the exhibit.

Chicago Penumatic Tool Co., Chicago, Ill. Air compressor.

Chisholm & Moore Mfg. Co., Cleveland, Ohio. Differential chain hoists in various sizes, including a 30-ton hoist.

Cincinnati-Bickford Tool Co., Cincinnati, Ohio. High speed 24-inch upright drill; high speed 20-inch upright drill; 5-foot high speed radial drill. Radial drill in operation.

Cincinnati Planer Co., Cincinnati, Ohio. Forge planer 37 inches x 37 inches x 8 feet with four heads and variable speed motor drive, in operation.

Cleveland Twist Drill Co., Cleveland, Ohio. Twist drills, taps, reamers, sockets, etc.

Coe Brass Mfg. Co., Ansonia, Conn. Extruded brass in various cross sections, used in the manufacture of locks, pinions, ratchets, gears, etc.

Cooper-Hewitt Electric Co., New York. Cooper-Hewitt mercury vapor electric lamp for shop lighting.

Davis-Bournonville Co., New York. Oxy-acetylene welding and cutting plant comprising torches, generators, and compressors. Demonstration of process.

Davis Expansion Boring Tool Co., St. Louis, Mo. Expansion boring tools, lathe tools, planer tools, etc.

Dudgeon, Richard, New York. Hydraulic jacks, comprising car inspector's railway, plain, base, claw, independent claw, horizontal and traversing jacks; electrical power pump, and several types of hand-operated pressure pumps.

Foster, Walter H., New York. Bolt turning machine, Lassiter stay-bolt threading and reducing machines, stay-bolt hole squaring machine; Potter & Johnston automatic machines; Lassiter bolt drilling machine, stay-bolt nipper, automatic nut tapper.

Goldschmidt-Thermit Co., New York. Exhibit of thermit-welded locomotive frames, driving wheels, connecting rods; and fire brick molds shaped to fit various locomotive parts used in thermit welding.

Gould & Eberhardt, Newark, N. J. 24-inch high duty shaper, driven by a direct-connected Northern variable speed motor. Machine in operation.

Greene-Tweed & Co., New York. "Favorite" reversible ratchet wrench and other specialties.

Hill, Clarke & Co., Inc., Boston, Mass. 5-foot triple geared high speed radial drill; Milwaukee plain milling machine; Milwaukee full universal milling machine with various attachments; Universal horizontal boring machine. Milling machines in operation.

Hammett, H. G., Troy, New York. Radius grinder for locomotive links, and other specialties.

Harrington, Edwin, Son & Co., Inc., Philadelphia, Pa. Geared and differential hoists, and I-beam trolley.

Keystone Drop Forging Works, Chester, Pa. Drop forgings for locomotive and car work.

Landis Tool Co., Waynesboro, Pa. Plain and universal grinders.

Landis Machine Co., Waynesboro, Pa. Motor-driven bolt and pipe threading machines, demonstrating high speed threading. Machine in operation.

Linde Air Products Co., Buffalo, New York. Oxy-acetylene welding and oxy-coal gas cutting apparatus.

Link-Belt Co., Philadelphia, Pa. Renold machine driving chains.

Lodge & Shipley Machine Tool Co., Cincinnati, Ohio. Engine lathe, 24-inch x 12 foot patent head, motor-driven; engine lathe 18-inch x 8-foot head, motor-driven. Machine in operation.

Manning, Maxwell & Moore, New York. Lathe, shaper, drills, inspirators, valves, and other specialties.

National-Acme Mfg. Co., Cleveland, Ohio. Automatic multiple spindle screw machine in operation.

Newton Machine Tool Works, Inc., Philadelphia, Pa. High duty radial drilling machine; cold saw cutting off machines; rapid production bolt threading machines.

Niles-Bement-Pond Co., New York. Pratt & Whitney toolroom lathe, tire gages, coupler gages, tire tapes, Pond rigid turret lathe, rapid action tool clamp for Niles driving wheel lathe, etc.

Norton Co., Worcester, Mass. Alundum grinding wheels.

Norton Grinding Co., Worcester, Mass. Norton gap grinding machine for locomotive work and other specialties. Machine in operation.

Queen City Machine Tool Co., Cincinnati, Ohio. 24-inch motor-driven shaper with gear-box driven by direct-connected Westinghouse motor. Machine in operation.

Revolute Machine Co., New York. Continuous electric blueprinting machine. Machine in operation.

Royersford Foundry & Machine Co., Royersford, Pa. Punching and shearing machines.

Russell, Birdsall & Ward Bolt & Nut Co., Portchester, New York. Finished and semi-finished castellated nuts, hexagon nuts, finished case-hardened nuts, etc.

Ryerson, Joseph T., & Son, Chicago, Ill. Rotary bevel shear, high speed friction saw, portable automatic key-seating machine, crank pin truing machine, flue welding machine, internal combustion riveter, etc. Riveter in operation.

Sellers & Co., William, Philadelphia, Pa. Line shaft hanger with cast iron boxes; photographs of new car wheel lathe, locomotive injectors, etc.

Standard Tool Co., Cleveland, Ohio. Twist drills, reamers, milling cutters, taps, and chucks.

Stoever Foundry & Machine Co., New York. Motor-driven automatic pipe-bending machine, in operation; motor-driven pipe-threading and cutting-off machine, in operation.

Tindel-Morris Co., Eddystone, Pa. High-duty cold sawing machine and inserted tooth high-speed steel saw blades.

Underwood & Co., H. B., Philadelphia, Pa. Portable cylinder boring bar; portable crank-pin turning machine, vertical boring machine for small gas engine cylinders, etc.

Watson-Stillman Co., New York. Hydraulic jacks, car wheel and crank pin presses, hydraulic rail benders and jacks, and turbine pumps.

Western Tool & Mfg. Co., Springfield, Ohio. Lathe and planer tool holders, expanding mandrels, etc.

Westinghouse Electric & Mfg. Co., Pittsburg, Pa. Electric motors and other electrical apparatus.

Westinghouse Air Brake Co., Pittsburg, Pa. Cross-compound air pump, 8½ inches in section, driven by duplicate pump.

Yale & Towne Mfg. Co., New York. Electric hoists, chain blocks, I-beam trolleys and other specialties.

* * *

PERSONAL

C. E. Chambers has been appointed general master mechanic of the Central Railroad of New Jersey.

C. L. Cook, formerly of the Fairmont Coal Co., has been appointed chief engineer of the Fairmont Mining Machine Co., Fairmont, West Virginia.

Edward S. Pomeroy has been promoted from the position of foreman to master mechanic at the Smith & Wesson, Inc., revolver manufacturers, Springfield, Mass.

Harold Wesson has been appointed assistant superintendent at the Smith & Wesson, Inc., revolver manufacturers, Springfield, Mass.

Richard B. Cavanagh has entered the firm of Macdonald & Macdonald, patent lawyers, 50 Church St., New York, and the firm name hereafter will be Macdonald, Macdonald & Cavanagh.

H. R. Swartley, Jr., who has been the New York manager for the Electric Service Supply Co., Philadelphia, Pa., has taken charge of the Chicago office of the Variable Speed Clutch Co., of Milwaukee, Wis.

E. W. McKeen, for many years connected with the mechanical department of the Union Twist Drill Co., Athol, Mass., has been appointed manager of the company's New York store at 54 Warren St.

H. F. Frohman, general manager of the S. Obermayer Co., Cincinnati, Ohio, read a paper at the May meeting of the American Foundrymen's Association of Cincinnati, entitled "Standardizing Foundry Facings."

Harold A. Richmond, president of the American Emery Wheel Works, Providence, R. I., sailed for Europe June 17 on the *Friedrich der Grosse*. Mr. Richmond will visit the company's agencies in Berlin, Vienna, Paris, and Copenhagen.

F. W. Jackson, who has been connected with the engineering and sales department of the Harrisburg Foundry & Machine Works, Harrisburg, Pa., for a number of years, has been appointed district manager of the company for the Baltimore district with headquarters at 1415 Continental Trust Building.

Curtis Dougherty, formerly superintendent of the Springfield division of the Illinois Central Railroad, has been promoted to the position of superintendent of the Queen & Crescent Route and Alabama Great Southern R. R., with headquarters in Cincinnati, Ohio. Mr. Dougherty left the Illinois Central R. R. February 1, 1907, to go to the Queen & Crescent Route as assistant general engineer to Mr. H. E. Warrington, who has just resigned.

W. A. Hopkins, who has had charge of the electric construction work of the Wabash Railroad, and who was the real organizer of the electrical department, has resigned, and is now in charge of the southwestern branch of the New York Safety Car Heating & Lighting Co., covering territory extending from St. Louis to the Gulf of Mexico and west to the Pacific coast including Mexico, and as far north along the coast as Washington. The company now employing Mr. Hopkins has for a number of years had exclusive control of the Pintsch lighting system, but now will push the electric lighting system of trains also.

OBITUARIES

Benjamin F. Jones, for forty-two years the timekeeper for the Collins Co., Collinsville, Conn., died May 14, aged seventy years.

John W. Brawn, of Brawn & Sellers, Holyoke, Mass., manufacturers of wire cloth, Fourdinier and dandy rolls, died at his home in that city June 3, aged sixty-nine.

George W. Hall, foreman of the polishing room in Smith & Wesson, pistol manufacturers, Springfield, Mass., died May 29, aged fifty-one years. Mr. Hall was treasurer of the factory relief association.

* * *

COMING EVENTS

July 8-10.—Massachusetts State Convention of the National Association of Stationary Engineers at Springfield, Mass. Exhibit of steam specialties and engineers' supplies in Graves Hall.

July 10-17.—Winnipeg (Manitoba) Industrial Exhibition from July 10 to 17. A. W. Bell, manager and secretary, Winnipeg, Manitoba.

August 9-14.—Seventeenth National Irrigation Congress, Spokane, Wash., for the consideration of an action on irrigation, drainage, forestry, good roads, deep waterways, and home building. Arthur Hooper, secretary, Board of Control, Spokane, Wash.

September 25-October 9.—Hudson-Fulton celebration of the three-hundredth anniversary of the discovery of the Hudson River by Hendrick Hudson in 1609, and the one hundredth anniversary of the successful application of steam to the navigation of the Hudson River in 1807. The headquarters of the commission are in the *Tribune* building, New York City, General Stewart L. Woodford, president, and Mr. Henry W. Sackett, secretary. The commission solicits the loan of collections of machinery, models, books, etc., having a bearing on the history of early steam navigation in the United States.

October 4-8.—Annual conventions of the American Street and Interurban Railway Association, American Street and Interurban Railway Accountants' Association, American Street and Interurban Railway Engineering Association, American Street and Interurban Railway Claim Agents' Association, American Street and Interurban Railway Transportation and Traffic Association, American Street and Interurban Railway Manufacturers' Association, at Denver, Col. Bernard V. Swenson, secretary and treasurer, 29 West 39th St., New York.

SOCIETIES AND COLLEGES

Armour Institute of Technology, Chicago, Ill. Bulletin No. 4 on the summer session which comprises courses in electrical engineering, chemical engineering, civil engineering, practical shop work, physics, mathematics, mechanics of engineering and drawing. Address for further information Dean of Engineering Studies, Armour Institute of Technology, Chicago.

Museum of Safety and Sanitation, 29 West 39th St., New York, announces the election of Arthur Williams to the board of trustees. Mr. Williams is the general inspector of the New York Edison Company and a member of the American Institute of Electrical Engineers. In 1907 he was decorated by the French Government. He is a member of the American section of the International Housing Congress and was a member of the Eighth International Congress of Social Insurances at Rome, 1908. Mr. Williams will serve on the lecture committee of the museum.

NEW BOOKS AND PAMPHLETS

Proceedings of the Twenty-eighth Annual Convention of the American Water Works Association Held at Washington, D. C., May 11-16, 1908. 800 pages, 6 x 9 inches. Published by the secretary, J. M. Diven, 14 George St., Charleston, S. C.

On the Rate of Formation of Monoxide in Gas Producers. By J. K. Clement. 47 pages, 6 x 9 inches. Published by the University of Illinois Experiment Station, Urbana, Ill., for free distribution.

Engine Lathe Work. By Fred H. Colvin. 180 pages, 4½ x 7 inches, 127 illustrations. Published by the Hill Publishing Co., New York. Price $1.

The work treats of the engine lathe, circular lathe work, driving the work, tools for turning, face-plate work, chucks and chucking, boring tools, taper turning, thread turning, test indicators, care of lathes, etc. It is partly made up of elementary articles published in the monthly edition of the *American Machinist*. It will be found generally useful by apprentices, students and trade schools and others desiring to obtain elementary knowledge of the construction, use and operation of the engine lathe.

Westinghouse E-T Air Brake Construction Pocket Book. By W. W. Wood. 242 pages, 5 x 7 inches, illustrated. Published by Norman W. Henley & Son, New York. Price $2.

This instruction pocket book on the Westinghouse E-T air brake equipment differs from other works on the air brake, in that it is not of the catechism form, which has been the popular method of explaining air brake apparatus and other apparatus used in railway and stationary engineering. The new E-T equipment is described in detail. In this equipment the entire apparatus, including the engine and tender brake, has been reconstructed, and although the principle of the common triple valve has been retained, the general construction of the new equipment is so different from the older form that railway men must study its construction in order to understand its operation and action. The book is illustrated with numerous colored diagrams showing the pipes, cylinders, reservoirs, etc., the pressures in the various parts of the apparatus being indicated in colors so as to make the study of the apparatus convenient and easy.

Gas Engine Theory and Design. By H. C. Mehrtens. 256 pages, 5 x 8 inches, illustrated. Published by John Wiley & Sons, New York. Price $2.50.

The increase in importance and general interest in the gas engine is to some extent indicated by the number of new books that have been published in the last few years. The book in review has been prepared for students, draftsmen, engineers and men who operate gas engines, and is based on the author's instruction work at the Michigan Agricultural College. It treats of the general principle of operation, heat, thermodynamics, combustion, fuel, laws of gases, gas engine efficiency, explosive mixtures, mixing valves and carbureters, governing, ignition, cooling, exhaust, selection of type, determination of the principal dimensions, forces acting in the gas engine, design and dimensions of parts, gas engine manipulation, testing designs. Tables are given on the physical properties of materials, petroleum distillates, properties of fuel gases, volumes and specific heats of gases, efficiencies at different altitudes, strength of materials, heat and power units, volume, pressure and temperature curves. The work has the appearance of being a practical and carefully prepared book that will appeal more to the student, draftsman and engineer than to the general run of men operating gas engines. We would not recommend it to the latter class unless they are interested in the problems concerning design and the thermodynamics of gas engines.

Calculation of Change Wheels for Screw Cutting Lathes. By D. De Vries. 83 pages, 5½ x 8½ inches. Published by Spon & Chamberlain, New York. Price $1.50.

In this work the author has handled the problem of change gearing of lathes in a very ambitious manner, but one discouraging to machinists who would buy a work of this character to obtain simple directions for gearing engine lathes. For a designer of machine tools who wishes to study the method for calculating approximate fractions at length he will find this part carried out in great detail. The book is divided into three chapters. The first describes the change mechanism of the engine lathe; the second and longest chapter is divided into heads, as follows: System; what change wheels are to be found on a lathe; the cutting of metric threads with a metric lead screw; the cutting of English threads with a metric lead screw; the cutting of English threads with an English lead screw; the cutting of metric threads with an English lead screw; the wheel with 127 teeth; method of calculating approximate fractions; the proof of the sum; fixing up the wheels; thread cutting with double compound threads; the cutting of left hand threads. In the third chapter the forms of thread sections, types of threads, screw cutting tools, etc., are discussed. We believe that the book would be better appreciated by the mass of machinists if the section on the method of calculating approximate fractions and finding the approximate fraction were simplified and made much shorter.

CATALOGUES AND CIRCULARS

American Blower Co., Detroit, Mich. Catalogue of Sirocco fans.

Skinner Chuck Co., New Britain, Conn. Pamphlet illustrating Skinner chucks.

Ball & Wood Co., Elizabethport, N. J. Catalogue of Rateau-Smoot low-pressure turbines and generators.

Emerson Electric Mfg. Co., St. Louis, Mo. Bulletin No. 3908 on factory sewing machine electric motors.

Waltham Machine Works, Waltham, Mass. Leaflet illustrating escape wheel cutting machines for watch work.

Linde Air Products Co., Buffalo, N. Y. Descriptive pamphlet of "Pyrokopt" apparatus for cutting metals.

Phillips Pressed Steel Pulley Works, Philadelphia, Pa. Blotter advertising Phillips pressed steel pulleys.

General Electric Co., Schenectady, N. Y. Bulletin No. 4662 of Thompson recording watt meters for switchboard service.

Westinghouse Electric & Mfg. Co., Pittsburg, Pa. Small catalogue of Westinghouse electric motors for the office, store and shop.

Jones & Lamson Machine Co., Springfield, Vt. Pamphlet containing detailed description of chip breaking turner for the flat turret lathe.

Crocker-Wheeler Co., Ampere, N. J. Bulletin No. 114, superseding Bulletin No. 77 on coupled type alternating current generators.

H. G. Hammett, Troy, N. Y. Leaflet illustrating radius grinder for locomotive links and link blocks. The machine can also be converted into a surface grinder.

S. Obermayer & Co., Cincinnati, Ohio. Pamphlet advertising Obermayer foundry products and containing a guide to points of interest in and adjoining Cincinnati.

Tindel-Morris Co., Eddystone, Pa. Bulletins Nos. 1, 2, 4 and 5 of Tindel high-duty inserted tooth cold saw blades, crank-shaft lathes and crank-shaft grinding lathes.

W. S. Rockwell Co., 50 Church St., New York. Pamphlet illustrating Rockwell melting furnace for copper, brass, bronze, aluminum, silver, gold, iron, steel, etc.

Electric Welding Products Co., Cleveland, Ohio. Booklet illustrating electrically welded gas engine valve stems and other welded products largely used in the manufacture of automobiles.

Warner & Swasey Co., Cleveland, Ohio. Pamphlet illustrating the Warner & Swasey turret lathe, telescopes, binoculars and other products exhibited at the recent Cleveland Industrial Exposition.

Gisholt Machine Co., Madison, Wis. Leaflet for loose leaf binder illustrating operations of finishing street-car motor pinions on the Gisholt 24-inch big bore turret lathe with 5-inch spindle hole.

Joseph Dixon Crucible Co., Jersey City, N. J. Booklet on care of belting, containing illustrations showing methods of lacing belts and giving practical pointers on general care of belts and application.

Richard Dudgeon, Broome & Columbia Sts., New York. Catalogue No. 6 of hydraulic jacks and power pumps made in a great variety of styles and sizes for all classes of service.

Cincinnati Iron & Steel Co., Cincinnati, Ohio. General catalogue of shears, punches, hoists, travelers, etc., for structural, boiler, machine, wagon, blacksmith, sheet, metal, and other shops.

Richard W. Jefferis Co., Camden, N. J. Folder illustrating Jefferis pressed steel lockers for use in armories, gymnasiums, factories, clubs, stores, offices, schools, shops, etc.

Hess-Bright Mfg. Co., Philadelphia, Pa. Catalogue of propeller thrust, ball bearing blocks for marine engines and other service requiring efficient thrust bearings.

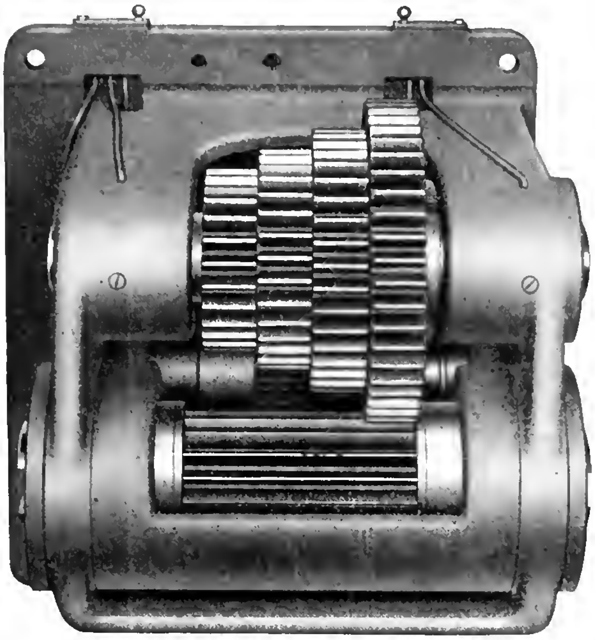
Cincinnati-Bickford Tool Co., Cincinnati, Ohio. Folder describing the Cincinnati 24-inch high-speed shaft-driven drilling and tapping machine with motor and gear box drive.

Consolidated Safety Valve Co., 85-89 Liberty St., New York. Reprint of paper by Philip G. Darling on safety valve capacity read before the American Society of Mechanical Engineers, February 23, 1909.

Electric Welding Products Co., Cleveland, Ohio. Booklet illustrating finished steel bolts and screws having the heads electrically

Severe Service Demands Substantial Construction

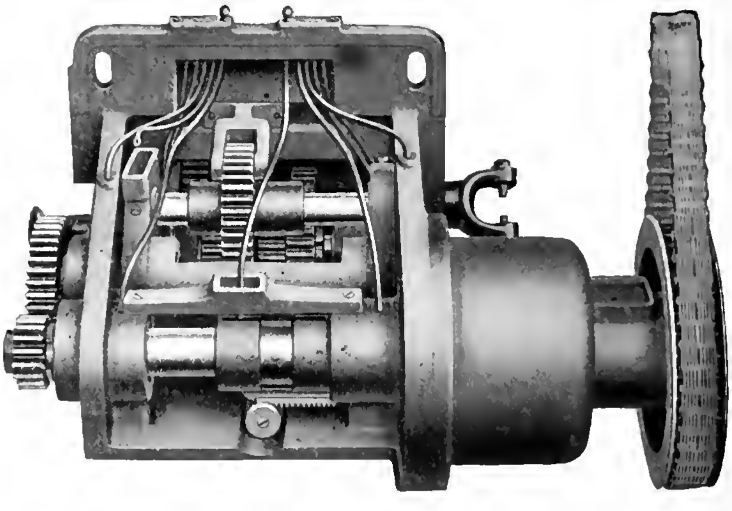
That is why so much care is given to the design and construction of each part of B. & S. Milling Machines.



THE accompanying cuts show excellent examples of the strong and rigid constructions employed in the **spindle speed** and **feed cases** of the

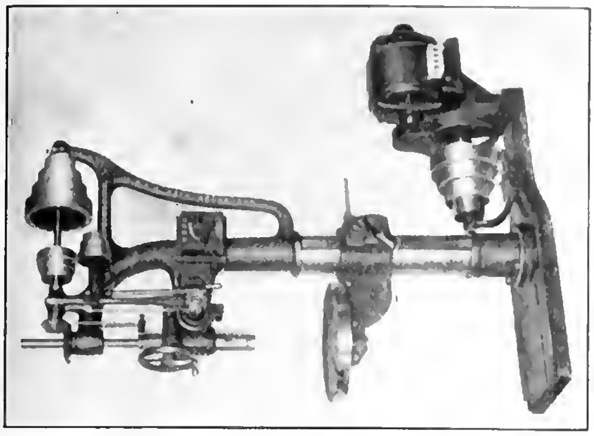
B. & S.
Constant Speed Drive Milling Machines

NOTE the rigid mounting of change gears and the compact and heavy proportions of supporting parts—All shafts are of steel, hardened and ground and run in bronze bearings—All gears are of hardened machinery steel and have long pointed teeth to afford instant engagement without employment of any auxiliary mechanism—The holes in all gears are ground concentric with the pitch circle after hardening; silent running is thus assured—The simplicity of the oiling arrangement is plainly apparent in both cuts.



Brown & Sharpe Mfg. Co.

PROVIDENCE, R. I., U. S. A.



This is our New 21" Power Feed Automatic Stop Drill

MOTOR DRIVE

This machine is accurate, powerful, and quickly operated. Will drill 1¾" hole in solid cast iron. It is equipped with 1 H. P. General Electric D. C. Motor. Great drill for light manufacturing purposes. For sale by Manning, Maxwell & Moore New York City.

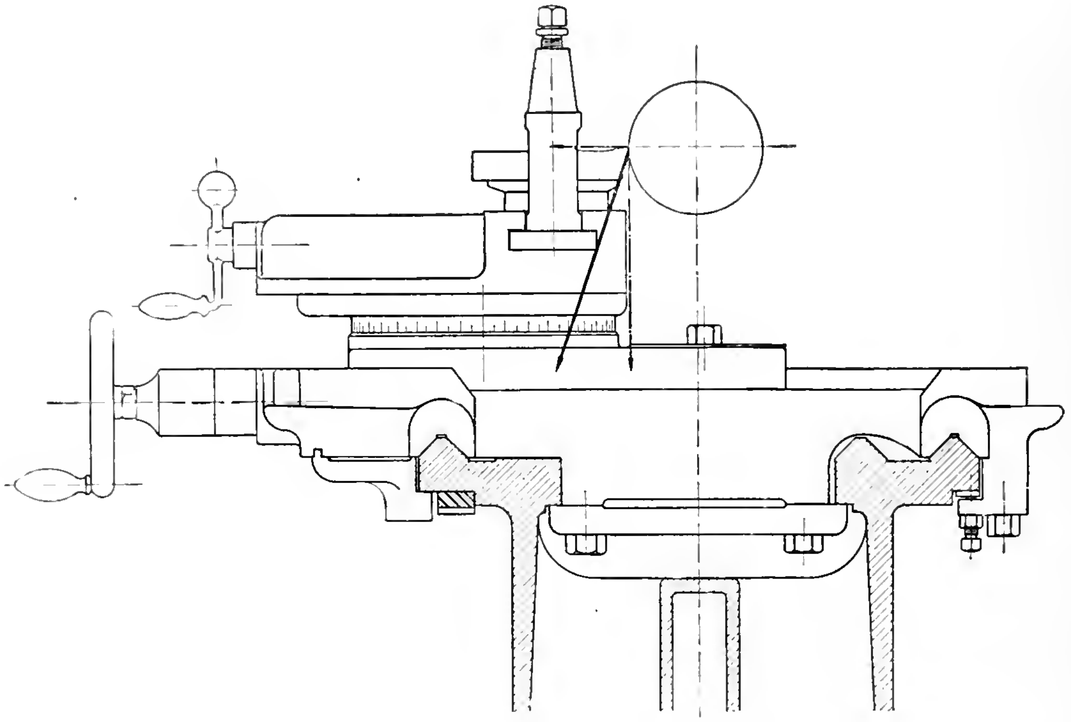
Tool Thrust

A LIGHT bridge will answer for light cuts on large diameters with the tool point directly above the front shear. But stresses are of a different sort when the lathe is under heavy cut on a small diameter.



The illustration shows the position of tool and compound rest on the 24" Patent Head Lathe when taking a 15 H.P. cut on work of 5" diameter. Heavy arrow indicates direction of pressure due to cut. Note the large bearing against the top and inside of bed directly in line with the tool thrust, in addition to the full length bearings of carriage upon front and rear V's. This extra bearing gives a solid support to the bridge just where it is needed, and positively prevents deflection or distortion even under the heaviest cuts.

MILWAUKEE MILLERS

have the advantages of simplicity, power, strength and capacity. They are equipped to turn out the work at the least possible cost and at the same time secure high grade product. The drive is through a single pulley without countershaft or overhead belts. Automatic forced lubrication of all gears and bearings reduces friction and wear to the minimum. Every machine is provided with pump for cooling and lubricating the cutters, and arrangements are made for return of the oil to the reservoir in the base of the machine. All adjusting and feed screws have ball thrust collars. Machines have extra wide tables, run noiselessly and smoothly and are adapted for hard, continuous service.

THE FAY & SCOTT EXTENSION GAP LATHE has advantages well beyond the ordinary gap lathe. It is designed and meets the demand for a lathe which will turn pieces of large diameter and extra length, and at the same time handle ordinary work with accuracy and dispatch. By sliding the top bed of the machine the gap can be widened or reduced to suit requirements, not only increasing the swing of the lathe but also increasing the distance between centers for turning long work. It is very rigidly and substantially built, has ample strength and power for work the full swing of the gap, yet no awkward or inconvenient features to interfere with ordinary turning. All improvements—belt or motor drive. May we send literature?

We carry a stock of high grade machine tools and shall be glad to demonstrate any of them, or to answer any questions on the machine tool subject. You can bank on the quality of our line of tools—you can rely on information from our selling force.

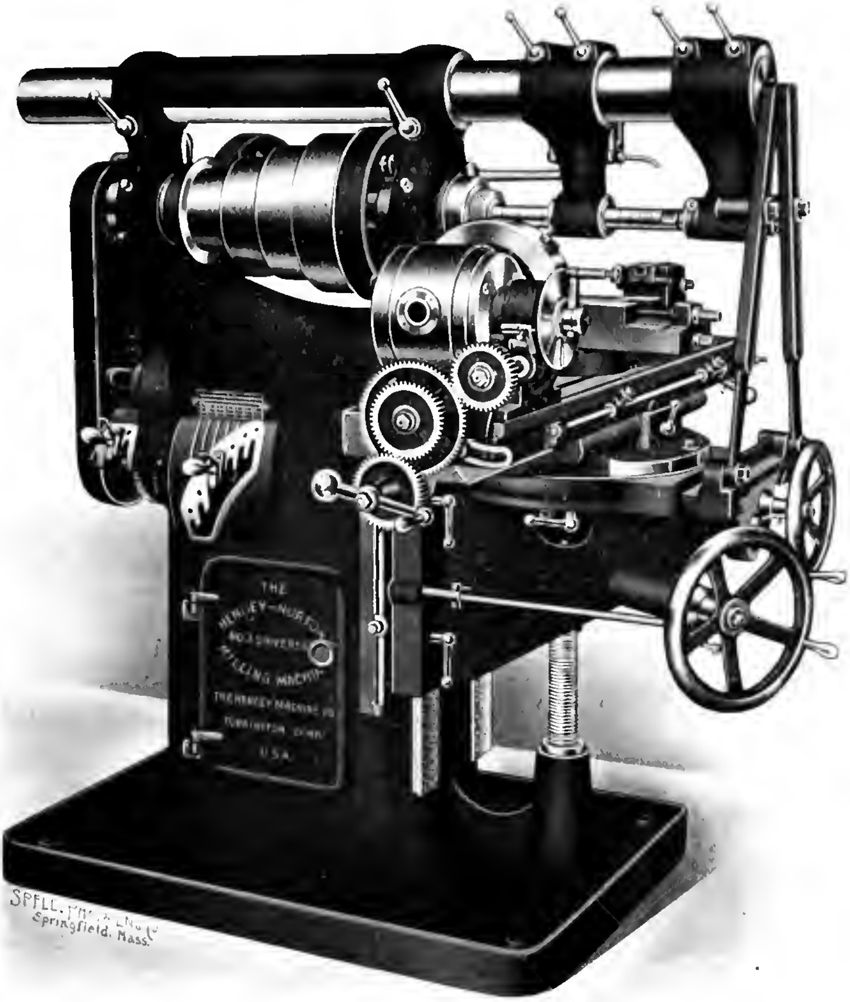
HENDEY No. 3 UNIVERSAL MILLER



Bearings for spindle are annular in form. Journals of spindle are tapered. Efficient lubrication is maintained by ring oilers for both bearings. Front bearing 5½″ long with taper diameter of 3⅝″ to 2⅞″.

Automatic Feeds to table, saddle and knee. 21 changes of feed, driven through heavy roller chain.

Working surface of table 48¾″ x 11″,

Range of feeds 30″ x 10″ x 19″.

Ball bearing thrusts to telescopic knee and table feed screws.

Knee is rigidly reinforced and has projected bearing on column.

Dividing head travels through an arc of 216 degrees. Has tool steel worm which runs in oil. Divisions of head are tested for accuracy on an 8″ diameter plate.

Swivel vise is quick acting with cam binder in base operated from front of vise and can be loosened and rotated without disturbing base binding bolts.

Each machine furnished complete with two speed friction pulley countershaft, wrenches, arbor and draw-in bolt, dividing head and foot stock centers, with raising block, center rest, universal chuck with extra plate, change gears, index plates for head, swivel vise, guard for nose of spindle, bushings in pendant for arbor, and instruction cards.

RESULTS—NOT TALK

THE "AMERICAN" WAY

The 24-inch American Geared Head Lathe, shown below, equipped with Multiple Tool Rest and Crowning Device, is possessed of such ENORMOUS POWER that all steps of the cone pulley, being worked upon, are ROUGHED—FACED—CROWNED—FINISHED, consecutively, at ONE SETTING OF THE TOOL, resulting in the following remarkable reduction of shop cost on the job.

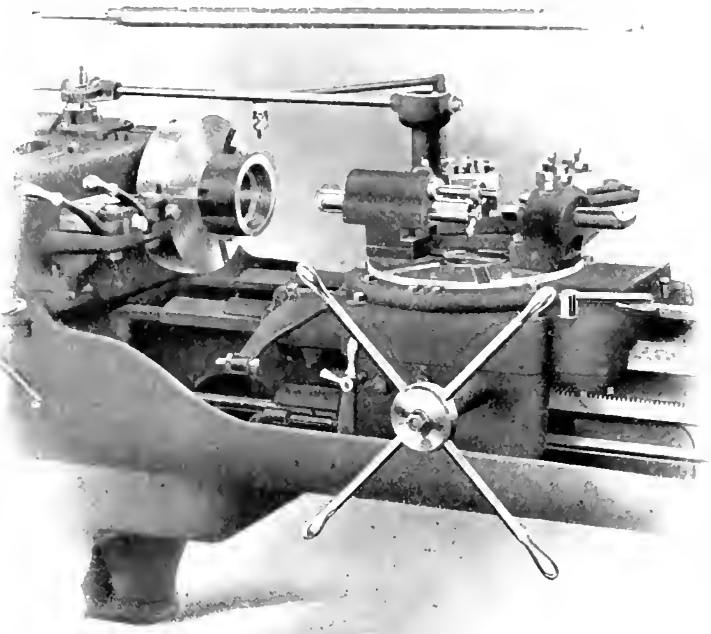
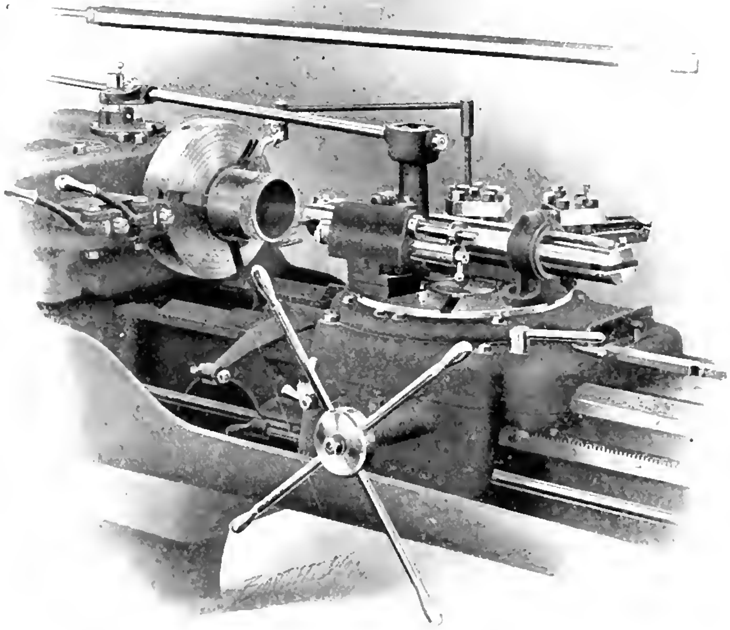
FOUR SPINDLE CYLINDER BORING MACHINE.
Revolving table 3 ft. square, four indexed positions. Cross adjustment of 10 inches by hand. A strong and effective tool.
Primarily intended for Automobile Cylinders, whether cast single or in pairs, and any center distance.

Thread Chasing on the





Our thread chasing device provides a means for producing accurate screw threads on chuck work that excels anything known to the art.

The only plea that can be made for continuance of the old methods must be made to our inborn tendency to stick to old methods, even though they were designed for conditions that have passed away.

The old scheme of chasing a screw thread by moving the entire carriage by a complicated system of gears and a long, or even a short lead screw, belongs to the engine lathe, and was intended to cut all

Springfield, Vermont,
U. S. A.

JONES & LAMSON

Germany, Holland, Belgium, Switzerland, Austria-Hungary, M Koyemann, Charlottenstrasse 112, Dusseldorf, Germany.

FLAT TURRET LATHE

kinds of screws, from long screws to short; whereas the present chucking machines are only required to chase short threads, seldom over four or five inches long.

There is no reason for sticking to the old method which is too slow, and as every one knows, is unreliable in the control of the tool. Every machinist knows that the first and last threads of a screw are "large." That means that they must be turned off after the screw has been chased, and it also proves that the scheme is unreliable in control of the threading tool, which is liable to dodge away from a hard spot in the work; and last but not least, the thread chasing attachment of our machine is the most rapid as well as the most reliable in control of tool.

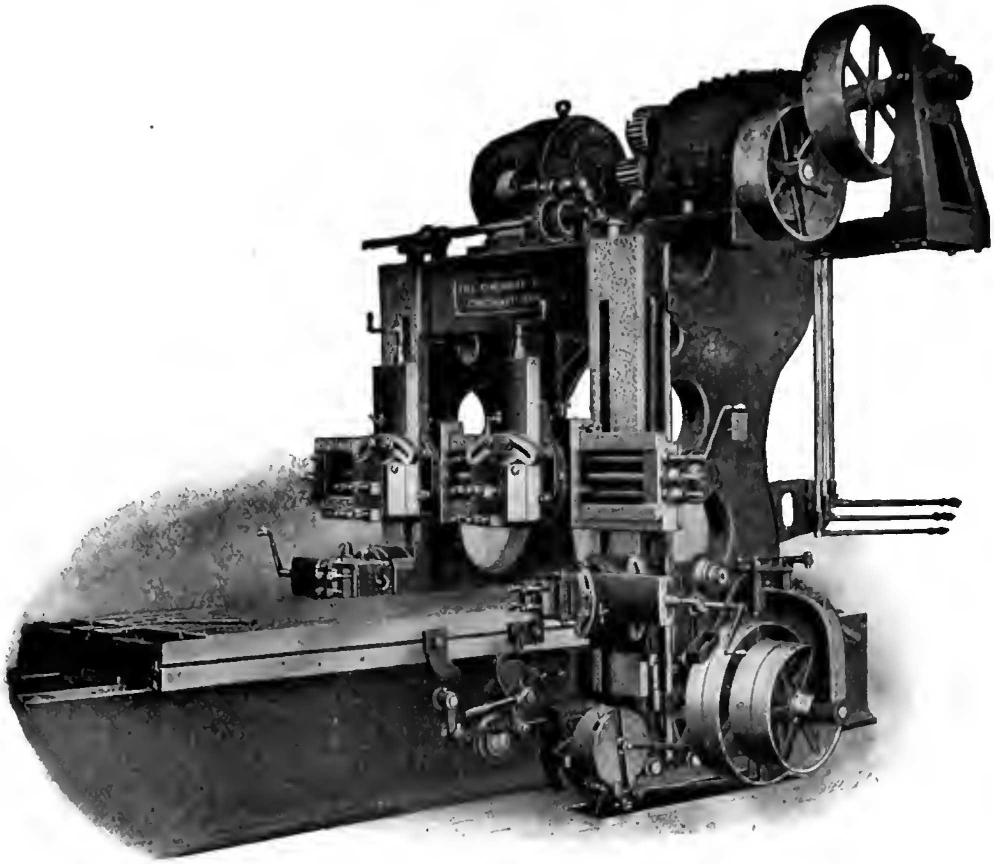
TURRET LATHES

MANY SIZES
AND STYLES



The Simplicity of the

Cincinnati Variable Speed Planer

is only Second to its Increased Efficiency

The variable speed drive consists of a speed box mounted at the top of the housings. It is completely enclosed, holds several gallons of oil, and as all gears and driving hubs are submerged in oil they run noiselessly and with very little wear. The bearings are also automatically lubricated so the speed box requires almost no attention. Speed changes are made by simply moving the levers at the side of machine, indexes being provided to show various speeds—no two speeds can be engaged at the same time.

THE CINCINNATI VARIABLE SPEED PLANER with a range of speeds from 15' to 50' per minute—constant return—permits planing at the exact and proper speed to suit the metal or the character of the work, has strength and rigidity for the heaviest cuts, and assures an every day saving of from 30 to 50 per cent. on operating costs and a very considerable reduction in maintenance expenses.

Write us for full description.

The Cincinnati Crank Planer

A high grade machine combining the advantages of the crank shaper with those of the standard planer. Rigid and massive and capable of very heavy work. Head swivels each side of vertical for angular planing. Stroke adjusted by conveniently placed crank wrench and hand wheel. Feeds operated automatically by power or by hand. Dimensions 20" x 20" x 24".

Ask us for the details.

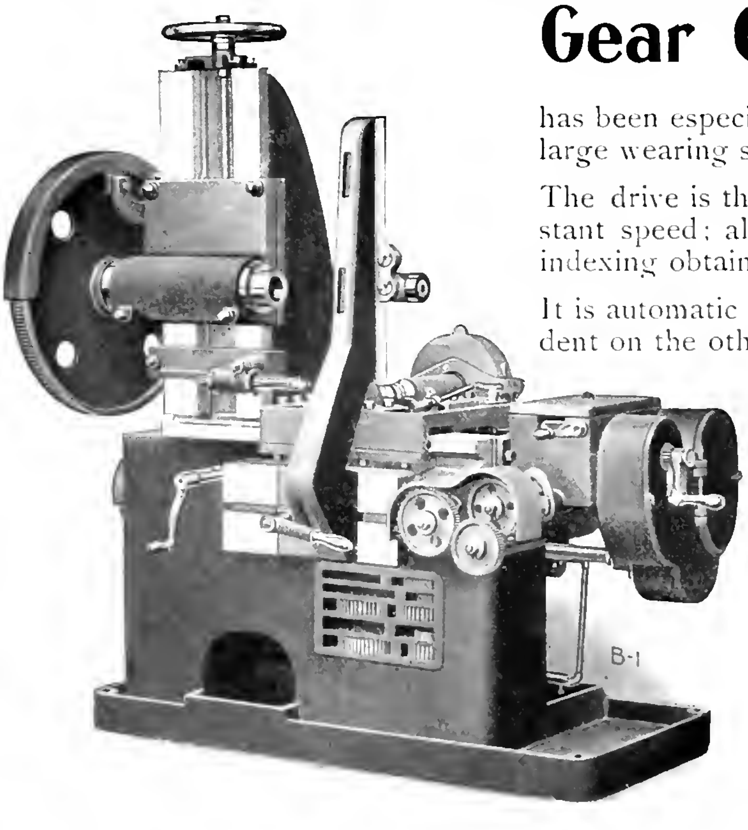
Schuchardt & Schutte, St. Petersburg, Vienna, Budapest, Berlin, Copenhagen, Stockholm. Thos. McPherson & Son, Melbourne.

The Design of the Cincinnati Automatic Gear Cutting Machine



has been especially directed toward securing rigidity, large wearing surfaces and simplicity of parts.

The drive is through a single pulley running at constant speed; all feed and speed changes, as well as indexing obtained through change gears.

It is automatic in all movements, and as each is dependent on the other, each movement must be completed before another can take place.

A rapid, accurate and economical machine for Spur Gears only.

Write us for particulars.

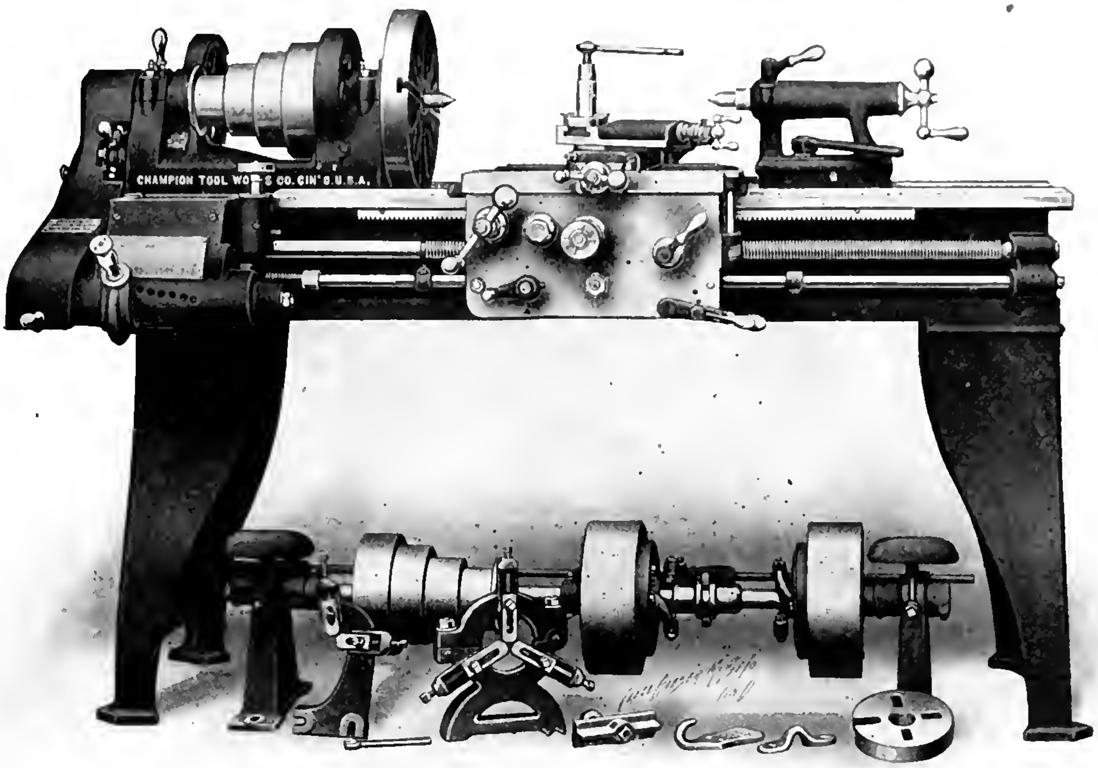
CHAMPION

12-in. Quick Change Gear Engine Lathe



For factory or tool room purposes is not surpassed, and is of that type of rigid construction which admits of the use of high speed cutting steels. The accuracy of the lathe is of the highest character.

IMPORTANT: There are not a few 10-inch lathes manufactured to swing 12 inches, and some 12-inch lathes to swing 14-15 and 16 inches, but do not get our **Standard 12-inch Lathe,** which swings 13⅛ inches, confounded with these tools, as they may be offered you as 11-12-13-14-15 and 16-inch lathes, when in reality they are only standard 10 and 12 inch lathes.

The Automatic Stop to longitudinal feed on the Champion Quick Change Lathes operates in either direction, and the screw and rod feeds cannot be engaged at the same time. The feed reverses from the apron, and with the **chasing dial** on carriage the operator can catch threads instantly without having to return the carriage by reversing the countershaft or stopping the lathe.

40 changes of feed and threads without the removal of a gear, including 11½ and all standard threads from 2 to 56 per inch. Feeds are 3½ times the threads. All changes made while the lathe is running, and every gear is covered.

Remember the **Champion does it quicker and better.**

Write for our printed descriptions.

5 sizes: 10, 12, 14, 16 and 18-inch Swing.

THE BICKFORD IMPROVED RADIAL DRILL

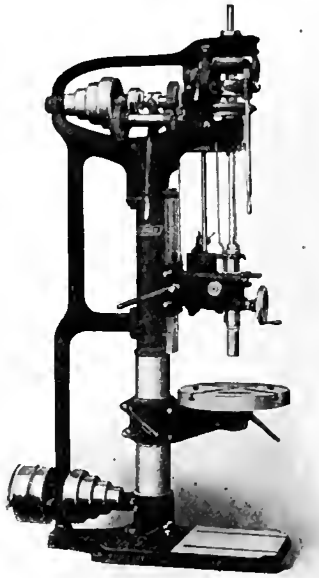
formerly made by

The Bickford Drill and Tool Company

THE CINCINNATI UPRIGHT DRILL

formerly made by

Cincinnati Machine Tool Company



THE CINCINNATI

21" Sliding Head Drill with Patent Geared Tapping Attachment.

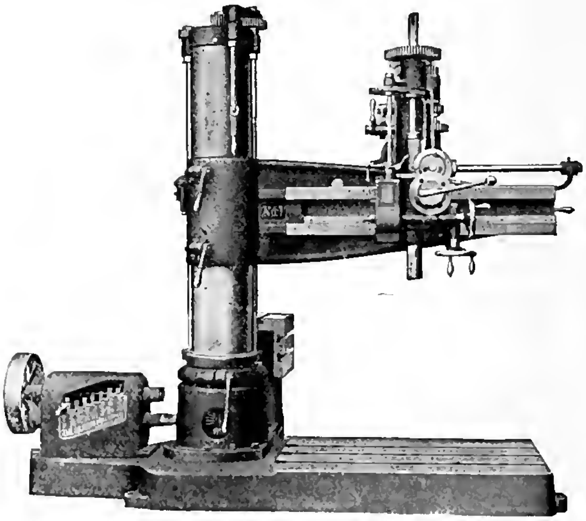
This is the largest and most complete line of UPRIGHT, PLAIN RADIAL, SEMI-RADIAL, HALF and FULL UNIVERSAL RADIAL DRILLS, also MULTIPLE DRILLS, GANG DRILLS and TAPPING MACHINES made in the world.

Bickford Radial Drills are made in six sizes and twenty-four styles, the sizes ranging from 2½' to 6'. These machines are furnished with three styles of drive, cone, gear and motor and with any style of table, such as box, swinging or swiveling.

The design of these machines is simple. They are rigid in construction, easily manipulated, have durability of wearing parts and will produce a volume of output and accuracy of work greater than any other drill on the market.

The Cincinnati line of Upright Drills consists of machines ranging from 20" to 42" and these machines can be furnished in every possible construction used in Upright Drill building. The Patent Geared Tapping Attachment on the Cincinnati Upright Drills is located directly on the spindle and is the most perfect attachment of this kind ever made. It can be completely disengaged when no tapping is to be done.

One feature found on the Cincinnati Upright Drills, and on no others, is an instantaneous stop for the spindle without stopping the machine to make changes of chuck or drills.



The Bickford Improved Radial Drill.

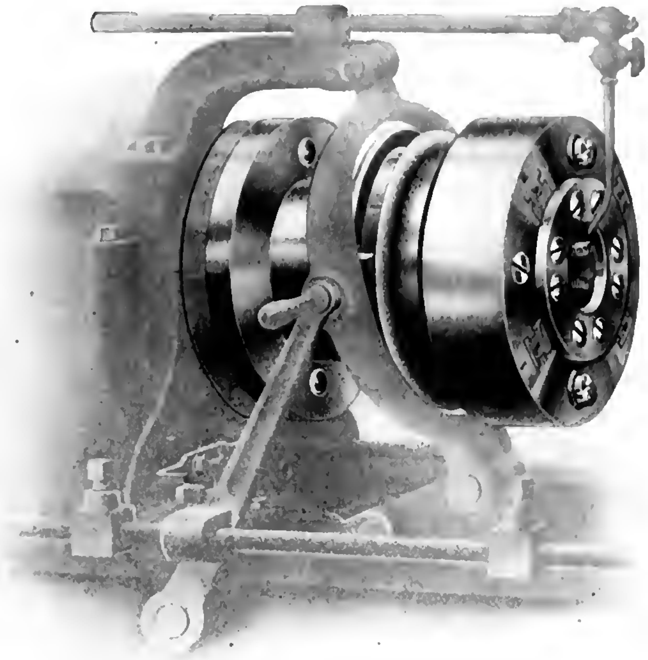
NATIONAL MACHINERY CO
TIFFIN OHIO USA



Tell Us the Ailments of your present Threader!

THE HEAD WITH A "POSITIVE" LOCK.
Used on all National Open Die Bolt Cutters.

Are you bothered with taper end-threads?

Are you compelled to recut off size bolts, and continually "gauge" thread when large lots are cut, and readjust the head to maintain "size"?

And does lost motion in other parts of the machine affect thread accuracy?

In other words, are you securing threads that satisfy your wants and those of your customers on a basis that makes your bolt cutter a paying proposition?

If not, would you be interested in "talking" new bolt cutter or re-equipping your present machine with a new head if it insured 100 per cent. better bolt cutter service than you are now securing?

The National Bolt Cutter

will do that, and give you a larger range in thread cutting besides, and a National Head on your present machine will give you next-best results. **The largest bolt manufacturer in the world is equipping his threaders with the National Head,** and that's one reason why **YOU** should be interested.

If we knew your needs, we could tell you what 'twould cost to secure 100 per cent. bolt cutter efficiency.

THE NATIONAL MACHINERY CO.
TIFFIN, OHIO, U. S. A.

Bulletins No. 10 on Single and No. 20 Multiple Spindle Bolt Cutters will be sent on receipt of your present address.

Sample Key Seats.

Key-seats cut in tool steel milling cutters—fifteen pieces, 3/8 inch thick—job finished in three minutes.

A 2 TO 1 Key-Seater

And by two-to-one we mean that while you are fastening, ready for key-seating, just one piece in your present machine, the

Giant Key-Seater

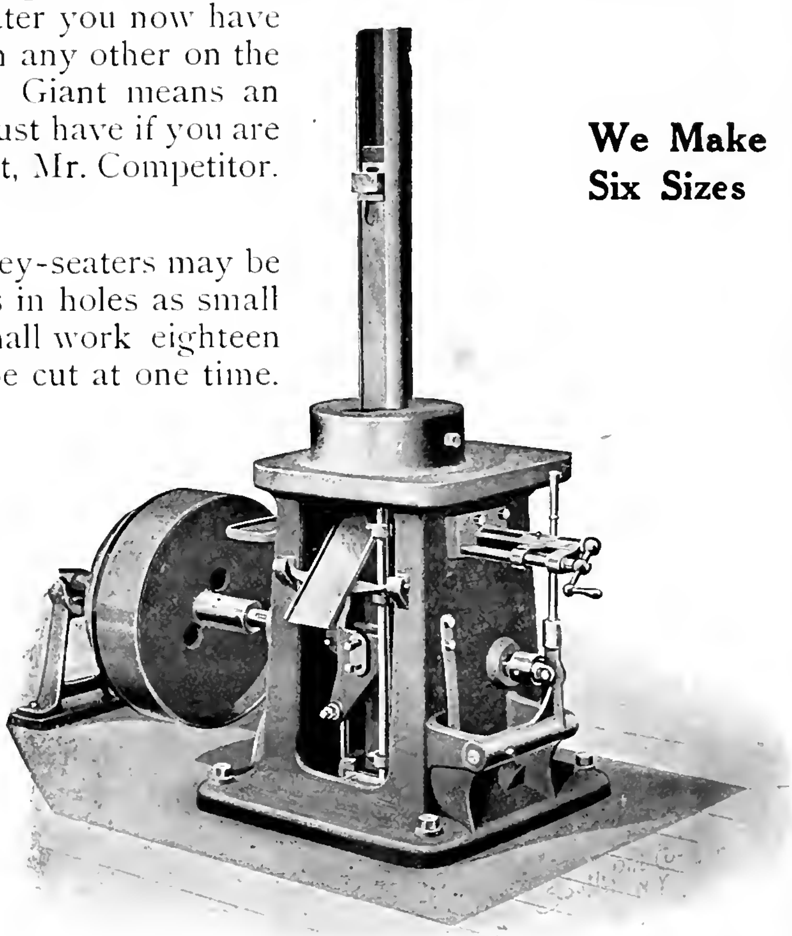
has finished two ordinary key-seats, producing perfectly true, straight key-ways, whether the hole is straight or taper, or the hub faced true, or left rough as it comes from the foundry.

And the "why" is to be found in the grooved post which holds the work and forms a guide for the tool. You won't find this feature on the key-seater you now have—you won't find it on any other on the market. Hence, the Giant means an advantage that you must have if you are going to meet, and beat, Mr. Competitor.

It means profit, too.

On special work our key-seaters may be fitted to cut key-seats in holes as small as ½ inch, and, on small work eighteen or more pieces can be cut at one time.

We Make Six Sizes



We'd like to send you a catalogue showing the money-making features the Giant has for you.

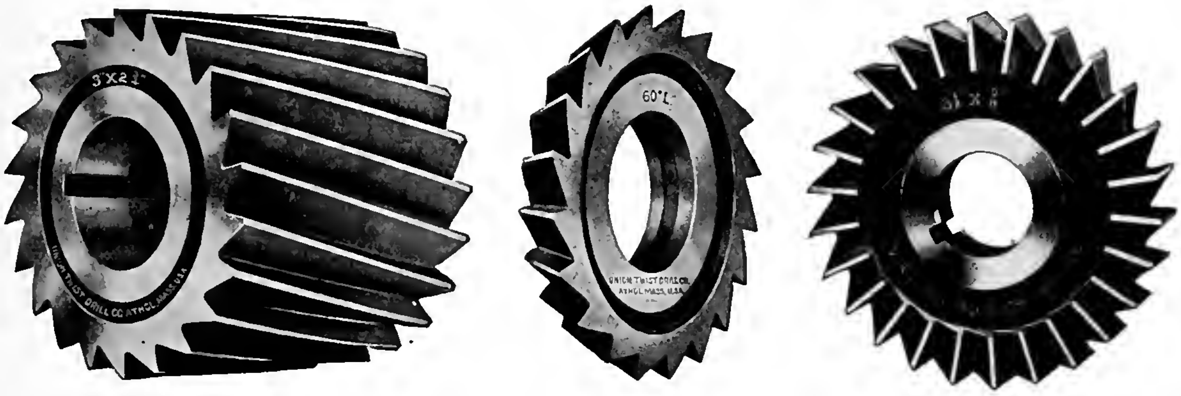
In Making an Investment

in Cutters QUALITY is of the greatest consideration

The most expensive cutters, no matter how low their cost, are those which fail to satisfactorily perform the service required of them.

Their failure may be due to several reasons.

We have a thorough knowledge of the reasons, as our experience in the use of cutters as well as their manufacture is very extensive.



The knowledge that we have gained is used for the benefit of our customers and we are often able to give advice and make suggestions which are helpful to them.

We invite you to take advantage of our experience and have the assurance that such cutters as we will furnish will be properly designed and constructed. They will be of the very highest grade and a source of constant satisfaction.

May we have your inquiries?

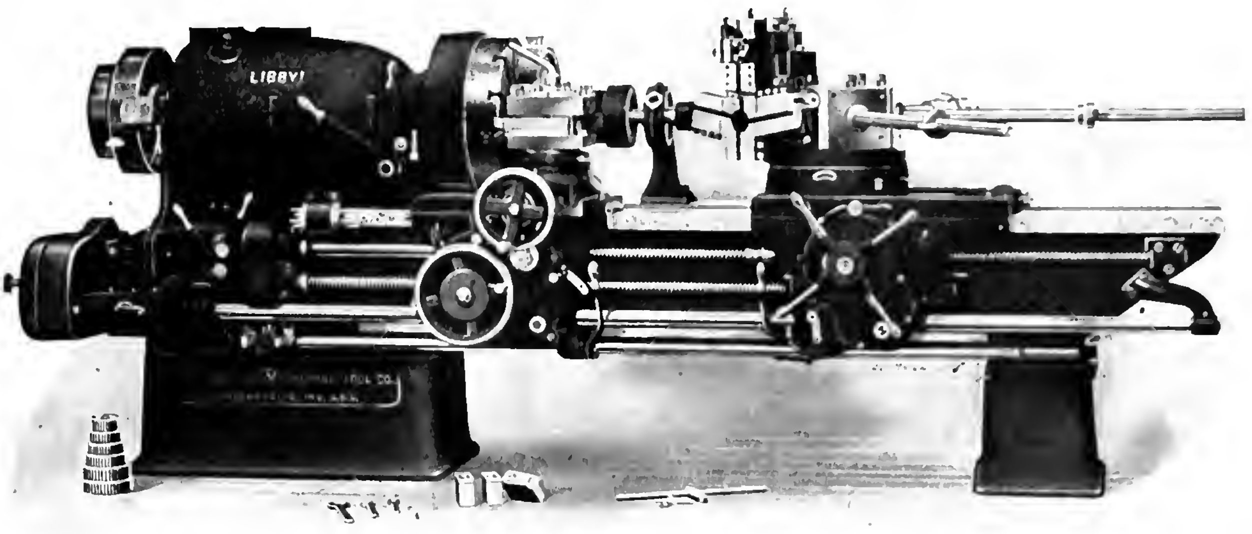
"The Machine Tool Hog"



Put the Heaviest Work and the Hardest up to the Libby Full Swing Side Carriage Turret Lathe

It has the strength and rigidity for heavy cuts and high speed steel; the drive is unusually powerful; there is a wide range of feeds and speeds; every convenience for handling, and with from two to six cutting tools in operation simultaneously there is no need to worry about output.

Other good points are—full swing over carriage, geared head stock, rapid power traverse for both carriages, automatic stop, indicator for position of cutters and the ease with which change from belt to motor drive can be effected. Especially adapted for duplicate work in quantities.

24-inch B. G. Crank Shaper.

At Atlantic City we demonstrated our ability to remove twice the metal on our 24-inch shaper, that any other could, and they were as big as 32-inch.

People who did not know our shaper were surprised at its great simplicity and convenience. It is just as superior in point of accuracy and speeds, and a glance will convince any mechanic of its durability.

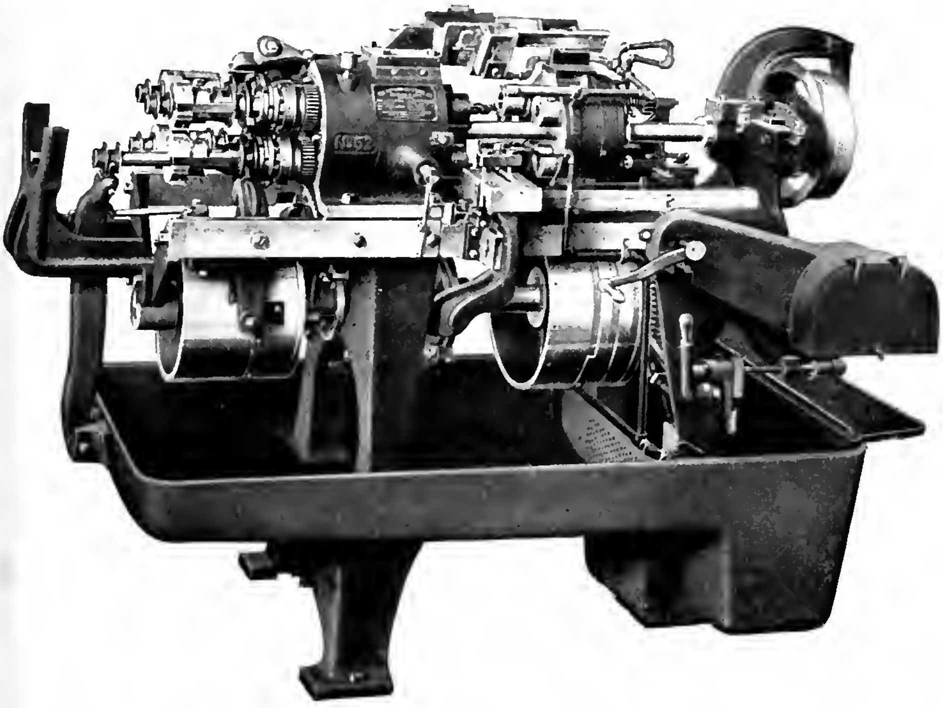
Don't you know it pays to buy the best? Then find out the best by test. Want a "Queen City" to try? It will not cost you one cent of expense, if it is not the best on earth. Yes, 100% ahead of its nearest competitor.

It not only does the actual work faster, but it is easier to set up the job for accurate work, and to get the stroke, feed, speed and positions. Ask about our table support, our feed, etc., and

DON'T BUY A SHAPER IMAGE!

Queen City Machine Tool Co., (Station V.) Cincinnati, O., U. S. A.

AGENCIES IN ALL THE PRINCIPAL CITIES OF THE WORLD



THE Acme's four spindles allow eight or more operations—at once—in the time of one – the longest if performed singly.

¶ The distinctive feature of the "Acme," the stationary Stock Spindle in threading, solves the question of rehandling parts for extra operations. Pieces are in many cases finished as quickly, including the operations of Drilling, Countersinking, Reaming, Milling, Slotting or Slabbing from the side or end, as without them.

¶ Before the recent development in the "ACME," Screw Machines were driven by Multiple Belts, a fruitful source of trouble, expense and delay. Now, one machine, the "ACME," is driven by a single belt—or a constant speed motor—any type—of standard make.

¶ Your Screw Machine operator can make more parts for you on a Single Drive ACME AUTOMATIC. It's built for the operator's convenience.

¶ Breakage of tools is practically impossible. It's fast, safe and economical.

Make a Cut in your Blade Bills with
Simonds Hack Saw Blades

Made from special steel by a special process, the set of teeth scientifically correct for fast, accurate cutting, our blades will successfully stand all tests for hardness, toughness, and cutting power, and will give absolute satisfaction from every point of view

The new handle fits the hand in a comfortable, natural way and is a big improvement on the old-style frame.

We are prepared to furnish blades on yearly contracts for large users.

Landis Bolt Cutters

The most economical tools for their purpose yet offered.

A feature of these machines is the improved Landis Die, fitted with long chasers which can be reground and set forward as required until the metal is entirely used up. No hobbing, retempering or annealing required; lead is positive; clearance correct; same chasers cut right or left hand threads, and the life of the ordinary hobbed die is exceeded twenty times.

More work at less cost. Write for booklet.

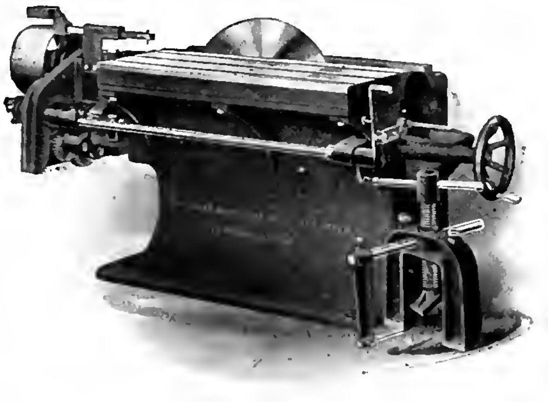
Twenty-inch Cutting-off Saw

WITH POWER SCREW FEED



This new saw is equipped with automatic knockout which can be set at any point, unusually large clamping table, and has a steady drive which eliminates backlash and reduces breakage of blades to a minimum. The rigidity with which the saw is held permits cutting solid steel or tubing with the same blade.

Price $160.00—Circulars on request.

Henley's 20th Century Book of Recipes, Formulas and Processes

Edited by GARDNER D. HISCOX, M. E.

Contains over 10,000 Selected Scientific, Chemical, Technological and Practical Recipes and Processes, including hundreds of so-called Trade Secrets for every business

Price $3.00 cloth binding. $4.00 half morocco binding.

This is the book everyone should have at his command who seeks practical, accurate knowledge and guidance in his every-day work, as no book has ever been published which so fully meets the multifarious requirements of the factory, the workshop, the laboratory, and the household.

The entire work is a veritable mine of practical information and up-to-date in every respect. A work which will prove of value to the Artisan, Mechanic, Engineer and all engaged in any way in any of the arts. From the contents we append only a few of the subjects treated, lack of space preventing the publishers from giving more.

COMPRESSED AIR IN ALL ITS APPLICATIONS.

By G. D. Hiscox. Fifth edition just issued. This is the most complete book on the subject that has ever been issued, and its thirty-five chapters include about every phase of the subject one can think of. It may be called an encyclopedia of compressed air. It is written by an expert, who, in its pages has dealt with the subject in a comprehensive manner, no phase of it being omitted. 545 illustrations, 650 pages. Price..**$5.00**

MACHINE SHOP ARITHMETIC.

By Colvin. Most popular book for shop men published. Shows how all shop problems are worked out and "why." Includes change gears for cutting any threads; drills, taps, shrink and force fits; metric system of measurements and threads. Price ....**50c.**

PRACTICAL PATTERN MAKING.

By F. W. Barrows. A book which teaches you just what you should know about pattern making. It contains a detailed description of the materials used by pattern makers, also the tools, both those for hand use, and the more interesting machine tools; having complete chapters on the Band Saw, the Buzz Saw and the Lathe. Individual patterns of many different kinds are fully illustrated and described, and the mounting of metal patterns on plates for molding machines is included. Price **$2.00**

DIES, THEIR CONSTRUCTION AND USE.

By J. V. Woodworth. A new work of 400 pages and 500 illustrations for all who wish to know about the latest practice in the working of sheet metals. It shows how dies are designed, made and used, and every one engaged in this line of work should secure a copy. It is right up to date. Price................**$3.00**

AMERICAN TOOL-MAKING AND INTERCHANGEABLE MANUFACTURING.

By J. V. Woodworth. A practical treatise of 544 pages on American Tool-Making and System of Interchangeable Manufacturing, describing and illustrating all of the different types and classes of small Tools, Fixtures, Devices and Special Appliances which are in general use in all machine manufacturing and metal-working establishments where economy, capacity and interchangeability in the production of machined metal parts are imperative. Price..............**$4.00**

MACHINE SHOP ARITHMETIC.

By Fred H. Colvin, Associate Editor *"American Machinist."* This is an arithmetic of the things you have to do with daily. It tells you plainly about: how to find areas of figures—how to find surface or volume of balls or spheres—handy ways for calculating—about compound gearing—cutting screw threads on any lathe—drilling for taps—speeds of drills, taps, emery wheels, grindstones, milling cutters, etc.—all about the Metric system with conversion tables—properties of metals—strength of bolts and nuts—decimal equivalent of an inch. All sorts of machine shop figuring and a 1001 other things, any one of which ought to be worth more than the price of this book to you, and it saves you the trouble of bothering the boss. 131 pages. Bound in cloth. 5th edition. Price........**50c.**

GAS, GASOLINE AND OIL ENGINES.

By Gardner D. Hiscox. Every user of a gas engine needs this book. Simple, instructive and right up-to-date. The only complete American work on this important subject. Tells all about the running and management of Gas Engines. 16th edition. Price **$2.50**

FREE **New Practical Book Catalogue sent FREE on request. All latest books included. Send us your name and address and receive it by return mail.**

☞ *Any of the above books sent prepaid on receipt of price.*

Our New Tool Book is Ready

THE 1909 Catalogue of B. & S. Machinists' Tools, Drop Forgings, etc. marks the rounding out of forty years of honest endeavor to make the best tools, in the best way and from the best materials.

The Billings & Spencer reputation has the solid basis of forty years of successful manufacturing. Our methods are the latest improved standards, our facilities unexcelled. We use the steel particularly adapted for the work in hand, employ the highest grade workmen—our trade mark on a tool is a guarantee of excellence.

Get your name in early for an early copy.

Front view of a Gridley Automatic Turret Lathe operated by two direct current Type CR General Electric Motors.

What Wages do you Pay your Machinery?

In paying your men you try to estimate their wages according to their producing power. You are careful to see that they do not idle away their time—that they are productive every minute of the working day.

Are you as careful to see that your machinery is working up to its highest efficiency?

Are "high salaried" machine tools wasting time because the power that moves them is not adequate?

Are your "low salaried" shafting, belts and pulleys wasting the power that should give impulse to the machinery?

In a word, are your machines giving you the returns you are paying for?

If driven by G. E. Motors they are.

Thousands of manufacturers who have thrown out other systems of motive power and replaced them with G. E. motors, will testify to the high earning power of these motors.

General Electric Motors have found extensive use in driving a great variety of Lathes, Drills, Grinders, Punches, Shears, Boring Mills, as well as many smaller tools.

There is no operation too small, no task too heavy or complicated to be satisfactorily and economically performed by a General Electric Motor.

The General Electric Company has a motor for every service, a controller for every motor, and engineers to combine them properly for any work.

Some of the Advantages of General Electric Motors for Machine Tools.

Economy of Power. In any belt-driven shop the line shafting, belts, pulleys, counter and jack shafts absorb from thirty to sixty per cent. of the total energy supplied by the prime mover. Where tools are driven by G. E. individual motors, practically none of the power is diverted from its useful purpose and the work done is almost exactly equivalent to the power used. Gangs of shafts, pulleys and belts are not adding an extra burden when the machinery is running, nor are they putting in time when the machinery is idle. If a rush job requires the use of only one or two machines, it can be put through without excessive factory costs.

Increased Production. In many cases the output of a factory has been *doubled* by the adoption of G. E. Electric Motors, *without the addition of a single tool,* through the use of individual and group drive as specific cases required. This increase in production is due to the advantages of speed control, ease of handling work and better arrangement of machines.

Ease of Control. Machines requiring it can be equipped with G. E. motors having a speed variation, making it possible to secure the highest efficiency and maintain constant cutting speeds for any and all classes of work. The Controller used on these motors is small and can be placed where most convenient to the operator.

Convenience of Handling. Where overhead cranes and trolley hoists are desired, G. E. individual motors make space available that in a belt-driven shop would be occupied by shafts and pulleys. Even where hoists are not required, the elimination of belts, shafting and pulleys contributes to cleanliness, light, safety and convenience in moving work.

Better Arrangement. With G. E. Electric Motors several tools used for a sequence of operations may be placed in the most advantageous positions for forwarding the work, which is not possible when the line shafting is the determining factor of location. This independence also permits the addition of motor-driven machines in belt-driven shops where little space is apparently available.

Ever ready Quality. G. E. Electric Motors are always ready. They will work where it is hot or cold, where cleanliness is essential or where dust and inflammable material fill the air.

Decreased Cost. G. E. Electric Motors eliminate the cost of expensive belt renewals, oiling and care of shafting and hangers, and the close attention which belt transmission makes necessary.

This No. 1 Portable Shaft Keyseater

is indispensable to the repair shop. It will mill keyseats in the middle or on the ends of shafting from 1¼" to 5" in diameter without removing from the hangers. It can be slipped over heavy shafting or spindles when desired; can be operated in the most awkward places, and will mill a keyseat 12' long without resetting.

Other advantages are its rapid operation, accuracy of work produced and the fact that it cuts without jar or chatter of any kind.

We shall be glad to send full details on request.

To Inspect and Measure a Punch-press Casting.

NOTE.—The object of this inspection is to ascertain if the casting is sound, and if it will probably finish up to the dimensions given on the drawing.

1. Examine the casting inside and outside for evidences of shrinkage cracks, blow holes and "spongy spots." With a hammer "sound" all suspicious spots for internal blow holes and shrinkage cavities.

2. With a square resting on the die-block base *A*, and the blade upward against the guides *B*, determine by measurement if the latter are central, and the proper distance apart, to finish to the required dimensions. With the square on top of the guides *B*, determine whether the bosses *C* are central, and the proper distance apart, allowing, as before, for finishing. Measure the distance between the outside of each boss to see whether the difference between this and the finish dimension is enough to allow for finishing.

3. Note if the cored holes at *C*, *D*, and the half hole at *E* are small enough to allow for finishing.

4. Fit pieces of brass across the holes in the bosses *C*, *D*, and the bearing *E*; and lay off centers on them.

5. Note if the vertical distances *a*, *b*, *c* and *d* are proper; that is, see if dimensions *b* and *d* equal the finish dimensions plus two finishes; *c* the finish dimension minus two finishes, and *a* the finish dimension minus one finish.

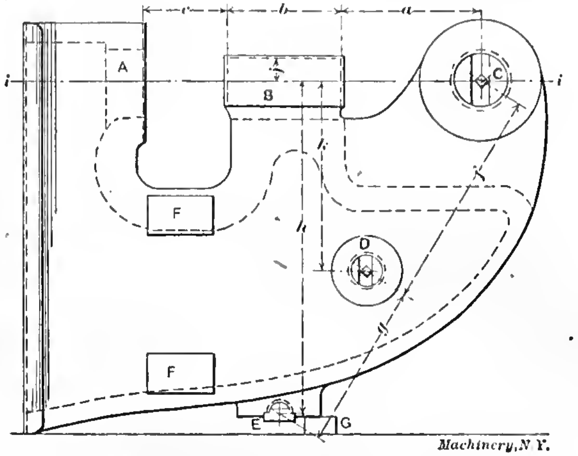
6. Note if a vertical line which is central with the guides *B* is also central with the bosses *C*.

7. Measure the center distances *f* and *g*, to see if they are correct; also the dimensions *k* and *h*, which should equal the finish dimension plus one finish.

NOTE.—When a single casting, of the kind shown, is to be machined, the preliminary inspection to determine the correctness of the casting is advisable, but when this is ascertained, if there were a number of similar castings to be finished, such detailed inspection would not be necessary.

SHOP OPERATION SHEET NO. 107.

Oscar E. Perrigo. MACHINERY, August, 1909.



Machinery, N.Y.

To Lay Out the Side of a Punch-press Casting for Machining.

1. Plane the bottom of the casting, setting it so that the base flange will be of uniform thickness. The amount of metal removed should be just enough to true the base. Care should be taken to see that the base will finish approximately at right angles with the center line *v—v* shown in Operation Sheet No. 108.

2. Chalk all surfaces on the rough casting where scriber lines are to be drawn.

NOTE.—The amount of stock to be taken off in roughing and finishing should be as nearly equal on all surfaces as possible.

3. Place the casting on a surface plate or planer table, in the position shown in the illustration. Set the finished base square with the surface plate supporting the casting by blocks, as at *G*.

4. With a surface gage test the centers *C* of the large bosses, on each side of the work; the casting should be adjusted until these centers are the same distance from the surface plate. Then with the pointer of the gage set to coincide with *C*, scribe center lines *i—i*; also scribe the center line *p—p*. (See Shop Operation Sheet No. 108.)

5. Scribe lines above the center line equal to dimension *j*. Lower the gage pointer a distance *k*, and scribe center lines for bearings *D*. Set the pointer to dimension *h* and scribe center lines for bearings *E*.

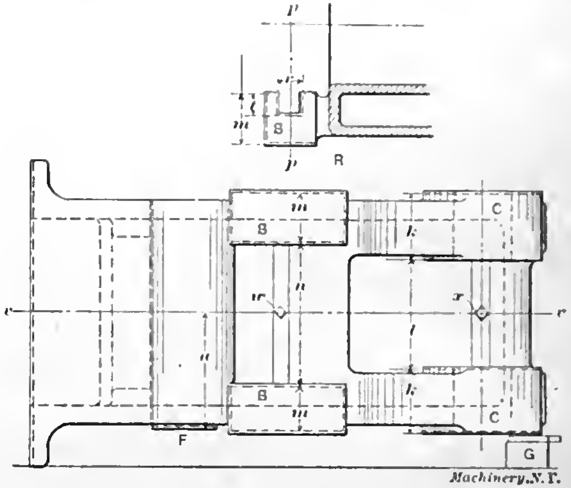
6. Set a pair of beam trammels to dimension *f* and, with point *C* as a center, locate centers of bearings *D*. Set the trammels to dimension *g* and locate centers of bearings *E*.

7. Place the casting in an upright position on its finished base. Set the pointer of the surface gage a distance *a* below center *C*, and scribe the finish lines for the tops of guides *B*. Lower the pointer distances *b* and *c*, successively, and scribe the remaining lines.

8. With a pair of dividers scribe circles equal to the size of the bearings *C*, *D* and *E*, on each side of the casting.

SHOP OPERATION SHEET NO. 108.

Oscar E. Perrigo. MACHINERY, August, 1909



Machinery, N.Y.

To Lay Out the Front of a Punch-press Casting for Machining.

1. Place the casting on the surface plate in the position shown in the illustration. Fit a wooden centering piece between the guides *B* and locate a point *w* central with the outside surfaces of the guides. Fit a second centering piece between the bosses *C*. Insert blocking and a wedge at *G*, and by means of the wedge, adjust the work until the finished base is perfectly square with the surface plate.

2. With a square ascertain if the center line *p—p*, which was previously scribed across the tops of the guides *B*, is at right angles with the surface plate. If it is necessary to adjust the casting, this may be done by inserting a thin steel wedge beneath the base flange.

3. Lay off on the front of the guides finish-lines to the required dimensions *n* and *m*, *m* working from the central point *w*. Transfer these lines to the top surfaces of the guides as illustrated at *R*, where a plain view of one of the guides is shown; this should be done with a surface gage.

4. The lines indicated by dimensions *t* and *r* are next laid out, the latter being parallel with the center line *p—p* and central with it.

5. The center *w* is now transferred to the center piece between bosses *C*, and lines to the dimensions *l* and *k*, *k*, laid off on the bosses central with the center *x*.

6. Lay off the dimension *u* for planing the pads *F*.

NOTE.—Upon first going over these lines it may frequently be found that at some point there is not stock enough to "clean up." Then the lines, involving several dimensions perhaps, must be changed to equalize the amount to finish off. It would be well before planing the base of this particular casting to locate the centers *w* and *x* and a line *i—i* (see preceding sheet), and then set the work so that the finished base would be at right angles with the center lines *v—v* and *i—i*.

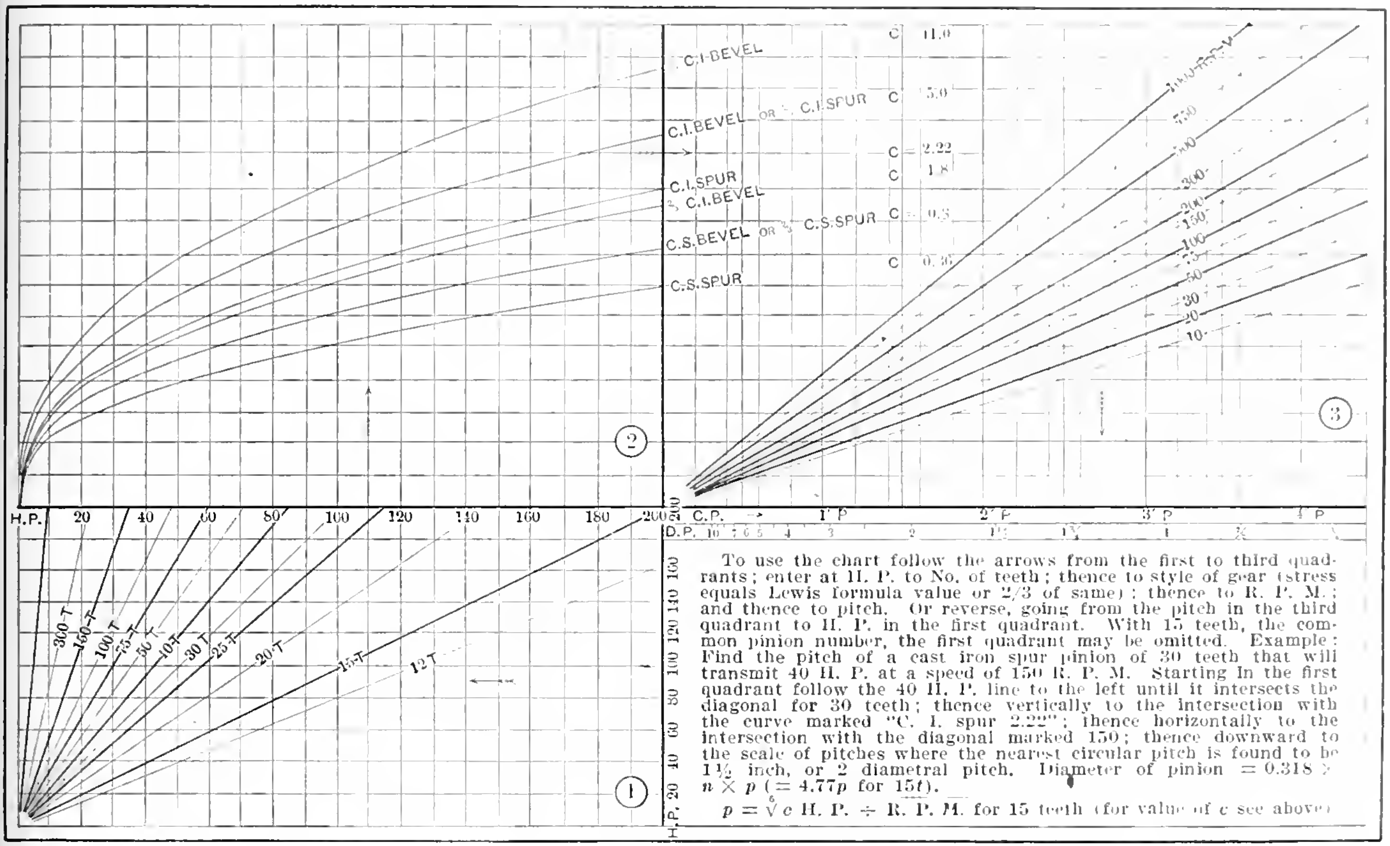
SIMPLIFIED GEAR FORMULAS*

HORSE-POWER, PITCH, DIAMETER, WEIGHT AND PRICE

C. R. WHITTIER†

It is generally conceded that the Lewis formula for the strength of gear teeth, with its accompanying tables, is the most accurate in form, as the maximum strength of each tooth is determined from its shape. It may be safely used for determining the strength of gears made by modern methods, but its tabulated form makes it difficult to use from the standpoint of the designers. It is well adapted to determine the strength of any given gear or pinion. But the reverse process—that of finding a gear suitable to meet the condition of a given horse-power and revolutions per minute is not so simple; the trial-and-error method being a lengthy one at the best. The following deductions give close and rapid approximations for preliminary work.



To use the chart follow the arrows from the first to third quadrants; enter at H. P. to No. of teeth; thence to style of gear (stress equals Lewis formula value or 2/3 of same); thence to R. P. M.; and thence to pitch. Or reverse, going from the pitch in the third quadrant to H. P. in the first quadrant. With 15 teeth, the common pinion number, the first quadrant may be omitted. Example: Find the pitch of a cast iron spur pinion of 30 teeth that will transmit 40 H. P. at a speed of 150 R. P. M. Starting in the first quadrant follow the 40 H. P. line to the left until it intersects the diagonal for 30 teeth; thence vertically to the intersection with the curve marked "C. I. spur 2.22"; thence horizontally to the intersection with the diagonal marked 150; thence downward to the scale of pitches where the nearest circular pitch is found to be 1½ inch, or 2 diametral pitch. Diameter of pinion $= 0.318 \times n \times p$ ($= 4.77p$ for $15t$).

$p = \sqrt[6]{c \text{ H. P.} \div \text{R. P. M.}}$ for 15 teeth (for value of c see above)

Machinery, N.Y.

Three Quadrant Gear Chart for Solution of Spur and Bevel Gear Problems, based on Lewis Formula M = s p f y; for 15-degree Involute and Cycloidal Teeth

As both the gear and its pinion are usually made of the same material, either cast iron or cast steel, the strength of the pair is determined by the strength of its weakest member, which is the pinion when made of the same metal as the gear. For economical reasons the pinion is usually limited to about 15 teeth, so we may take that number as a convenient base. Circular pitch is used in the calculations, but the circular pitch can finally be transformed to diametral pitch if this is desired.

In a train of gears, the maximum reduction on any pair is usually taken at 4 or 5 to 1, so the number of reductions and ratios may be quickly deduced. Then the problem is usually presented as follows:

Given the H. P. and R. P. M. to find the Working Stress, Pitch, Face and Diameter

Given the horsepower and revolutions per minute of the pinion, what will be the allowable working stress, pitch, face, factor of strength and diameter?

The majority of trade gear lists give the horsepower of gears at 100 r. p. m. with an allowable stress for cast iron of 3,000 pounds per square inch. But it is more difficult to transform this horsepower to suit the other conditions, than to proceed independently.

The values of s, the safe working stress, which Mr. Lewis adopted tentatively, as they gave satisfactory results in practice, were as follows:

Let v = speed of teeth in feet per minute and s = safe working stress, then

For v =	100 (or less)	200	300	600	900	1,200	1,800	2,400
For cast iron:								
s =	8,000	6,000	4,800	4,000	3,000	2,400	2,000	1,700
For cast steel:								
s =	20,000	15,000	12,000	10,000	7,500	6,000	5,000	4,300

When these values are plotted, it will be seen that the curves, though slightly irregular, closely approximate curves of the hyperbolic form. The equations of the curves which most nearly agree with the Lewis values, are found to be the following:

$$\text{For cast iron, } s = \frac{88{,}000}{\sqrt{v}}.$$

$$\text{For cast steel, } s = \frac{220{,}000}{\sqrt{v}}.$$

---

* For additional information on this subject, see "The Variation of the Strength of Gear Teeth With the Velocity," January, 1908, and articles there referred to, and Data Sheet supplement, January, 1908.

† Address: 204 West 111th St., New York.

These formulas give the following comparative values:

When v =	100	200	300	600	900	1,200	1,800	2,100
For cast iron								
s =	8,800	6,250	5,000	3,600	2,930	2,540	2,080	1,790
For cast steel,								
s =	22,000	15,625	12,500	9,000	7,325	6,350	5,200	4,475

The agreement with the Lewis assumed values is remarkably close. The new values will probably come much nearer the true ones, as they are in much better line. They are also much more dependable, as the stress suitable for any speed can be easily found from the formula to the fraction of a pound if desired, on a true curve; whereas, the use of the tabular values results in the substitution of values which descend by variable steps of from 2,000 to 300 pounds at a jump, or if ordinary interpolation is used the result is still inaccurate, as the interpolation necessarily follows a straight line between the two nearest values, and is thus too high. The new curve values also come nearer to the comparative Harkness values as given by Kent.

The face of gears, f, is another variable quantity; but in the manufacturer's standard lists of to-day the face is usually about 3 times the pitch, and this may be adopted as close enough for preliminary work. It will be found that the majority of stock gears have either 15-degree involute or cycloidal teeth, so these styles will be used in these calculations. The factor of strength, y, in the Lewis tables for a 15-tooth pinion of these types is 0.075. We have, therefore, the following data for a 15-tooth cast iron spur pinion:

Let s = safe working stress, in pounds;
p = circular pitch, in inches;
f = face, in inches;
y = factor of strength;
v = speed of pitch line, in feet per minute.

The Lewis general formula reduces to

$$\text{H. P.} = \frac{spfyv}{33{,}000}.$$

From our average determination above, we have:

$$s = \frac{88{,}000}{\sqrt{v}},$$

$$f = 3\,p.$$

$$y = 0.075.$$

Substituting these values in the general formula and reducing, we have for a 15-tooth cast iron spur pinion:

$$\text{H. P.} = 0.6\,p^2\sqrt{v} \quad \dots\dots (1)$$

By a similar process, we find for a 15-tooth cast steel spur pinion:

$$\text{H. P.} = 1.5\,p^2\sqrt{v} \quad \dots\dots (2)$$

For a bevel pinion, let
d = small diameter of bevel.
D = large diameter of bevel.

$$\text{Then H. P.} = \frac{spfyv}{33{,}000} \times \frac{d}{D}.$$

As $\frac{d}{D}$ usually equals $\frac{2}{3}$, we can say:

$$\text{H. P.} = \frac{spfyv}{33{,}000} \times \frac{2}{3}.$$

and for a 15-tooth cast iron bevel pinion,

$$\text{H. P.} = 0.4\,p^2\sqrt{v} \quad \dots\dots (3)$$

For a 15-tooth cast steel bevel pinion,

$$\text{H. P.} = p^2\sqrt{v} \quad \dots\dots (4)$$

We now wish to find v in terms of revolutions per minute. For a 15-tooth pinion, approximately:

$$v = \frac{15 \times \text{r.p.m.} \times p}{12} = 1.25\ \text{r.p.m.} \times p.$$

Substituting this value in (1) we have:

$$\text{H. P.} = 0.6\,p^2\sqrt{1.25\ \text{r.p.m.} \times p}.$$

$$\text{Squaring,}\quad \text{H. P.}^2 = 0.36\,p^4\,(1.25\ \text{r.p.m.} \times p).$$

Reducing, and solving for p, we have for cast iron spur pinion:

$$p = \sqrt[5]{\frac{2.22\ \text{H. P.}^2}{\text{r.p.m.}}} \quad \dots\dots (5)$$

A similar substitution and reduction in formulas Nos. (2) (3) and (4) gives the following:

$$\text{For c. s. spur, } p = \sqrt[5]{\frac{0.36\ \text{H. P.}^2}{\text{r.p.m.}}} \quad \dots\dots (6)$$

$$\text{For c. i. bevel, } p = \sqrt[5]{\frac{5.0\ \text{H. P.}^2}{\text{r.p.m.}}} \quad \dots\dots (7)$$

$$\text{For c. s. bevel, } p = \sqrt{\frac{0.8\ \text{H. P.}^4}{\text{r.p.m.}}} \quad \dots\dots (8)$$

For rapidly varying loads, or where there is much starting and stopping, it is well to reduce the safe stress to two-thirds that allowed by the above formulas. We then have:

$$\text{For c. i. spur, H. P.} = 0.4\,p^2\sqrt{v};\ p = \sqrt[5]{\frac{5\ \text{H. P.}^2}{\text{r.p.m.}}} \quad (9)$$

$$\text{For c. s. spur, H. P.} = p^2\sqrt{v};\ p = \sqrt[5]{\frac{0.8\ \text{H. P.}^2}{\text{r.p.m.}}} \quad \dots\dots (10)$$

$$\text{For c. i. bevel, H. P.} = 0.27\,p^2\sqrt{v};\ p = \sqrt[5]{\frac{11.0\ \text{H. P.}^2}{\text{r.p.m.}}} \quad (11)$$

$$\text{For c. s. bevel, H. P.} = 0.67\,p^2\sqrt{v};\ p = \sqrt[5]{\frac{1.8\ \text{H. P.}^2}{\text{r.p.m.}}} \quad (12)$$

The fifth root can be easily determined by logarithms on the slide rule, or from the usual tables, but the values for the common cases are given in the following:

Corrections for Tooth Numbers

It now remains to determine the correction for different numbers of teeth.

As the teeth of pinions generally range from 12 to 30, we need not go outside these limits. Let n = number of teeth. Plotting the Lewis values for y for this case, and determining the nearest curve, we find that the straight line formula:

$y = \frac{2n + 45}{1{,}000}$ expresses this curve very closely, as will be seen by the following comparative table:

No. of Teeth, n	y by Formula	y from Lewis's Tables	No. of Teeth, n	y by Formula	y from Lewis's Tables
12	0.069	0.067	19	0.083	0.087
13	0.071	0.070	20	0.085	0.090
14	0.073	0.072	21	0.087	0.092
15	0.075	0.075	23	0.091	0.094
16	0.077	0.077	25	0.095	0.097
17	0.079	0.080	27	0.099	0.100
18	0.081	0.083	30	0.105	0.102

Therefore, for other teeth, we can multiply the horsepower given in the above formulas by $\frac{2n + 45}{75}$, or more briefly, by $0.027\,n + 0.6$.

Correction for Increased Velocity

We must also correct for the increased velocity of this larger pinion, *i. e.*, multiply the result by $\sqrt{\frac{n}{15}}$ or $0.26\sqrt{n}$.

The continued product of these last two multipliers might be used, but this does not simplify the calculation. These corrections need seldom be applied for preliminary work.

To Find the Pinion Diameter

Lastly, to find the diameter of the pinion, approximately:

$$\text{diameter} = \frac{n \times p}{\pi}, \text{ or}$$

$$\text{diameter} = 0.318\,n\,p,$$

or for a 15-tooth pinion,

$$\text{diameter} = 4.77\,p \quad \dots\dots (13)$$

If diametral pitch is desired, it is sufficiently close to say:

$$\text{diametral pitch} = \frac{3}{p} \quad \dots\dots (14)$$

The following formulas, therefore, Nos. (5) to (14) (as deduced above), give closely enough for all preliminary determinations, the size of pinion required of 15 teeth.

$$\begin{array}{rcc} & \text{Stress = Lewis' Tables} & \text{Stress = Lewis Tables} \\ \text{c. i. spur, } p = & \sqrt[5]{\dfrac{2.22\text{ H. P.}^2}{\text{r.p.m.}}} & \sqrt[5]{\dfrac{5.0\text{ H. P.}^2}{\text{r.p.m.}}} \\ \text{c. s. spur, } p = & \sqrt[5]{\dfrac{0.36\text{ H. P.}^2}{\text{r.p.m.}}} & \sqrt[5]{\dfrac{0.8\text{ H. P.}^2}{\text{r.p.m.}}} \\ \text{c. i. bevel, } p = & \sqrt[5]{\dfrac{5.0\text{ H. P.}^2}{\text{r.p.m.}}} & \sqrt[5]{\dfrac{11.0\text{ H. P.}^2}{\text{r.p.m.}}} \\ \text{c. s. bevel, } p = & \sqrt[5]{\dfrac{0.8\text{ H. P.}^2}{\text{r.p.m.}}} & \sqrt[5]{\dfrac{1.8\text{ H. P.}^2}{\text{r.p.m.}}} \end{array}$$

$$\text{diameter} = 4.77\, p.$$

$$\text{diametral pitch} = \frac{3}{p}.$$

Practically, stock gears are made up to 3 inches circular pitch by ¼-inch steps, and a pitch of less than 1 inch is seldom used.

The following table will therefore determine the roots for the nearest common pitch.

No. or Root	Fifth Power	No. or Root	Fifth Power	No. or Root	Fifth Power
¾	0.24	2	32	3½	525
1	1	2¼	58	4	1,024
1¼	3	2½	98	4½	1,845
1½	8	2¾	158	5	3,125
1¾	16	3	243	5½	5,033
				6	7,776

In case the revolutions per minute of the pinion are less than 80, which is exceptionally slow, care must be taken in applying the formula, or the allowable stress may be exceeded. With a 15-tooth pinion:

80 r.p.m. = 100 feet per minute for 1-inch p.
40 r.p.m. = 100 feet per minute for 2-inch p.
27 r.p.m. = 100 feet per minute for 3-inch p.
20 r.p.m. = 100 feet per minute for 4-inch p.

Chart for Rapid Solution of Gear Problems

I have prepared a simple three quadrant chart for the rapid solution of these problems by mere inspection, good for any number of teeth, and for all the different styles, materials, and stresses of gears given by the above formulas, but for occasional preliminary determination, the formulas are sufficient, as their solution is simple. For working drawings, if the proportions vary from those assumed above, the dimensions should be checked by the more extended data in Kent's handbook, or by the use of a special chart.

It will, of course, be understood that the teeth considered in these formulas are those of the usual standard dimensions, in which the height of tooth equals seven-tenths of the pitch. What are known as "short tooth gears," in which the height of tooth equals half the pitch, are undoubtedly stronger, but their smaller working face is supposed to cause more rapid wear, and their use is not common. Although machine-molded cast gears run quietly at low speeds, they should not be used for rim speeds much over 1,000 feet per minute. For speeds of from 1,000 to 3,000 feet per minute cut gears should be substituted.

For a quick approximation of the diameter of the pinion shaft in inches:

$$\text{Shaft diameter} = p + 1.$$

The weight of pinions and gears varies with different makers. Pinions of from 12 to 30 teeth are usually made slightly wider than gears, even if they are not shrouded; and the smaller sizes have solid webs in place of arms. It is found that a formula of the form

$$\text{Weight in pounds} = \text{coefficient} \times p^2 f n,$$

will usually fit the weights.

For many tables, the coefficients of the following values will serve:

$$\text{Weight of pinion} = 0.35\, p^2 n f,$$
$$\text{Weight of gear} = 0.45\, p^2 n f,$$

or where $f = 3p$,

$$\text{Weight of pinion} = p^3 n,$$
$$\text{Weight of gear} = 1.35\, p^3 n,$$

or when diameter and p are known, as $n = \dfrac{\pi d}{p}$,

$$\text{Weight of pinion} = 3.1\, d\, p^4$$
$$\text{Weight of gear} = 4.2\, d\, p^4.$$

The price of gears varies largely with different manufacturers. The price of cast tooth spur gears can be usually expressed by a formula of the following form.

$$\text{Price} = (\text{coeff.} \times p\, n) + (\text{coeff.} \times p)$$

Cut tooth gears usually cost about 20 per cent more than cast tooth; and cast steel gears from 50 to 75 per cent more than cast iron gears of the same size.

* * *

TOOL-MAKERS' FILES—HOW TO ORDER

Almost every tool-maker knows from experience that an order calling for an assortment of files which merely states the length, shape and cut will rarely bring him the files he wants, unless he specifies the brand or maker's name. There are differences in makes of files which often make it impossible to use the files secured on the order, although they may be nominally what are called for. The following information regarding tool-makers' files received from the American Swiss File & Tool Co., 24 John St., New York, therefore will doubtless be appreciated by many tool-makers and others who have been troubled by inability to get exactly the files they desire.

The most marked difference in files has heretofore been found between those of domestic manufacture and imported Swiss files, appropriately called by their makers, "files of precision." But as these files of precision are now successfully produced in the United States, the terms "domestic" and "imported" have largely lost their significance as designating two distinct classes of files.

The ordinary domestic files range in length from 3 to 25 inches, and are made in five cuts, which are designated as "rough," "bastard," "second-cut," "smooth," and "super-smooth," while tool-makers' files are made in sizes from 2 to 12 inches in length and in eleven cuts, the cuts not being named but numbered. The first five numbers correspond approximately in fineness (the number of teeth to the inch) to the domestic files as follows: No. 000 same as "rough"; No. 00 same as "bastard"; No. 0 same as "second-cut"; No. 1 same as "smooth"; No. 2 same as "super-smooth." All tool-makers' file cuts above No. 2 to No. 8 have no equivalent in ordinary files.

The exact number of teeth per inch varies in both classes of files and with the different makes of the same class, but not sufficiently to make the difference noticeable until the file is used. To avoid mistakes in ordering files of precision, the order should invariably specify tool-makers' files.

* * *

In a short article in *Technik und Wirtschaft* for May, 1909, Mr. H. Noelke of Tokio, Japan, reviews the Japanese machine trade during 1908. The value of the imports of machines and tools, in round figures, from the leading industrial countries were as follows: From Great Britain, $10,500,000; from the United States, $4,600,000; from Germany, $2,250,000. Locomotives were imported from Great Britain valued at $500,000, and from the United States valued at $1,200,000. The value of the total imports of various classes of machine tools were as follows: Planers, $180,000; shapers, $18,000; slotters, $33,000; milling machines, $250,000; lathes, $475,000; automatic screw machines, $135,000; drill presses and boring mills, $425,000. The total value of the imports of machine tools amounted to about the same as the imports in 1907.

* * *

Nickel-chrome rails are, at the present time, attracting the attention of a number of the railroad companies, and the Bethlehem Steel Co. has furnished several lots of these rails to the Lehigh Valley, the Lackawanna, and other companies. While definite information concerning the experience with these rails has not been made public, it is understood that they apparently give at least three times the service of the ordinary Bessemer rail now sold at $28 a ton. As the nickel-chrome rail is sold at $51 per ton, a distinct saving is apparent wherever the traffic is heavy. The nickel and chrome produce a rail of great toughness and coarse grain, and the high carbon content which it is possible to use in connection with these two elements make the rail very hard.

LOCOMOTIVE REPAIR SHOP PRACTICE—1

THE C. M. & ST. P. R.R. SHOPS AT MILWAUKEE*

ETHAN VIALL†

It is always interesting to note the various ways in which the same class of material is handled in different shops. For instance, one shop may do a majority of the work on lathes, while another a few blocks or a few miles away, will machine exactly the same parts in less time on drill-presses, or perhaps the first shop may mill everything while the second uses planers or shapers for the same operations. Of course this difference is sometimes a case of necessity rather than choice, as a shop is often originally planned and equipped for an entirely different class of work than that for which it is finally used, but even where shops have been fitted up expressly for certain similar lines of work, the divergence in method or tool is often very marked. Railroad shops, as a rule, are of a class that must make the best of existing conditions, new shop equipment not being easily available, for in many cases the shops are the first and longest to suffer from hard times or the economical methods of a saving regime. It is possible that this is the reason that practice in railroad shops varies as widely as it does. However, a few of the railroad companies are managed by men broad enough to see that the mechanical department is not the only place in which to try to effect a saving, and that it must have suitable machines and tools with which to turn out work quickly and in a first-class manner; consequently liberal allowances are often made for machine tool equipment.

Generally speaking, the work handled in a railroad shop is of a heavy nature, and the more practical way is to use this weight to help hold the work in position while it is being machined rather than to carry the weight suspended by heavy jigs or fixtures. It is this idea that has apparently been kept in mind in equipping the Chicago, Milwaukee & St. Paul Railroad shops at Milwaukee, Wis., and by so doing many operations have been simplified and expensive jigs

---

* For additional information concerning the arrangement and equipment of these shops see the articles: The Shops of the Chicago, Milwaukee & St. Paul Railway, which appeared in the January, February and March, 1904, numbers of RAILWAY MACHINERY.

† Associate Editor of MACHINERY.

or fixtures dispensed with or replaced by very simple ones. In these shops a large part of the work which other shops do on lathes is done on boring mills, where the pieces can rest solidly on the horizontal face-plates instead of being suspended by jigs or straps, and in consequence the time taken to place a piece in position is reduced to a minimum. Slotters are also favorites for many jobs usually done in other shops on shapers or planers, and slotters of all makes, shapes and sizes are in evidence all through the plant.

The superintendent of motive power at the Milwaukee shops is Mr. A. E. Manchester; the master mechanic Mr. C. F. Winn, and the machine foreman in the locomotive department Mr. E. Moran, and it is to these three men that I am especially indebted for the information contained in this article. I am also under obligation to F. C. Kneller, floor foreman, C. L. Fuller, assistant to Mr. Moran, and a number of others who will be named in connection with their several departments

Handling and Machining Frames

The principal repair work of the system is done in these shops. The locomotive frames handled vary from light to the extremely heavy ones, and Fig. 1 shows one of the largest side frames being made ready for welding in the blacksmith shop, which is in charge of A. Bennett. The method by which these frames are handled, is more clearly shown in the picture of the small one, Fig. 2. In this engraving, the way the hoist chain is applied, and the channel-rimmed wheel which is clamped around the middle of the frame, which facilitates turning the latter, and the handles clamped on the end, are clearly shown. A round weight is also shown fastened inside of the frame to balance it properly and make the handling as easy as possible. By using this apparatus the heaviest locomotive frame is handled and placed in any position as easily as if it only weighed one or two hundred pounds.

Leaving the blacksmith shop for the present, we will take up some of the operations through which the new frames pass. Fig. 3 shows a three-head Bement slotter at work on a pair of frames for one of the large types of locomotives. This slotter will machine two of the heaviest or four of the light frames at once. The slotter heads with their respective feeding mechanisms are entirely separate from each other and require an operator for each one.

Fig. 4 shows a 74-inch by 38-foot Niles-Bement-Pond planer planing the sides of two heavy frames, while Fig. 5 shows an Ingersoll miller cutting an offset of ½ inch × 38½ inches on the front end of an extra heavy frame in order to get the front deck properly in place on the engine.

Fig. 6 is a five-spindle Bement frame drill at work on a frame.

Removing and Boring Tires

The method of heating locomotive tires for removal or replacing, is about the same as that used in other large shops except that two heaters are used at once, as shown by Fig. 7, gas and compressed air being used for fuel. Tires are held on a boring mill while being bored out, in practically the same way as they are at the Northwestern shop, as was shown in the May issue, except that the centering jaws used here are specially made and the clamping hooks are tightened by nuts, as in Fig. 8, instead of by taper pins. Either way is quick, however, and effectually prevents springing or slipping of the tire under a heavy cut.

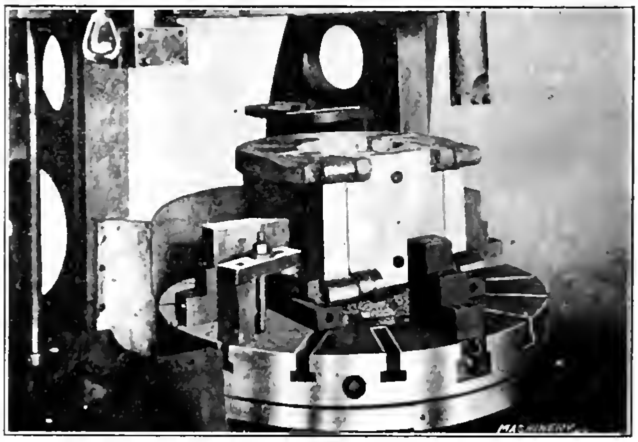

Fig. 19. Boring the Driving-box Brasses

Machining Cylinders

In Fig. 9 is shown a Pond machine planing the back walls of two cylinders at one time, and Fig. 11 shows a machine for boring out and facing off both ends of a cylinder at once, while in Fig. 10 is shown a machine which will bore out both cylinders of a compound at once, though the illustration shows a job where only one boring-bar is being used. Both the inside and outside of cylinder bushings are turned at once on a boring mill, as shown in Fig. 12. This is unusual, as most shops do this on lathes in two separate operations, or, if it is done on a boring mill, only one tool is used at a time in many shops.

Fig. 20. Cutter Heads used for Blocking out Holes in Solid Connecting-rod Ends

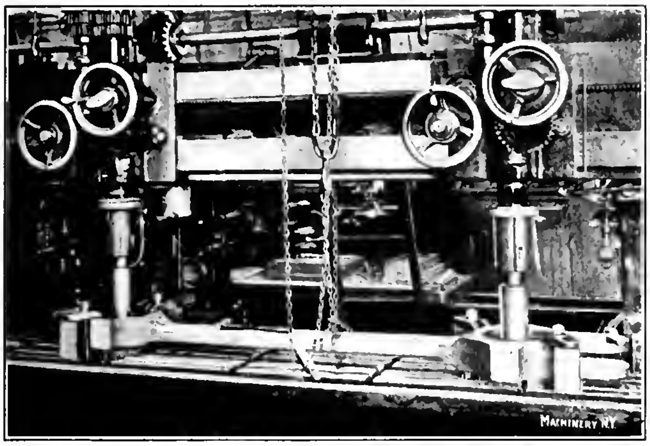

Fig. 21. Finishing the Holes in a Connecting-rod in a Two-spindle Drill Press

Working out Valve Bushing Ports

In order to machine out the cored port-openings in valve-bushings, a rotary attachment has been fitted to a shaper, as shown in Fig. 13. The valve bushing is held between two flanged disks, one of which is fastened to the spindle of the worm gear which runs in a bearing bracket bolted to the shaper column, while the other disk is clamped to the work by a bolt running through the middle. The outer end of this bolt is steadied by a center and bracket. The cutting is done by an extension tool held in the clapper block shown lying on top of the bushing. This clapper block is simply a plain block with a hole in it for the tool in place of the usual tool-post, and the tool is clamped in place by the long set-screw shown. The feeding mechanism of the rotary attachment, is too plainly shown to need explanation and this, together with the traveling shaper head, gives whatever motion is needed and by using suitably shaped tools the openings are cleaned out in good time without leaving the fillet which is the result of ordinary methods.

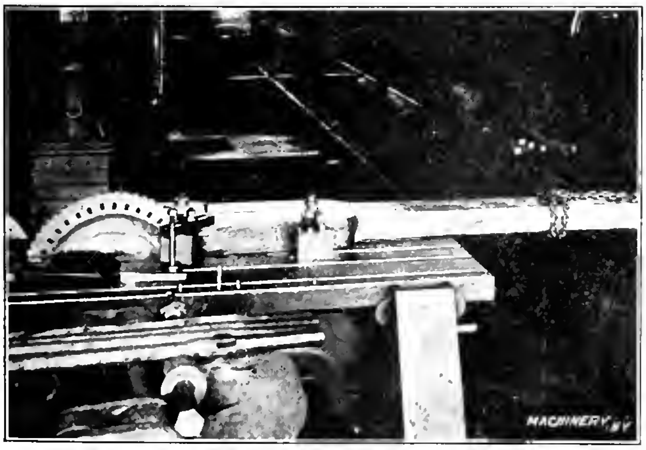

Fig. 22. Sawing out the Metal in the End of a Main-rod with a Higley Cold Saw

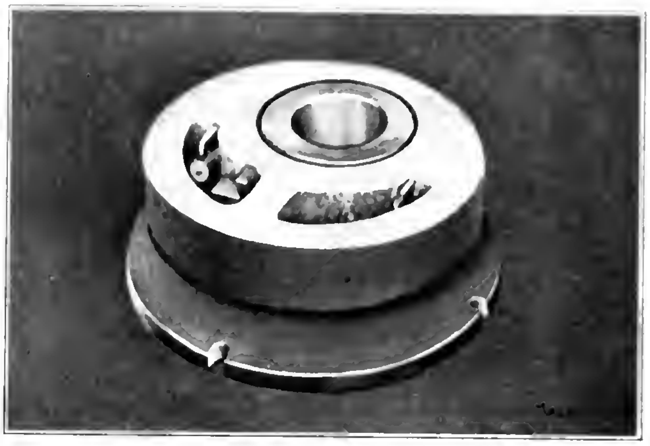

Fig. 23. Fixture for Holding Eccentrics on the Boring Mill while turning the Outside

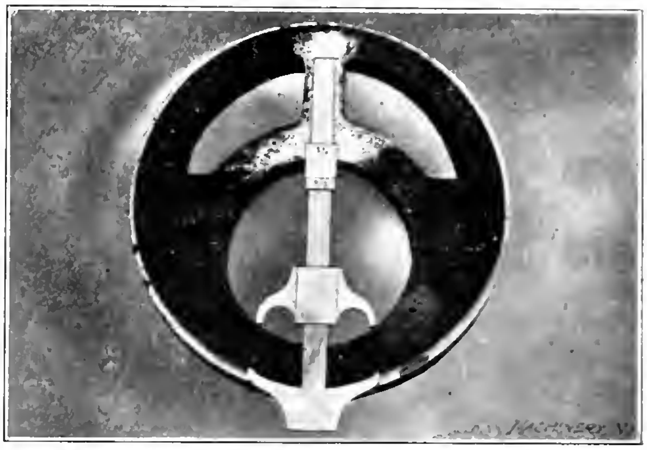

Fig. 24. Tool for Laying Out Eccentric Keyways

Turning, Boring and Cutting Packing Rings

Packing rings are bored and turned in a boring mill in the same way as cylinder bushings. They are then cut off with a gang tool, the cutters of which are so set that the top ring is cut off a little ahead of the one below it, as shown in Fig. 14. The method used to hold the packing ring casting to the table is rather unusual. Four "legs" are cast on the bottom of the casting and special jaws or "sockets," into which these legs fit, are used on the face-plate. These sockets are held by

Fig. 25. Rounding the Ends of an Eccentric-rod Jaw on a Vertical Miller

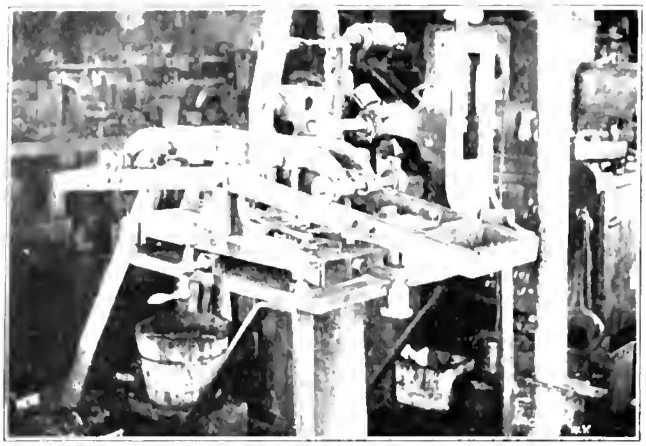

Fig. 26. Grinding Link-blocks on the Machine shown in Fig. 30

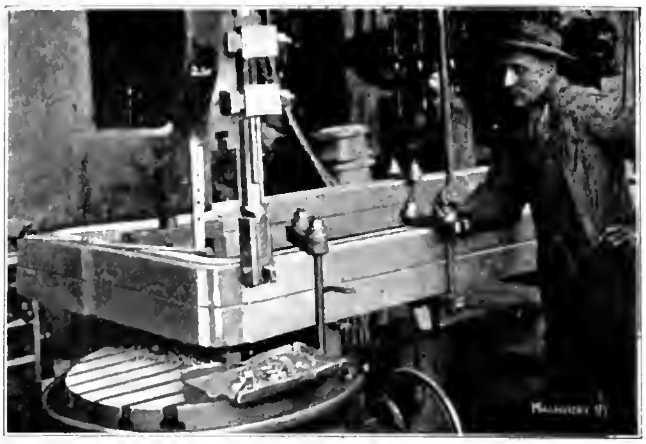

Fig. 27. Slotting Mud-rings

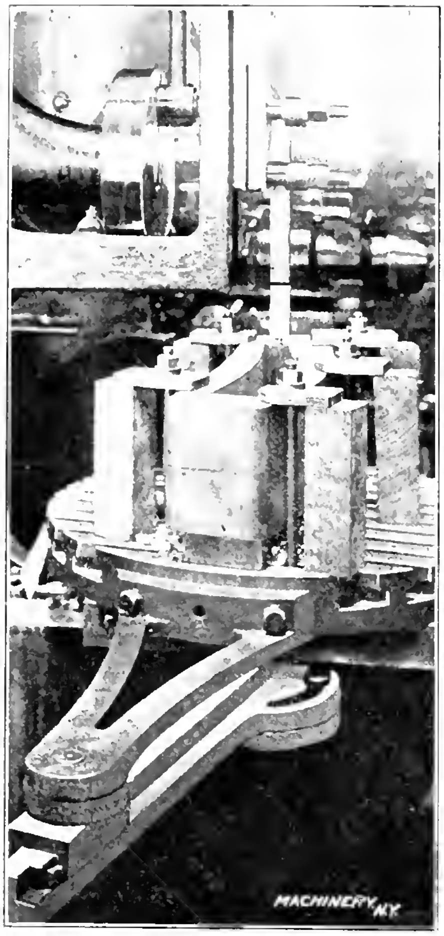

Fig. 28. Slotting Links by the use of an Attachment which gives the desired Radius

set-screws from the side and centered by set-screws from the inside. The plan of using legs on the casting, has many advantages over the usual flange or flaring lugs, as it is utterly impossible for the casting to twist, and only a minute or so is needed to center and clamp it solidly in place, with no tendency to spring it out of round. After being cut off, the rings are milled for a lap joint, and then finished two at a time, in the jig shown in Fig. 15.

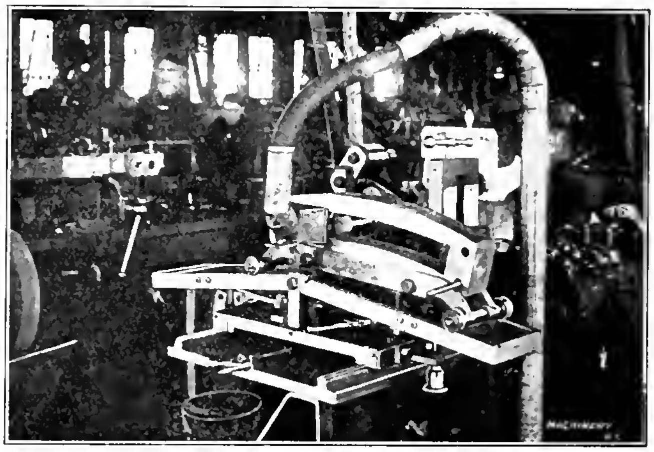

Fig. 30. Grinding the Links on a Special Grinder

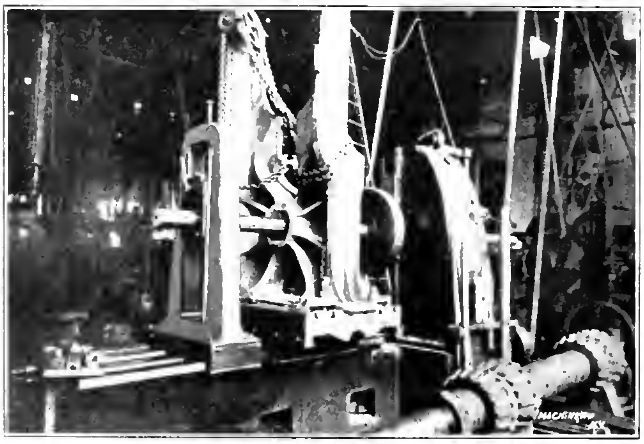

Fig. 31. Boring the King-pin Hole in the Front Deck Casting

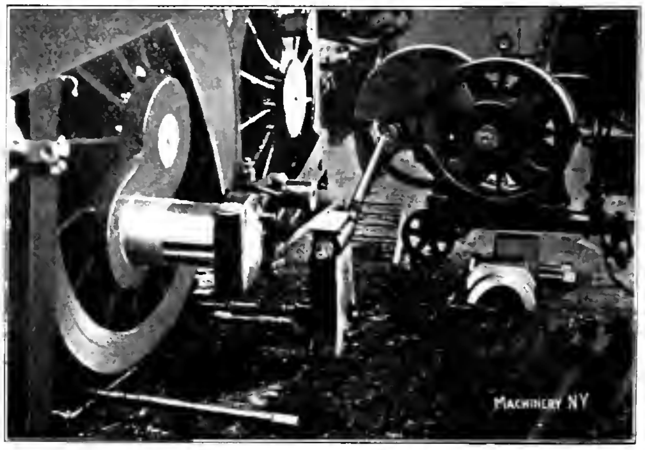

Fig. 32. Valve-setting Machine, which is driven by an Electric Motor

Driving Boxes

Driving-boxes are machined out inside for the brasses one at a time, on a slotter using a single cutting tool and a rotary table feed as shown in Fig. 17, and the brasses are held in a fixture on a boring mill (Fig. 18) while the outside is turned. The straight edges are then surfaced off, the brass forced into the box and the inside bored out, the end turned and the inside edge rounded, as shown in Fig. 19.

In order to reach the sides of the driving-box between the

flanges, extension chuck jaws have been made that fit over the top of the regular jaws of the boring mill.

Fig. 16 shows the fixture used to hold the truck cellars while machining the sides in a shaper.

Boring Side-rods

Side-rods have a hole drilled in each end, where the center of the bearing is to be, for the pilots of the cutter-heads shown in Fig. 20. The bulk of the metal is cut out in round blocks, and the holes finished with single-cutter boring tools in a two-spindle drill press as in Fig. 21. Driving rods have a row of holes drilled across the end of the intended fork, and the metal is then roughed out in two cuts on a Higley cold saw as in Fig. 22.

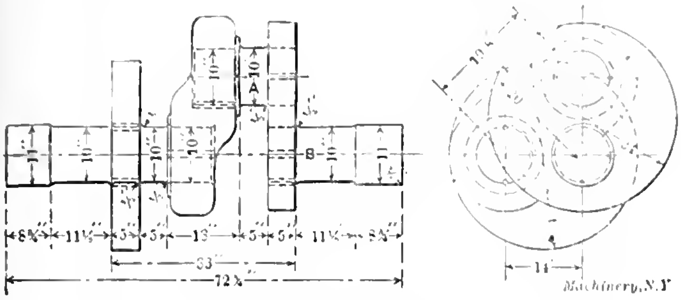

Fig. 33. Crank-axle, the Pins of which are turned by the Tool shown in Fig. 34

Eccentrics and Eccentric Rods

A fixture for holding eccentrics on a boring mill while turning the outside is shown in Fig. 23, and in Fig. 24 is a tool made expressly for laying out the keyways in eccentrics. This tool is made for laying off either 1⅛ or 1¼ inch keyways by simply reversing the small slide on the bar. A shoulder on the under side of the slide, allows it to be placed just right for the depth of the keyway wanted. By using this tool the keyways are laid off absolutely straight and directly in line with the thickest part of the eccentric. The ends of eccentric-rod jaws are rounded on a Bement-Miles vertical mill with rotary table feed, as shown in Fig. 25.

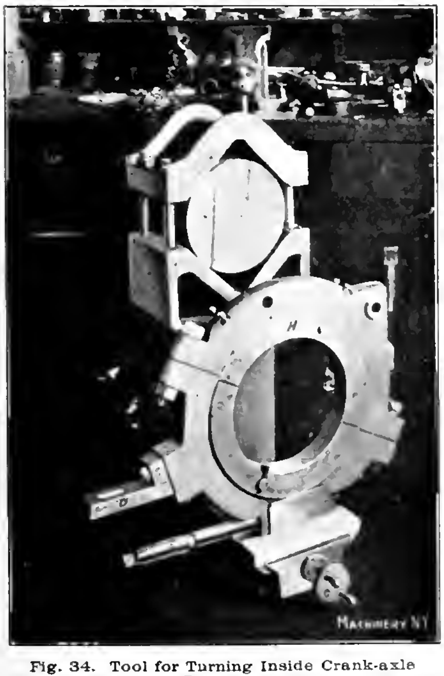

Fig. 34. Tool for Turning Inside Crank-axle Bearings

Fig. 35. Machine in which the Crosshead Pins are turned

Fig. 36. View showing the Mechanism of the Crosshead Pin Turning Machine

Machining Link Slots

Some of the most interesting operations of the shop are those through which the links are put while the arc-like slot is being machined, as the machines and attachments are unusual. The slot in the link is roughed out to the proper radius on a Sellers slotter, using the cross-slide feed of the table and a special attachment shown in Figs. 28 and 29. This attachment consists of an arm solidly bolted to the circular table, to the end of which is fastened a pivoted slide running on a guide which is bolted to the knee of the slotter. The guide is so made as to be easily adjusted, to a limited extent, to different angles with the cross-slide ways, and in this way the work is caused to describe a different arc past the cutting tool if desired. While the cross feed is in use the circular table is, of course, left unlocked and free to revolve on its center as far as the attachment will turn it during the cutting operation.

Fig. 37. Special Chuck used for Planing Shoes and Wedges

Two link-slots are roughed out at once on the slotter, after which the links are placed one at a time on a special grinder, Fig. 30, and finished inside. The carrier of this grinder, to which the link is clamped, is a small four-wheeled truck running upon a double-inclined track, one incline of which is adjustable up or down to change the arc of travel described by the link. The whole attachment of track and carrier is mounted on the grinder table so that it can be fed to or from the wheel by turning the ball-crank on the feed screw. The grinding wheel has vertical adjustment, and an air pipe keeps the work free from dust and metal as the link is pushed back and forth by hand.

Fig. 26 shows the same machine arranged for grinding a link block to the proper curve. By fastening the block to an auxiliary bracket which is attached to the link carriage, as shown, both the top and bottom can be ground at one setting so as to exactly fit the slot.

The method of machining mud-rings two at a time on a slotter, is shown in Fig. 27. Fig. 31 shows the hole in the front deck over the pony truck being bored out. The form of shoe and wedge chucks used to hold the shoes or wedges when planing them on a small Gray planer is shown in Fig. 37. The set-screws in the lugs on the end of the chuck in the fore-ground, plainly show how the chuck is tilted to get the right bevel on the wedge.

Novel Tool for Turning an Inside Crank-axle Bearing

A rather unique fixture used to turn the crank axle bearing (A, Fig 33) is shown in Fig. 34. The crank-axle is held between centers in a lathe for convenience in handling and the fixture is clamped onto it, the bearing *B* of the crank-axle being where the wooden block is shown in the engraving, the ring *H*, carrying the cutting tool, being around the part *A*. The part *D* is placed on top of the tool carriage of the lathe to steady the fixture and keep it from turning. An electric motor is coupled to the shaft *E*, the inner end of which is a worm, meshing with teeth cut in ring *H*. The tool is fed along the cut by the hand wheel *G*. Formerly an air motor was used to drive the cutting mechanism, but it was found to run too jerkily to cut right so an electric motor was substituted with good results.

Turning Crosshead Pins

Crosshead pins are turned in the machine shown in Fig. 35, the parts of which are shown in Fig. 36. This tool is somewhat similar in principle to the one just described in Fig. 34, but a pinion and gear teeth are used to drive the cutter instead of a worm and worm gear, hand feed being used in both cases. The crosshead is adjusted for height on the machine, by means of the wedges *A-A*.

The usual locomotive valve-setting device has been supplemented in these shops by a Westinghouse 7½ H. P. reversible electric motor, mounted on a hand truck and made to drive the rollers which turn the locomotive wheels, by means of gears and a universal jointed shaft, as shown in Fig. 32.

BEARING METALS[*]

JOSEPH H. HART[†]

By conservative estimate the value of the bearing metal in actual use in the United States exceeds $50,000,000, of which fully one-half is used on the locomotives and rolling stock of the railroads of this country. In view of the increase in the amount of machinery and rolling stock steadily going on, and the constant wearing out and replacement of bearings, the value and importance of this product cannot be over-estimated. The life of a machine is largely dependent upon its bearings, and in view of this, the fact that knowledge in regard to bearing metals and alloys is not more general, is remarkable. Again, the nature of the production of these alloys is such that while in some cases they have been patented and are manufactured under trade names, in many others they are made up of scrap, with widely varying proportions of the different metals incorporated in their structure; on this account, probably no phase of engineering progress in machinery construction and operation is the subject of more difficulty and dissatisfaction.

The fact that bearing metals have to be taken largely on faith or else tested by more or less complicated processes for their chemical constituents, and the further fact that trade conditions in this field are such that the properties of metals are apt to vary greatly in different shipments is a matter of grave import to the average machinery manufacturer and operator. Only the largest consumers can afford to make the necessary tests and investigations of a given consignment in order to test its quality, and, in addition, a definite amount of special knowledge is requisite for this purpose, in view of the often wide variations in properties of the alloy, with a comparatively small variation in the proportion of its constituents. Under these circumstances the average small machine shop and consumer in this field accepts bearings on faith alone and is dependent largely upon the commercial reputation of the firm furnishing the material. That this should not be so is a foregone conclusion, but in view of this condition of affairs the rapid progress of the firm whose standing can be relied upon in this field is readily explained.

Bearings are usually composed of alloys of copper, lead, tin, antimony and zinc, and are known as babbitt metal (after the name of the discoverer of this material), white metal, brass, phosphorous bronze, and various other trade names. Quite a number of these are patented, such as "plastic bronze," etc., but many are sold merely under trade name, and in some instances are of uncertain composition.

The principal qualities which a good bearing metal should have are good anti-frictional properties, so as to withstand heavy loads at high speed, without heating, and second, sufficient compressive strength so as to neither be squeezed out of place under high pressure, nor crack or break when subjected to sudden shocks. In addition to these, many other properties must be considered in a choice of bearing metals depending upon the special purpose for which the material is to be utilized. Temperature variation is often an important factor, especially in refrigerating plants, and the coefficient of expansion should be considered to prevent undue binding, with consequent destruction of the bearing and the possible variation in other properties, such as brittleness, ductility, etc., under various temperature conditions. In addition, many bearings must operate under conditions where they are subject to chemical action, whether that of brine or ammonia in refrigerating plants, or acids, alkalies, etc., in chemical establishments, and in dynamo and motor construction and operation, the electrical conductivity must be considered as well. This statement applies equally to all bearings incorporated in electrical machinery, where these must serve as electrical conductors such as the bearings for the wheels in trolley cars, etc.

The chief properties to date which have been developed to a greater extent than others in machine design are, that of friction elimination and resistance to compressive loads. Theoretically all metals have the same friction, according to Thurston, and the value of the soft white alloys for bearings lies chiefly in their ready reduction to a smooth surface after any local impairment of the surface, such as would result from the introduction of foreign metal between the moving surface and the bearing. Under these circumstances the soft alloys flow or squeeze from the pressure into the irregularity, forming a larger area for the distribution of the pressure, thus diminishing its amount per unit of area. Further, the larger area over which the pressure is extended the less becomes the liability to over-heating and consequent binding. Under these circumstances the frictional properties of a bearing are in inverse ratio to their compressive resistance, and invariably the best bearing alloys, from a high speed viewpoint, are unsatisfactory for utilization in heavy machinery. The recent introduction of an iron or steel grid to form the base of the main bearing, and to be filled with much softer bearing metals than could ordinarily be installed, or in some cases even graphite, is a step in the right direction and presents possibilities of great importance in this field of machine development.

Lead flows more easily than any of the common metals under pressure, and hence it has the greatest anti-frictional properties. Of course, a number of metals exceed lead in this property, but their cost or some other factor render them unavailable. Lead is the cheapest of the metals, except iron, and in comparison to the other metals used in the formation of bearing alloys their relative prices are somewhat in the following order per one hundred pounds: Lead, $4; zinc, $5; antimony, $9; copper, $13; and tin, $30 or more. It can thus be seen that the more lead that is used in a given bearing, the softer it is, the less friction it possesses, and the cheaper it can be furnished. It is, however, too soft to be used alone, as it cannot be retained in the recesses of the bearing even when used simply as a liner and run into a shell of brass, bronze or gun-metal or some other alloy. Various other metals have been alloyed with it, such as tin, antimony, copper, zinc, iron and a number of non-metallic compounds, such as sodium, phosphorus, carbon, etc., and the effect of the different ingredients is to-day fairly well understood.

If antimony is added to the lead it increases its hardness and brittleness, and if tin is added as well it makes a tougher alloy than lead or antimony alone. Nearly all of the various babbitt metals on the market are alloys of lead, tin and antimony in various proportions, with or without other ingre-

---

[*] For additional information on this and kindred subjects, see the following articles previously published in MACHINERY: The Study of Alloys Suitable for Bearing Purposes, October, 1903, engineering edition; Oil Grooves and Bearings, May, 1905; The Design of Bearings, December, 1906, January and February, 1907, engineering edition; Hot Bearings, Their Causes and the Means of Avoiding Them, November, 1907. See also MACHINERY's Reference Series No. 11, *Bearings*.

[†] Address: University of Pennsylvania, Philadelphia, Pa.

dients added. In such babbitts, the wear increases with the antimony as a general thing, and the price with the tin. The higher antimony babbitts are used in heavy machinery, as they are harder, while those low in antimony are used in high speed machinery. The steady increase in speed at which various operating units are maintained is responsible for a wide deficiency in this field in the duty performed by the bearing metal. The chief difficulty to-day in the operation of the modern turbine is undoubtedly the maintenance of satisfactory bearing surfaces. Soft babbitts have never sufficient strength to sustain the weight and shock of heavy machinery bearings and can only be used as liners. The tendency to increase in speed as well as weight or size of machinery is limited to-day simply by the satisfactory operation of the bearing metal itself.

Undoubtedly, in investigations in this field, sufficient attention has not been paid to the effect of temperature on the bearing properties of the alloys used for these bearings. More rigid investigation in this field and limitations in regard to the temperatures permissible, with means for maintaining these within fairly close limits, will undoubtedly result in a great increase in the possibility of improvements in speed and weight of various types of machinery. More or less extensive experiments along these lines are being conducted in regard to the bearings used in turbine construction, since the speed here has rendered the problem an acute one and is necessary for efficient operation of the turbine itself.

COMPOSITION OF BEARING METALS

Alloys.	Lead.	Tin.	Antimony.	Copper.	Zinc.	Other Constituents.
Babbitt 1	80.00	20.0				
Babbitt 2	72.0	21.0	7.0			
Babbitt 3.	70.0	10.0	20.0			
Babbitt 4	80.5	11.5	7.5	0.5		
Babbitt 5	0.5	68.0		1.0	31.5	
Babbitt 6		20.0			80.0	
Babbitt 7		86.0	10.0	4.0		
White metal	82.0		12.0	6.0		
White Brass		64 0		2.00	34.0	
Magnolia metal	80.00	4.75	15.0	trace		$Bi = 0\ 25$
Car brass lining	80.5	11.5	7.5	0.5		
Ajax plastic bronze.	30.0	5.0		65.0		
Ajax metal	11.5	11.5		77.0		
P. R. R. car brass, B.	15.0	8.0		77.0		$P = 0.80$
S bearing metal	9 5	10.0		79.7		
Delta metal	5.1	2.4		92.4		$Fe = 0.1$
Camelia metal	14.8	4.3		70.2	10.2	$Fe = 0.5$
Tempered lead	98.5	0.08		0.11		$Na = 1.30$

Bi = bismuth; P = phosphorus; Fe = iron; Na = sodium.

The accompanying table will doubtless prove interesting as showing the various constituents of the more or less common bearing metals now on the market. The original babbitt-metals were very expensive materials, on account of the proportions of the more expensive metals found in them, and have been much modified in actual practice. A wide deviation in the composition of babbitt is readily shown in the first part of the table. The first babbitt is a fairly good alloy for high speed machinery but is not very hard. Its melting point is about 500 degrees F.; in fact, the properties of all alloys or bearing metals can be very widely deduced from their melting point. The second babbitt is somewhat harder and melts at a higher point. Both of these are used largely for lining purposes. The fourth babbitt is used very widely for heavy machinery. All of the babbitts mentioned have been fairly successful.

Babbitt 6 has good wearing properties but cannot be used for high speeds. Most of the other metals included in the table where copper is not used in excess can be regarded as in the same class as babbitts. The "white" class has a fairly good electrical conductivity, much greater than that of ordinary babbitt, and is used in the bearings of generators, motors, electric cars, etc. A rather interesting thing about the alloys containing sodium is based upon the fact that sodium by oxidation produces a material which will saponify with the oil used in the bearing and produce soap, thus assisting lubrication. The extent and amount of such action is scarcely as yet understood, and practically no experiments have been made with this investigation in view. Possibilities along this line, however, are great, not only for this particular alloy but for many others not as yet considered.

The other alloys included in the table consist to a very great extent of copper, tin, and lead, and usually have a thin liner of lead or some soft babbitt, and hence wear much better than an entire bearing of the soft babbitt. The tendency to wear decreases with increase of lead and increase of tin. Increase of lead, of course, diminishes the frictional effect of the alloy and hence its heating properties. A certain amount of other metal, however is necessary to keep the lead from separating from the copper. A study of the table itself, with a knowledge of the various properties of the metals themselves, will show conclusively the bearing properties of the different alloys. Pure copper is so tenacious that it is practically impossible to work it with any tools whatever without preliminary treatment and this same property extends into and influences its bearing properties.

The structure and treatment has more to do with the production of suitable bearing alloy than is generally considered. The tensile strength of solder and, in fact, all alloys, decreases very greatly with the pressure or tension at the time of solidification and in general the cooling process, and the influence on tempering affect the structure and consequently compressional resistance to a much greater extent than is generally considered. The same properties which influence the hardening and tempering of steel by heat, extend to a greater or less degree to all metals and are much more pronounced in alloys than in the simple elements.

Sufficient has been said to show the importance of the bearing metals in machine design to-day, and to give a brief outline of the situation in regard to the character and type of the metals available, with a few of the properties of the same. The possible combinations of alloys for this purpose are very great. Comparatively little progress has been made along investigations covering all possible alloys of different materials in different proportions. The recent introduction and placing on the market of a large number of metals, such as calcium, etc., very common in nature, and ultimately bound to be furnished at a very low rate, and many of them possessing very suitable properties for bearing alloys, is undoubtedly bound to influence the situation; and various engineering devices, such as the steel grid, recently developed, will undoubtedly receive attention in the immediate future with consequent increase in efficiency in this field. The development is but at its inception along this line, and standardization of the alloys at hand should be at once insisted upon and maintained by the various machine manufacturers. This latter is the chief difficulty to-day in commercial development. The scientific end will largely take care of itself. The effect of different metals upon alloys by their presence in various proportions can be foretold to-day largely from theoretical considerations; but that the commercial situation to-day, however, is unsatisfactory, is a foregone conclusion.

* * *

A British firm has recently completed what is believed to be the largest crane in the world. The total height of the crane is 166 feet; it is of the revolving cantilever type and will lift 160 tons at a 95-foot radius. The crane is driven by five large electric motors, the machinery being placed on the rear end of the cantilever and thus acting as a counter-balance of the load. At the tests the crane showed itself capable of lifting and moving loads up to 240 tons. The crane itself weighs about 950 tons.

* * *

A company which is to purchase the exclusive rights for the Wright aeroplane for the German Empire and its colonies, as well as for Sweden, Norway, Denmark and Turkey has been formed at Berlin with a capital of $125,000. The arrangement with the Wright brothers will extend over a period of fifteen years, during which time the company is to be entitled to all improvements made by the inventors during this time. The Wright brothers have also made arrangements with the Italian government, and in England they are building a number of machines for private sale. It is stated that not less than forty Wright aeroplanes are at the present time under construction in France.

INFLUENCE OF THE SCLEROSCOPE IN METALLURGY AND MANUFACTURING*

A. F. SHORE†

The scleroscope is an instrument in a measure dependent on sensitive touch; or, in other words, it feels the substance much the same as the human fingers. When we touch two or more objects as, for instance, an orange and an apple, we know that the orange is softer because it yields under pressure more than the apple. We are powerless to measure the hardness of any object that is harder than the finger tips, and there is no way of telling how hard it may be by finger pressure alone.

The sensitive touch of the scleroscope is produced by a tiny hammer dropping from a height of about ten inches onto the metal, hardened steel, etc., which it penetrates slightly. The hammer moves freely, yet snugly, within a glass tube and weighs about 40 grains. Its striking point consists of an inserted diamond of rare cleavage formation, annealed sufficiently to withstand shocks. This jeweled point is slightly convex and has an area of about 0.001 to 0.025 square inch. When the plunger strikes the metal to be tested, it reacts or rebounds. The height of this rebound is read against a graduated scale, and an accurate determination of the quantitative hardness of the piece under test is thus obtained.

The static testing of soft metal, using a steel ball which is forced into it with a known pressure so as to cause an indentation which can be measured with the microscope, is on a par with the testing of a peach or apple with the unaided nerve cells of the fingers; it fails in dealing with hardened steel, as it is like touching brass and steel to determine the difference in hardness. We could detect no yielding tendencies in either, and they would, therefore, seem to be of equal hardness. By tapping the two with the ball end of a hammer, however, we could tell which of the two is the harder, in that one would yield more and thus absorb more of the energy of the hammer blows; in other words, the harder the metal, the less yield, the less work done, and the higher the rebound of the hammer. On this principle the scleroscope is based. Some have said, for this reason, that the instrument is really a measure of elasticity. This, however, is not true. The elasticity of the metal or material is utilized as a motive force to work the sensitive indicator as will be demonstrated in the following.

Hardness vs. Elasticity

When the hammer of the scleroscope is allowed to drop with no other force than its own weight, and the point is so flat that absolutely no impression is made on the surface of very hard steel, then the rebound will be about 90 per cent of the fall. This phenomenon is known as the elasticity of solid bodies. Now, since hardness is resistance to penetration, in its clearest definition, it stands to reason that the point of the hammer must be somewhat reduced and rounded. Therefore the relation between the weight of the hammer and its point should be such that when it drops on hardened steel, a permanent impression must always be made, so that if we had not the rebound to go by, the microscope would still show the values. What is the result now? When the area of the hammer is thus reduced enough to make a permanent impression, a certain amount of the energy stored in the hammer is utilized in doing work. This overcomes the tendency of the metal to resist penetration, depending on how hard it is, or the resistance it offers, and naturally it must rebound considerably less. The hammer always delivers a blow of exactly the same force. If now we get a rebound of 75 per cent on very hard steel, we know that 15 per cent of the hammer's energy was spent in its efforts to overcome the resistance of the steel before it had a chance to react and repel the missile.

The Instrument

Instead of dividing the whole length of the fall of the indicator into a scale consisting of 100 divisions, the figure 100 is carried down to a point representing about 68 per cent of the total height of the scale as shown in Fig. 1. This was not an arbitrary provision, but was adopted after consultation with the leading metallurgists, one of whom was Dr. Paul Herault, of aluminum and electric steel making fame, of France. These authorities agreed that in the scleroscope, hardened steel of average hardness should be taken as the standard with which all other less hard metals should be compared: 100 is the average hardness of hardened steel; 90 is a low value, while 110 is a very high value. This scale therefore makes it an easy matter to compare the various metals which have to be cut or worked with steel, as we shall see further on.

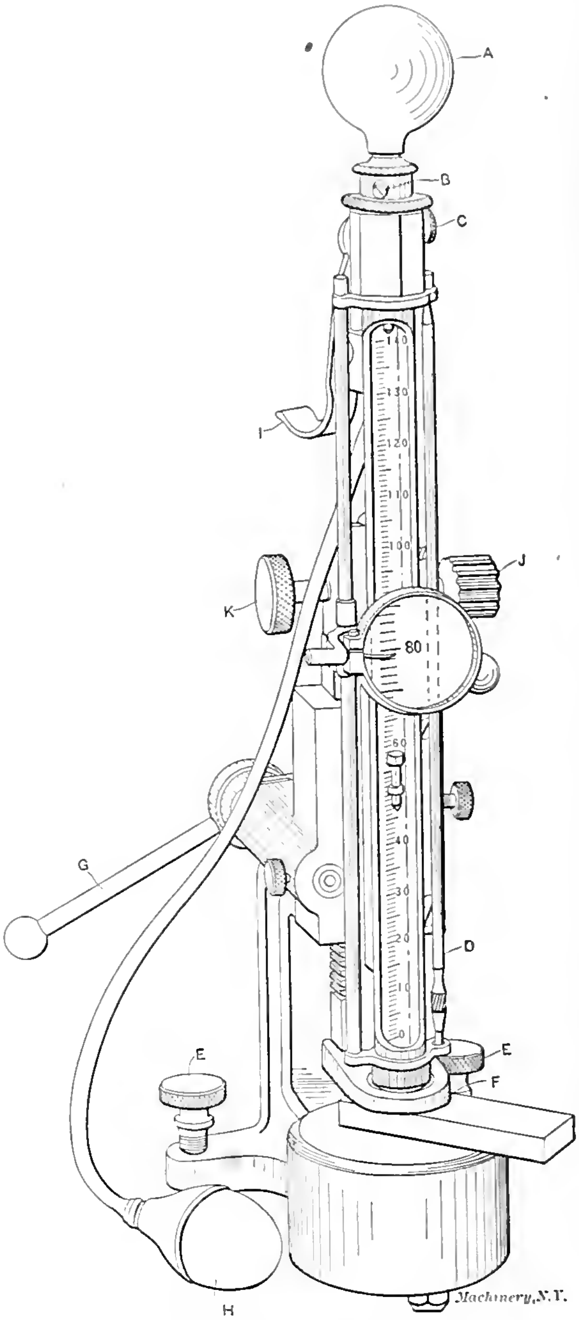

Fig. 1. Detail View of the Scleroscope—an Instrument for Testing the Hardness of Metals

The operation of the instrument is very simple. When the hammer is to be raised to the top, the bulb *A*, Fig. 1, is pressed and then released suddenly. This sucks up the jeweled plunger hammer referred to, so that it may be caught by a hook which is suspended exactly central in the glass tube and engages with an internal groove on the top of the hammer. Adjusting screws *B* for the hook and its spring are contained in the removable knurled cap. *C* is a cylinder and piston for releasing the hook and hammer by bulb *H*, whenever a test is to be made. *I* is a valve and hook which is pressed and thus opened at the same time to avoid a vacuum when the hammer drops. *J* is a pinion knob for moving the instrument up and down independently of the heavy rack and clamp *F* actuated by the lever *G*. At *E* are shown leveling screws and at *D*

---

[*] For additional information on the testing of metals, see "The Brinell Method of Testing the Hardness of Metals" (engineering edition), September, 1908, and "A New Mechanical Test for Hardness" (engineering edition), October, 1908.

a plumb rod. When flats and sheets and small pieces are to be tested, the scleroscope, self-contained with its clamp and anvil, is employed. When the ends of drills, rods and many other tools are to be tested, they are clamped in a bench vise, as in Fig. 2, and a swinging arm is employed. In this case, the instrument is removed from its post on the clamp frame by knurled set-screw *K*, and is attached in the same way to the post on the swinging arm. A kind of female dove-tailed finger ring, adapted to be clamped on the dove-tailed rack bar of the instrument, is provided for use in free hand testing and very large floor work, on parts of machinery being assembled, or on the stock rack, etc. It will thus be seen that the apparatus is universal in its application.

Philosophy of the New Method

When the hammer falls through a height of ten inches onto hardened steel, it will deliver a striking energy equal to about 20,000 times its own weight, acting through a very short space, of course. With a hammer weighing about 40 grains, and an indentation of, say, 0.002 inch depth, a working pressure of about 100 pounds is obtained. This force acting on a convex point about 1/64 inch diameter, is concentrated. The pressure thus available is about 500,000 pounds per square inch, which is ample to exceed the elastic limit of the hardest and strongest steel in existence.

A remarkable feature of this instrument is that it is self-compensating with regard to the energy of the hammer blows on the softer metals. This is due to the yielding of the material and the comparatively slow stoppage of the hammer. In lead, for example, a deep impression is made. This requires a great amount of energy, which is nearly all spent in doing work, and there is very little rebound afterward—about 3 degrees as against 110 for the hardest steel. The constant pressure developed by the hammer is thus only 12 pounds instead of 100 or more for good hard steel, and, of course, the pressures for intermediate hardnesses as on brass and soft or tempered steel are always in proportion to the physical hardness of the brass or steel.

Application to Shop Work

The manufacturer who wishes to get high efficiencies out of his tools will not benefit by the help of such a commodity as the scleroscope in detecting good and bad tools, unless he is willing to amend the errors in practice which he may find. The observation of this principle is the foundation of the success which hundreds of firms in this country and Europe are having with this instrument. While tool work is a line requiring the most careful attention, the material worked and produced is none the less important. In this connection the scleroscope is very commonly applied to industrial systems, with admirable results. An instance may thus be cited showing how these results are obtained.

More than a year ago the Brown & Sharpe Mfg. Co. adopted the new method as a guide in the laboratory, particularly for the study and selection of such fine steel as is required in standard commercial tools. The attention of the company was then turned to its high-grade automobile gears of alloy steels, etc. Meanwhile the Packard Motor Car Co. used the scleroscope to study the past performances of the various gears and parts of old Packard cars, and made careful records. This was also done by many other concerns, and these records showed that alloys, steel or nonferrous metals would give a certain efficiency if the hardness was just right. As the best is, in the end, the cheapest, in high grade apparatus, the Packard engineers began to issue orders to their various auto part making houses for material which was specified to require a given degree of scleroscope hardness. Gears were made for them by the Brown & Sharpe Mfg. Co. and the Gleason Works both of whom were using the scleroscope to aid them in filling orders. Wyman & Gordon, who supply forgings to Brown & Sharpe, were able to make them to the required specifications, but, in order to do so, they had to see that the raw material was of the proper hardness. This brings the matter back to the open-hearth or crucible and chemical laboratory where again the scleroscope is used to great advantage. Before the completion of an automobile of the guaranteed kind, often a dozen instruments are used among the specialty makers who supply the various parts. The ball-bearing manufacturers are required and prefer to test every part before assembling. The Hyatt Roller Bearing Co. and the Hess-Bright Mfg. Co. are obliged to use a number of scleroscopes which are operated by women, carefully trained, who are able to pass on a large number of pieces daily. This testing is to ascertain principally two factors on which success in service depends, *viz.*: the right degree of hardness, and the uniformity of this hardness—and both are equally important. In the latter case it is necessary to test the parts in a number of places, which must be done very rapidly to keep down the additional costs, particularly as in the manufacture of standard parts such as these, there are always losses due to the rejection of some parts which do not conform to the specifications.

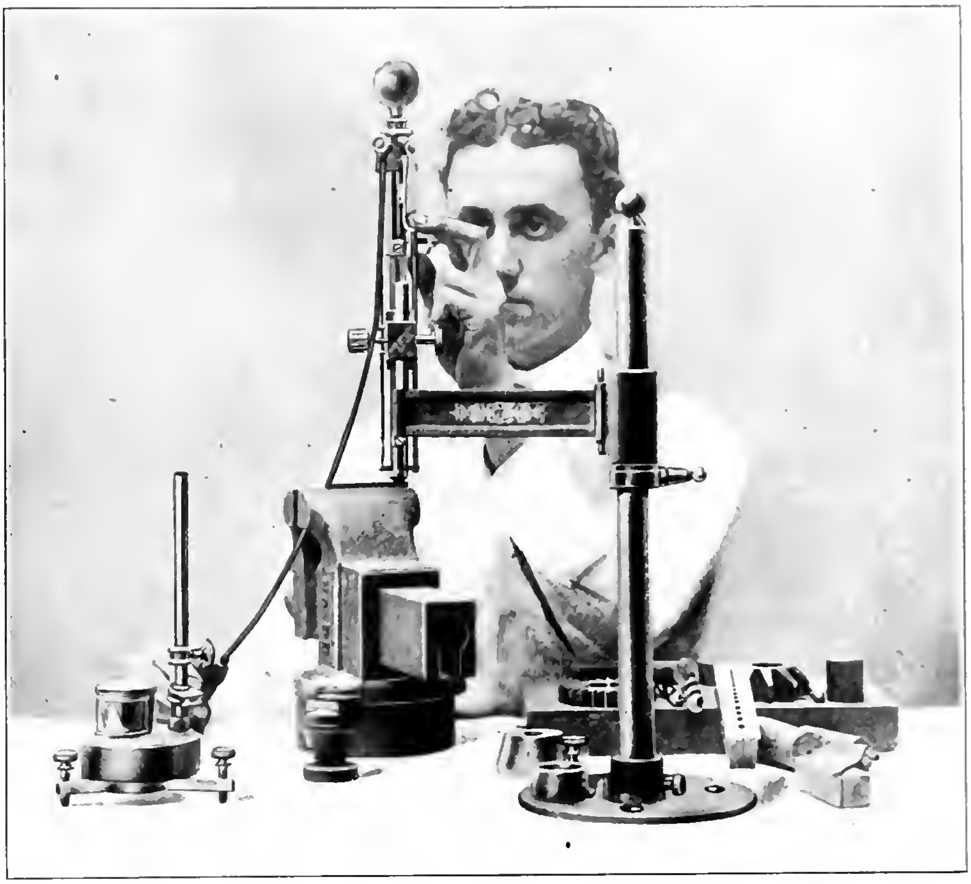

Fig. 2. Scleroscope equipped with Swinging Arm for Testing Pieces clamped in Bench Vise

The Lunkenheimer Co., the Light Mfg. & Foundry Co., and other up-to-date manufacturers, use the scleroscope in the standardization of castings adapted to various needs. These houses also make auto parts for the Packard Co., etc., and by the use of the scleroscope are enabled to live up to their specifications. In these auto shops the instrument is used for all classes of work, although it is most needed in the inspection department for the examination of parts and material, particularly of those not made by the builders.

Tool Steel and the Scleroscope

Since for most uses (other than for turning or planing tools) plain carbon steel is as yet adequate, many manufacturers have turned their attention to the art of obtaining much

higher efficiencies by aid of the scleroscope after good steel has been selected. The method of doing this is interesting, and was first hailed as a revelation by many authorities. Thus, when a steel having a carbon content of 0.90 of one per cent and over is heated to the right temperature and is then properly quenched, the limit of hardness and strength is obtained. Now, attaining this temperature is such a delicate matter, that unless the very best facilities are at command, anything but the exact heat required may be obtained, and if the heat is too low the tool will be hard only on the edges, while if it is only a trifle overheated such as is regularly done by the average hardener who takes chances by depending on skill of the eye, something like from 50 to 75 per cent of the strength due to rolling or forging is lost. This appalling loss in strength so vitally important in any tool is accompanied by a slight drop in the hardness—not more than 5 per cent. This is detected by the scleroscope as shown in charts, Figs. 3 and 4. The former is a hardness curve taken from a tool steel of about 0.90 carbon, while the latter is one taken from a steel having 1.65 per cent. The difference between these curves is indeed very striking and very significant to those who have mastered the elementary principles of the study of tool steels by aid of the scleroscope. The curves are obtained from the Metcalf test as follows: A piece of steel a few inches long and about one-half inch square is heated to a bright yellow on one end and manipulated so that the temperature is less and less toward the other end until a red is scarcely visible. The piece is then quenched in water, ground clean, and tested by the scleroscope at intervals of about ¼ inch along the bar, beginning at the unhardened end. As each section is tested, a reading is obtained which corresponds with the exact hardness that would be obtained by quenching a similar piece at whatever heat the said test piece had in that location. This hardness number is plotted out on a chart in the usual way so that a true curve is obtained showing the character of the changes in hardness and strength which vary directly with the carbon content. In fact the most accurate analyses of this element are made in this way—but that is a subject by itself.

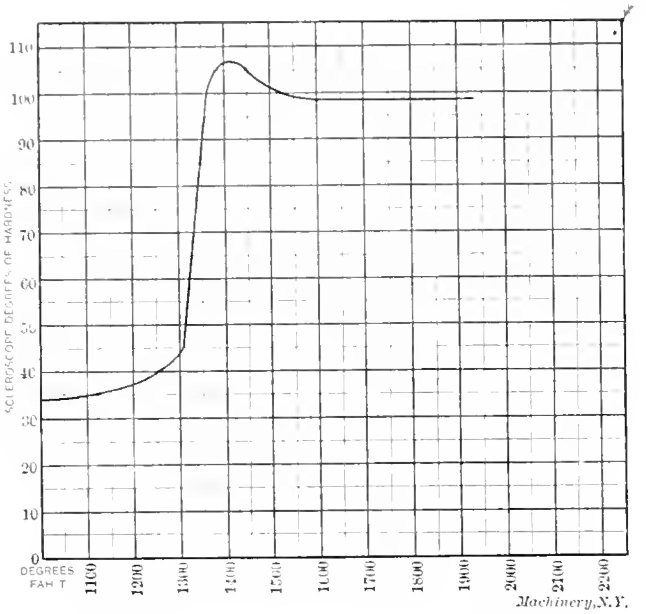

Fig. 3. Hardness Curve for Tool Steel of about 0.90 Carbon

The test piece thus obtained represents a stock bar, of the steel which is to be worked into tools, dies, etc., hardened at temperatures that vary more widely than could occur in any well-regulated hardening room, and somewhere within these limits is the temperature that yields the maximum hardness. It supplies an expedient whereby the hardener may know exactly what temperature is most suitable for each tool made from the steel thus tested. His future work is guided and facilitated by stamping on each tool a number corresponding to the hardness number given to the said stock bar. It also enables the hardener or the inspector to intelligently test all hardened tools. Thus, if a die is hardened to 95, we can determine by referring to the test piece of steel, whether this is the highest degree of hardness obtainable with this steel. If the test piece showed the hardness to be, say, 100 or 110, and the die only showed 95, it would indicate that the die did not fulfill the necessary requirements.

SCLEROSCOPE HARDNESS SCALE

Name of Metal	Annealed	Hammered
Lead (cast)	2—5	3—7
Babbitt metal	4—9	
Gold	5	8½
Silver	6½	20—30
Brass (cast)	7—35	
Pure tin (cast)	8	
Brass (drawn)	10—15	24—5
Bismuth (cast)	9	
Platinum	10	17
Copper (cast)	6	14—20
Zinc (cast)	8	20
Iron, pure	18	25—30
Mild steel, 0.15 carbon	22	30—45
Nickel annode (cast)	31	55
Iron, gray (cast)	30—45	
Iron, gray (chilled)		50—90
Steel, tool, 1 carbon	30—35	40—50
Steel, tool, 1.65 carbon	35—40	
Vanadium steel	35—45	
Chrome—nickel	47	
Chrome—nickel (hardened)		60—95
Steel, high-speed (hardened)		70—105
Steel, carbon, tool (hardened)		90—110

NOTE.—These figures are subject to variations owing to nature of composition or compression of metals.

Advantage of Testing

It is noticeable in every shop that out of every lot of tools made there are always some "freaks"—tools that are jewels among others—although all are seemingly made alike. Some reamers will hold their size ten times longer than others; lathe tools, particularly thread and cutting-off tools, remain faithful to the setting through thick and thin and are usually kept in reserve for critical jobs. This may be because of defective steel, but usually the good and bad are made from the same bar, in which case we must look to our methods of hardening since the finest steel is most easily ruined, and is thus apt to make the poorest tools.

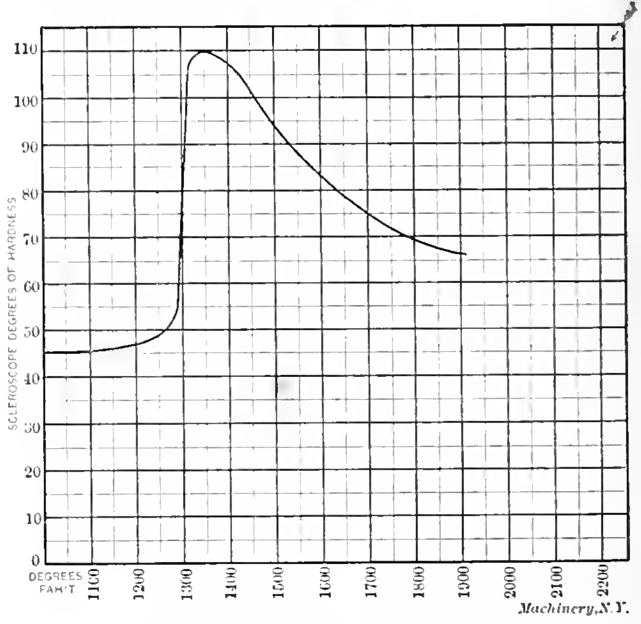

Fig. 4. Hardness Curve for Tool Steel of 1.65 Carbon

This latter fact has been known to steel makers for years, and because the abuse of tool steel is so general, none of the finest steels can be procured on the open market, but are made to order only. The explanation of this condition is simple. Tool steel is so sensitive to heat and water that only the photographic plate can be compared to it; it will produce a tool having 100 per cent efficiency only when treated just right. Like the novice in photography who occasionally gets a good picture if his lens is good, so is tool hardening a hit-and-miss process unless the workman be guided constantly. In this way workmen are enabled to acquire such precision of judgment that results seemingly incredible are obtained, and often testing instruments are used less constantly than one would think. Among many instances thus noted by the writer, one particularly interesting is the way in which the Winter Bros.

Co., Wrentham, Mass., who manufacture taps and dies, undertook to produce tools of the "jewel" variety as a regular product. Some of their taps were used on tough bronze in a turret lathe on a large scale, and often freaks were found which would never break until worn out. The most remarkable of these (7/16 inch diameter) held out three weeks at the rate of 10,000 holes per day as against only a few hours service for some taps. This tap was returned to the maker to be studied by aid of the scleroscope. The stock used was of tempered high-speed steel. The hardness remaining was measured although it was not known what the original hardness was nor exactly what temperature was used to draw it down to that hardness. The manager then ordered that 50 taps be made of high-speed steel and tested by the scleroscope. All these taps were hardened the same as the "freak" sample, and all were tempered with a heat which was variable (in fact it was unknown, except for the average) for the object in view was to get all pieces of the same hardness in the end, which was accomplished. The whole lot was next put to work and watched. After all had been worn out it developed that each tap proved to have the same efficiency as the freak. This resulted in the formal adoption of this method of hardening for taps of this steel and for the class of work mentioned, while other problems involving carbon steel were also gradually being solved along similar lines.

As a matter of fact, if only part of the new methods adopted since the first appearance of the scleroscope were described in detail, it would reveal something more than an incipient revolution, not only in metallurgy, but in most of the allied lines of industry and wherever tools are used and made.

The scleroscope is now regularly used to great advantage in naval construction, in the selection of materials for construction as castings and forgings, alloys, steel of all kinds and particularly in testing the hardness of projectiles and armor plate. All the United States government arsenals are thus equipped as well as those of foreign governments, including Japan. Likewise numerous mints and engraving bureaus are guided in their work, in which great economy must be practiced. Similar instruments are also to be found at the Bureau of Standards of Weights and Measures, and the leading railroads are using the scleroscope in their laboratories in the study of newer and superior rails, and rolling stock materials. In the steel mills a new departure has been made in that carbon content and other determinations can be made before the molten metal is poured from the hearth into the ladles, by means of a new dynamic method made possible by the scleroscope. This method allows the metallurgist the chance of making corrections before it is too late, which is of great importance. In the manufacture of non-ferrous metals such as brass sheet, rods, wire, etc., much can be told, by measuring the billets after casting, as to what will happen to the rolled or drawn products as well as what must be added or subtracted from the melts. The scleroscope also works very well on carbon, which fact was first demonstrated by the General Electric Co. All American carbon manufacturers now use it, and every dynamo or motor brush made of this material is first tested as to its suitability for the special work for which it is intended. Applied to glass, etc., it shows at once whether or not these materials are too brittle to be good. Wood rubber and other fibrous materials can only be tested by an especially sharpened drop hammer.

HIGH SPEEDS

TOUCHING ON THE EXTERIOR BALLISTICS OF THE MODERN HIGH-POWERED RIFLE

J W JR

Probably the highest speed of rotation familiar to the layman is that of the later automobile engines which turn 3,000 R. P. M. more or less, while that which is best known to the engineer is the 30,000 R. P. M. which the rotor of the smaller De Laval steam turbine acquires. These speeds are high enough to present extraordinary difficulties to the designer but fast as they are they are quite outclassed by an object familiar to us all to a greater or less extent, the ordinary rifle bullet.

While the enormous number of revolutions per minute which one of the higher velocity bullets makes is not appreciated, yet every huntsman or target shot knows that it must acquire a rotation around its geometrical axis on account of the twist of the lands of the rifling in the barrel. The terrific speeds attained with some of the latest military ammunition are realized only by the ballistic expert, but play a very important part in the design and balancing of the bullets for the finer target ammunition.

Of the smaller calibers the best known and most popular all-round cartridge is probably the 0.22 "long rifle," the bullet of which is made of lead and weighs 40 grains. Its velocity as it leaves the muzzle of the gun is approximately 1,000 feet per second or a little over 11 miles a minute, quite a fair speed even in this day of fast automobiles and high-speed trains. The lands of the rifling have a twist of one turn in 18 inches, imparting to the bullet a rotative speed of 660 revolutions per second, or 39,600 R. P. M., which is "going some" but still quite within our conception. On account of its light weight, however, the 0.22 caliber bullet strikes a blow of less than 100 foot-pounds, enough nevertheless to put the ordinary squirrel or woodchuck out of business.

Fig. 1. Springfield Model 1903 Army Rifle, Latest Pattern, with Cartridge Clip in Place ready for Loading

The most talked of and deservingly most popular of the higher power sporting rifles for use with smokeless powders is the 0.30-30 Winchester, Marlin or Savage. The cartridge for this gun is loaded with a metal-cased or soft-point bullet weighing 165 grains, which upon being fired attains a muzzle velocity of 2,020 feet per second, or 23 miles a minute, and strikes a blow of 1,480 foot-pounds. After all it is not so wonderful that this little missile carries a message of death with every shot. The twist in a 0.30-30 barrel is generally about one turn in 12 inches, which imparts to the bullet a rotative speed of 2,020 revolutions per second, or 121,200 R. P. M. From this it appears that the steam turbine "is not in it" for speed, although it may be doing far more for the industrial development of society.

The most interesting problems for mechanical analysis, however, are presented by the new rifles and cartridges recently adopted by the United States Government. The new 0.30 caliber Springfield ammunition is the first to be scientifically developed, using a pointed or Spitzer bullet. This new bullet is slightly over an inch long, tapered like the end of a cigar to a point 0.050 inch diameter and weighs only 150 grains, by far the lightest bullet ever used for a military arm with the exception of the 6 mm. (0.236 inch) U. S. Navy Model which was soon discarded. The idea of using such a light bullet is to

produce an exceedingly high muzzle velocity with the same or only slightly increased pressure in the rifle chamber. The result of this high velocity is that the bullet travels in a trajectory which is very flat, requiring far less accurate estimates of target distances and so producing a much more efficient and deadly weapon in the hands of the inexperienced marksman.

The velocity of the bullet as it leaves the muzzle of the rifle is 2,700 feet per second, or over 30 miles a minute, which gives it a tremendous shocking power, striking a blow of 2,500 foot pounds, enough apparently to put a whole regiment out of commission. The great linear velocity of this bullet produces an unexpected effect when fired from a rifle equipped with one of the new Maxim silencers. There is no doubt that this silencer destroys practically all of the noise caused by the sudden escape of the expanding powder gases, yet a shot fired under these conditions can be heard, under normal circumstances, for nearly a mile away from the firing point. This noise is undoubtedly caused by the rapid passage of the bullet through the air, which is separated so quickly that it returns with a crack or crash, producing an effect very similar to that caused by lightning.

While not only attaining such remarkable linear velocity this little high-speed projectile also rotates on its own axis at the rate of 194,400 R. P. M., the twist in the rifle lands being one turn in 10 inches. We have nothing to serve as an example for comparison with this speed and can only partially comprehend it when we realize that the periphery of this small nickel cylinder has a linear velocity of 3 miles a minute, or three times as fast as we consider it safe to run the best of cast iron fly-wheels.

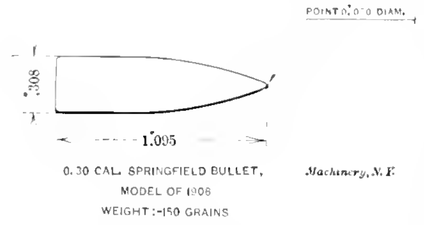

Fig. 2. Dimensions and Shape of Spitzer 150-grain Bullet

The amount of energy which this bullet possesses is much out of proportion to its size, and consists of the sum of that due to its rotation and that due to its linear velocity. To get at the amount of rotative energy involved, suppose we consider the bullet is made up of a cylinder 0.308 inch diameter, 0.595 inch long and a cone 0.308 inch diameter at the base with an altitude of 0.500 inch, the cylinder weighing 113 grains and the cone 37 grains. If M_1 is the mass of the cylinder; M_2 the mass of the cone; r the radius of the cylinder and the base of the cone; n the revolutions per unit of time; g (32.16) acceleration due to gravity; and I_p the moment of inertia around the geometrical axis of the bullet (polar moment), then

$$I_p = \tfrac{1}{2} M_1 r^2 + 0.3 M_2 r^2$$

The angular velocity $= \omega = 2 \pi n$.

Hence the rotative energy

$$\tfrac{1}{2} I_p \omega^2 = \tfrac{1}{2} (\tfrac{1}{2} M_1 r^2 + 0.3 M_2 r^2) 4 \pi^2 n^2$$

If the energy is required in foot-pounds per second we have:

$M_1 = 113 \div 7000g$,

$M_2 = 37 \div 7000g$.

$r = 0.154 \div 12$.

$n = 194{,}400 \div 60 = 3{,}240$ revolutions per second.

Substituting these values in the equation above and carrying out the calculation we get:

$$1/2\ I_p\ \omega^2 = 10 \text{ foot-pounds per second.}$$

This figure is of course negligible when we consider the 2,500 foot-pounds per second, or 4.5 H. P. which this small missile develops by virtue of its linear velocity at its maximum speed in flight.

The jacket of the bullet is composed not of steel as is commonly supposed, but of an alloy of 85 per cent copper and 15 per cent nickel. This metal possesses a high tensile strength which we find is quite necessary to prevent the jacket from stripping, *i. e.*, tearing apart and separating from the enclosed slug. The tearing effect of fouling in the rifling is of course an unknown factor, but we do find that the tensile strain set up by centrifugal force alone is very important and must be allowed for. Suppose we consider a small section of the bullet as a fly-wheel with the jacket acting as the rim, the thickness of which is about 0.020 inch, making the mean diameter 0.288 inch.

The mean velocity of the rim $= V = \pi \times \dfrac{0.288}{12} \times 194{,}400 =$ 14,650 feet per minute $= \dfrac{14{,}650}{60} = 244$ feet per second.

The sum of the centrifugal (radial) forces of the whole rim of a fly-wheel is

$$F = \frac{Wv^2}{g\,R} = \frac{4\,W\,\pi^2\,Rr^2}{3{,}600\,g} = 0.000341\ WRr^2,$$

where F = centrifugal force in pounds,

W = weight of rim in pounds,

v = velocity of rim in feet per second,

$g = 32.16$,

R = mean radius of rim in feet,

r = revolutions per minute.

The resultant of half of this force tends to disrupt one half of the rim from the other half. The rupture is resisted by the two sections of the rim at each end of the diameter. The resultant of half the radial forces is to the sum of half of the radial forces as the diameter of a fly-wheel is to half its circumference, or

$$\frac{\text{resultant}}{\text{sum of half the radial forces}} = \frac{1}{\frac{1}{2}\pi};$$

$$\text{resultant} = \frac{2}{\pi} \times \text{sum of half the radial forces}$$

$$= \frac{2}{\pi} \times \frac{0.000341\ WRr^2}{2} = 0.00010854\ \ WRr^2.$$

As this resultant force is resisted by the section at each end of the diameter, each section must resist a force

$$S = \frac{0.00010854\ WRr^2}{2} = 0.00005427\ WRr^2.$$

The weight of a rim of cupro-nickel, one square inch in section, is about 23.95 R pounds, R being in feet. Hence $S = 0.0013\ R^2r^2$.

But as $v = \dfrac{2\,\pi\,Rr}{60}$, and $v^2 = \dfrac{4\,\pi^2\,R^2r^2}{3{,}600}$, we have

$$S = \frac{0.0013\ v^2 \times 3{,}600}{4\,\pi^2} = 7{,}070 \text{ pounds per sqnare inch.}$$

Without doubt this is well within the safe stress for the metal used, but when one becomes familiar with the highly trying conditions to which it is subjected and appreciates the rapidity with which the bullet is accelerated within the rifle barrel, the uniformly satisfactory results obtained are surprising. The Ordnance Department and the commercial manufacturers are constantly at work to produce more efficient and more deadly ammunition and if the progress in the next few years is anything like that made since the Spanish-American war, the mechanical problems presented will be by no means inconsiderable, and will become as essential a part of bullet design as the ballistic problems are to-day.

FORM GRINDING OPERATIONS IN THE SHOPS OF THE LANDIS TOOL CO.

RALPH E. FLANDERS*

The grinding wheel has found but a limited application for grinding other than plane, cylindrical and conical surfaces. In this respect its field is not so universal as that of the milling machine and the lathe, which readily adapt themselves to the use of form cutters and tools. In the grinder the difficulty lies in the shaping of the periphery of the wheel to the form it is desired to reproduce in the work. This operation offers more of a problem than in the case of a cutter or lathe tool, it being necessary to provide attachments with mechanical means for guiding a diamond point to follow the outline desired on the wheel surface. Despite this handicap, the Landis Tool Co., of Waynesboro, Pa., has found it profitable to make extensive use of such truing attachments for simple operations. Examples of work formed in this way are herewith illustrated and described.

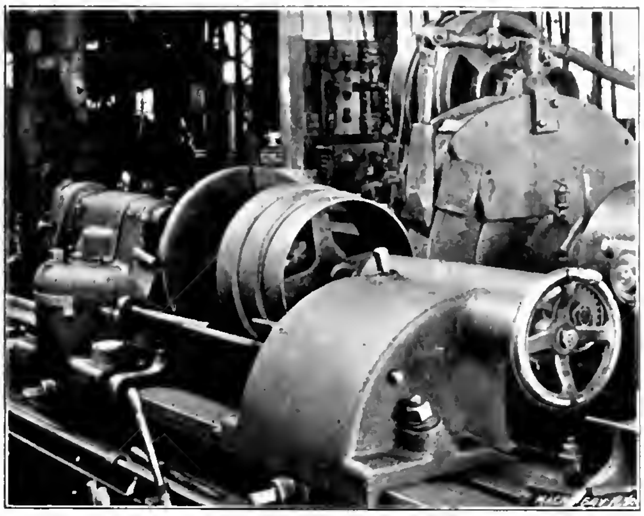

Fig. 1. Grinding the Crown on the Faces of Cone Pulleys in a Landis Grinder

Crowning Cone Pulleys

In Fig. 1 is shown a cone pulley, mounted in a large plain grinding machine, which carries a wheel shaped to give the desired crowning for the belt surface. To produce this, the wheel is concave to the proper radius and fed directly into the face of each step of the pulley, thus giving it the proper shape and the desired fineness of finish in the same operation.

The interest in this operation attaches, of course, to the means provided for grinding the concave contour on the wheel. The attachment shown in use in Fig. 2 is employed for this purpose. This consists, it will be seen, of a base mounted on the clamping surface of the work-table, and carrying a pivoted arm through which is adjustably mounted a swiveling diamond holder. This holder may be rotated about an approximately horizontal axis by means of the worm and worm gear and hand-wheel shown. By adjusting the arm about its pivot and the holder about the arm, the axis of the latter may be so located with reference to the wheel, that a concave surface of any reasonable radius may be cut out from the wheel. The adjustment is so flexible, in fact, that a practically straight, or even a convex surface can be produced on the wheel if it is required.

Grinding Fillets on Crank-shafts

Another example of form grinding occurs in the finishing of crank-shafts. The crank-pins and journals are provided with fillets at their junction with the cheeks of the crank. To produce a satisfactory job, these fillets should be formed by the edges of the wheel, which should be carefully shaped to the desired radius. Figs. 3 and 4 illustrate the fixture designed for this operation.

The frame of the fixture *A*, is mounted on top of the regular back-rest of the machine as shown. The diamond is set in the end of holder *B*, which is in turn supported by arm *C*, which swivels about axis *x x*. The radius to which the corner of the wheel is formed is determined by the distance from the point of the diamond to this axis. This radius is adjusted by thumb-screw *D*, suitable graduations (not shown in the engraving) being provided for making this adjustment. Holder *C* is supported at the upper end in the bearing in frame *A*. At the lower end it is provided with a roll *E*, which bears against a semi-circular seat in frame *A*, concentric with axis *x x*. By adjusting the nut and stud at *F*, thus clamping together the split shown in arm *C*, roll *E* is kept firmly pressed against its seat. This takes the thrust of the diamond against the wheel at the lower end of *C*. The diamond and its holder are rocked about axis *x x* by handle *G*, playing between stops *H*.

The operation of the device is as follows: The diamond in *B* having been adjusted by thumb-screw *D* and the graduations to the proper radius, stops *H* are set in the proper holes for the corner of the wheel to be trued. These stops give 90 degrees of movement, allowing the diamond to swing from the front face around to the side. Holding handle *G* in the position shown, so that the diamond is in front of the axis of rotation, the wheel is first trued up on its front face by the usual movement of the wheel back and forth past the diamond. When this has been trued up, without disturbing the cross feed of the wheel, the diamond is moved off to one side and handle *G* is rocked down to the 90 degree position on that side as determined by the stops. Rocking handle *G* back and forth through the 90 degrees, the table is gradually fed up to the corner of the wheel until the latter is completely rounded to the radius desired. For the other corner, handle *G* is brought back to the central position, stops *H* are changed to permit 90 degrees of movement in the other direction, and the diamond is fed back to the other corner, which is rounded in the same way.

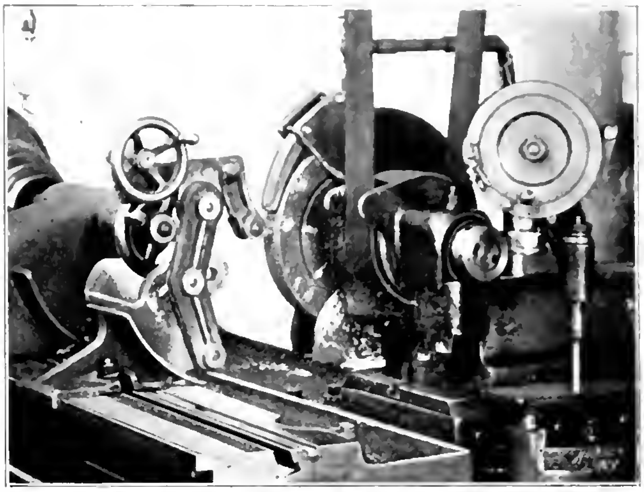

Fig. 2. Fixture for Shaping a Concave Face in the Wheel for Crowning Pulleys

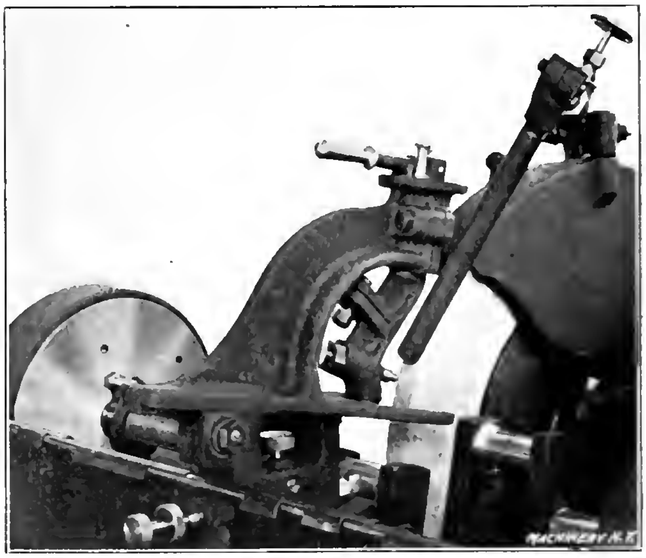

Fig. 3. Truing Device for Forming Wheel to Grind Fillets on Journals and Pins of Crank-shafts

---

* Associate Editor of MACHINERY.

Fig. 4 also shows quite plainly the construction of the regular back-rest used in the Landis grinding machine. The work is supported by two rests of maple at *J* and *K*. The lower rest *K* is mounted on a pivoted arm *L*, which may be swung toward or away from the work by thumb-screw *M*. This adjustment does not have to be changed often, since the variation in the height of the work makes practically no difference in the diameter. Thumb-screw *M* is therefore provided with a clamp-bolt at *N*. The upper rest *J* is mounted in the end of a plunger *O*, which is backed by thumb-screw *P*, having knurled lock screws *Q*. In long, slender cylindrical work this rest is constantly set up by the workman as the grinding progresses, the adjustment being made for each rest at a time when the wheel is at work at another part of the shaft; it is possible at that time to be guided by the sense of touch in setting up the back-rest. For crank-shaft grinding it is ordinarily not necessary to adjust the rests during the operation.

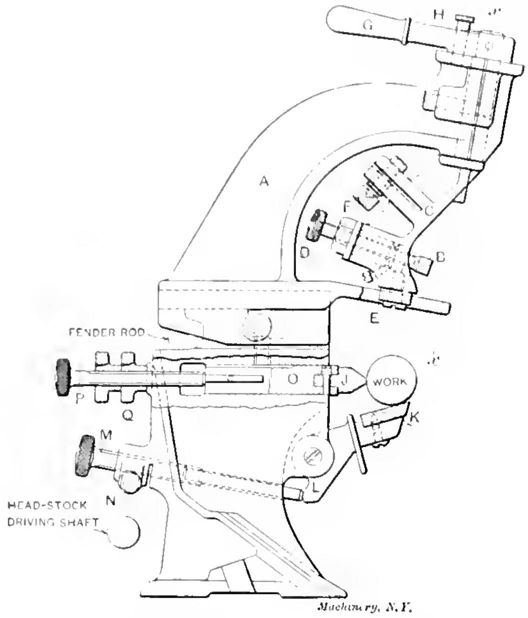

Fig. 4. Detail of Radius Forming Attachment

What may be considered a form grinding operation, though of the simplest order, is performed on the piece of work in Fig. 6. This shows a wheel spindle for the Landis grinding machine. It will be noticed that a portion of the spindle at the right end is turned down to a small diameter to receive the thrust and adjustment collars. This shaft is case-hardened. Difficulty was experienced in the hardening from the breaking off of this ⅝-inch diameter extension. To remedy this, the present method is to carry the 1.488-inch diameter clear out to the end of the shaft at the right, and case-hardening it in that condition, the shaft being finished except for this portion. After hardening, the spindle is placed in the grinding machine again, and a wheel the full width of the part to be machined (that is to say, about 3 inches face) is used to grind below the case hardening. The wheel is not traversed back and forth as in ordinary grinding, but is fed straight in, reducing the diameter about 3/16 inch. It is then possible to finish the arbor at this point in the lathe, as the core of the spindle is soft. It will be seen that this is a form grinding operation, in spite of its simplicity.

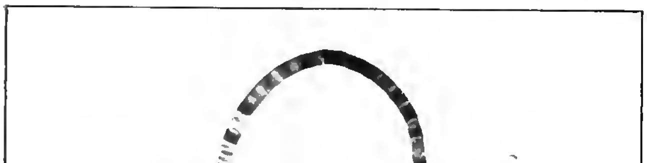

Fig. 5. Example of "Chip" Produced in Heavy Cross-feed Grinding

An interesting, though now well-known, phenomenon is connected with this operation. If the hardness and grain of the wheel is exactly right, forcing it into the work with a heavy feed will produce a "chip" very strongly resembling that produced with a wide form tool under the same conditions. When these chips first appeared, there was considerable discussion as to their nature, but it is now pretty definitely settled that they are formed of molten bits of metal, which rapidly accumulate and are fused together into the solid, ribbon-like form shown in Fig. 5. There is no advantage in producing these chips, but they are bound to appear if conditions are right for them.

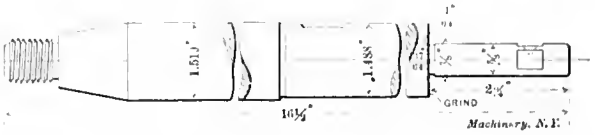

Fig. 6. A Grinding Machine Spindle; the ⅝-inch Diameter is machined after Case-hardening

* * *

THE SILVER DOLLAR CHECK SYSTEM

W. L. B.

When I was running a lathe in the old railroad shops at Scranton, a new man came in one morning and took a big lathe opposite mine. He was a country jay of the greenest kind, but he soon showed that he could do a good piece of work, though his queer way of doing it would make us wonder what kind of a country shop he came from. The boys gradually broke him in to our ways by their own gentle methods. Jim, who ran a lathe which was on the other side of the new man, was particularly active; he soon fixed up a game with one of the apprentice boys, and started right in. Jim called the boy, and pitching him a big silver dollar in a way to attract the attention of the country man, told him to go to the tool-room and get a file. The boy did so, and then, on the quiet, returned the dollar. Soon Jim called the boy and, again pitching him the silver dollar, told him to get a wrench, and so it went on, Jim calling the boy and every time giving him the dollar as he told him to get some tool.

The country man observed this careless exchange of money until he couldn't keep in any longer; then he asked Jim why he gave the boy a dollar every time he wanted a tool. Jim's chance had come and he started right in to improve it. He said that the rule of the place was that fifty cents had to be deposited for every tool taken from the tool-room, and when the tool was returned it was examined and a charge made for the wear. The other fifty cents was graft for the tool-room keeper, who was a crank and who wouldn't give the men any tools unless they put up the fifty cents which he put in his own pocket. Jim went on to say that it was useless to kick against the system as the foreman insisted on the work being done, and as they had to get the tools from the tool-room, there was no other way.

The country man was taking the bait fine, and in his interest he asked Jim how much he made a week. Jim said twelve dollars, but as his board was five and drinks five more and as the tools cost him a couple of dollars a day he was not getting along very fast.

Our country friend went back to his lathe in a dazed condition, and it was comical to watch the exceeding slowness with which the bright light of truth percolated that country head.

He made good in the shop all right, but for some reason he and Jim never became chums.

* * *

Brass for brazing should contain at least seventy-five per cent of copper in order to prevent its melting and flowing away during the brazing.—*Brass World.*

DON'TS FOR DRAFTSMEN*

JOHN S. MYERS†

Don't forget fillets.
Don't forget impact.
Don't omit oil holes.
Don't scoff at theory.
Don't omit oil grooves.
Don't omit dimensions.
Don't forget check-nuts.
Don't slight the details.
Don't repeat dimensions.
Don't use fancy lettering.
Don't show fancy oil grooves.
Don't claim credit not due you.
Don't despise accepted practice.
Don't crowd bolts too near ribs.
Don't work without a slide rule.
Don't be stingy about clearances.
Don't forget the value of graphics.
Don't start unprofitable arguments.
Don't be afraid to soil your hands.
Don't put foolish notes on a drawing.
Don't put unnecessary finish on parts.
Don't pretend to be what you are not.
Don't bend levers if it can be avoided.
Don't imagine you own the company.
Don't forget to allow for adjustments.
Don't get the patent bee in your bonnet.
Don't forget clearance for moving parts.
Don't be unpractical in applying theory.
Don't fail to keep notes on valuable points.
Don't repeat same detail in different views.
Don't put figures of no account on drawings.
Don't be timid or you will soon be a door-mat.
Don't leave too much for the tracer to fix up.
Don't go into needless refinement of figures.
Don't work all the time—recreation brightens.
Don't show plan view of nuts—life's too short.
Don't, if a checker, make unnecessary changes.
Don't raise a howl when asked to make changes.
Don't forget that blacksmith work is expensive.
Don't look for snaps—they are not worth having.
Don't be afraid to acknowledge you were wrong.
Don't think the company cannot do without you.
Don't make two parts where one will do the trick.
Don't think a checker has a cinch; try it yourself.
Don't be biased; keep your mind open to conviction.
Don't hesitate to make some original investigations.
Don't forget that looks sometimes sells the machine.
Don't make new patterns when old ones can be used.
Don't scale drawings when dimensions are available.
Don't provide awkward or poor means for lubrication.
Don't be disloyal to an employer who uses you square.
Don't forget the old saw, "Experience is a dear teacher."
Don't trust set-screws to deliver much power; use a key.
Don't forget that keys sometimes have to be drifted out.
Don't hold extended conversations during working hours.
Don't section line a lead pencil drawing except free-hand.
Don't forget that a little knowledge is a dangerous thing.
Don't use cast gears for high speeds; cut teeth are better.
Don't be afraid to show enough views to make things clear.
Don't use a slide-rule for calculations which must be exact.
Don't save ink—heavy lines and bold figures are the thing.
Don't put set-screws 180 degrees apart; 90 degrees is better.
Don't give dimensions in 32nds when 8ths are close enough.
Don't put ribs in tension if they can be put in compression.

Don't put important dimensions where they may be overlooked.

Don't be without one or two good papers bearing on your work.

Don't forget what class of workmen are to handle a machine.

Don't omit minor details, it causes endless confusion and delay.

Don't put a stud where a through bolt can just as readily be used.

Don't set down dimensions from scale until you have checked them.

Don't forget that any fool can criticize, but any fool cannot do.

Don't join a $\frac{5}{8}$-inch rib on a section 3 inches or 4 inches thick.

Don't lay a thing out when you can trace it from an old drawing.

Don't put dimensions on top of lines; make them out in the open.

Don't use any other kind of note-book but the loose leaf variety.

Don't forget that most calculations are at best but approximations.

Don't worry over infinitesimals or non-essentials—eliminate them.

Don't waste your noon hour—a trip through the shop will help you.

Don't be close-fisted with your data. Swap with your associates.

Don't balk at an excursion into the unknown; it may be profitable.

Don't imagine a man falls onto success like a blind pig into a well.

Don't stay out late with the boys—a big head is not a clear head.

Don't consider strength alone—rigidity is often the prime object.

Don't draw anything without some idea of how it is going to be machined.

Don't use standard nuts on parts much adjusted—use special long ones.

Don't trust to the eye for proportions of important parts—calculate them.

Don't hesitate about changing a drawing when the design can be improved.

Don't imagine every idea you get is a new one—this earth is fairly old.

Don't forget that drop forging saves money when in sufficient quantity.

Don't forget your ideas are your own if not worked up on the company's time.

Don't be unsystematic; you may thereby be going the longest way round.

Don't accept matters of opinion when matters of fact can be clearly shown.

Don't branch off onto matters extraneous to the points under consideration.

Don't hesitate to propose improvements or new ideas—you will gain thereby.

Don't make special parts when a standard part can be made to fill the bill.

If weak in the chest, don't be a draftsman—be a surveyor or get a milk route.

Don't forget it is easier to rub out lines on paper than to change iron and steel.

Don't wear cuffs; take off your coat and roll up your sleeves—be untrammeled.

Don't forget that good judgment is often the highest court of appeal in design.

Don't forget that your view-point might be changed if you owned stock in the company.

Don't locate holes which have to be laid out, in angular measure—give the chord.

Don't put bosses on opposite sides of forged levers if it can be avoided.

Don't expect to have everything ideal; you will nearly always have to compromise.

Don't tell all you know unless it doesn't take long, in which case it is immaterial.

Don't forget that a hand pointing to an important note will catch the workman's eye.

---

* For "Don'ts" previously published in MACHINERY see: Don'ts for the Blacksmith, February, 1909; Don'ts for Inventors, January, 1909; Don'ts for Machinists, March, 1908; More Draftsmen's Don'ts, June, 1906; Hard Lines for Draftsmen, October, 1905; Practical Don'ts for Machinists, 1, June, 1905; 2, January, 1906; 3, February, 1906.

† Address: 2456 Almond St., Philadelphia, Pa.

Don't change dimensions from your figures to the checker's until you have confirmed them.

Don't forget that the tracer wants to be a draftsman, and give him a chance whenever you can.

Don't forget to consider the pattern-maker and molder—their work costs money.

Don't search all over the room for a protractor; use your tables of sines and tangents.

Don't start a job until all the requirements and available data are secured and digested.

Don't refrain from calling attention to points you know the chief would like a say-so on.

Don't put 1/16-inch and ⅛-inch finish pads where ¼-inch and ½-inch ones can be used.

Don't forget that force travels in straight lines or else produces bending stresses.

Don't forget that curved ribs are more expensive in the pattern shop than straight ones.

Don't forget that new drawings of old parts can best be made directly on the tracing cloth.

Don't forget center lines. A circle without its center lines looks like a bald-headed man.

Don't forget that the company is not running an art gallery, but a manufacturing establishment.

Don't have too much all-abiding faith in the factor of safety to cover up inadequate design.

Don't get the graphic bug (or any other) in your head to the exclusion of better methods.

Don't put a lot of cored work on a "one-casting-only" job. A little extra metal is cheaper.

Don't disregard the erector; take the machine apart and assemble it while making the drawings.

Don't use dowel pins for heavy thrusts when fitted bolts or tongues can be used to advantage.

Don't have a different tool for each different line; a few simple ones save time in the end.

Don't forget the machinist when dimensioning; his dimensions should be from finished surfaces.

Don't use an over-hung pin if it can be supported on both ends as readily.

Don't ask the chief questions you can answer yourself by second thought or by the use of your eyes.

Don't imagine rough castings come just like the drawing; they vary and you must allow for it.

Don't set down a dimension without laying your scale on it—it is a mighty good check.

Don't be given to snap judgment. Have some foundation upon which to base your opinions.

Don't imagine that all parts have to be made in your own shop. Sometimes you can do better outside.

Don't use studs when tap-bolts make the part easier to remove, unless for other good reasons.

Don't say theory when you mean hypothesis; call a thing by its right name, whatever it be.

Don't make picture drawings for the workman—when such drawings are required, hire an artist.

Don't make extra machine work on parts to save a little metal unless weight is mighty important.

Don't form the whistling habit—it annoys others and distracts your own mind from the work.

Don't, when lines are close together, make arrows so the workman cannot tell which line they go to.

Don't forget that a change of position often kicks a man out of a bad rut.

Don't say "¾-inch cored holes" or "core ¾-inch holes for ⅝-inch bolts"—say ¾-inch core.

Don't say, "drill and tap for ¾-inch gas pipe"—it makes the machinist tired. Say ¾-inch pipe tap.

Don't put special threads on the drawing until you know how they are going to be cut.

Don't forget that cores require support and vent, and that provision must also be made for clearing them out.

Don't raise objections to everything proposed—manage to see the good points also.

Don't try to impose your personal opinions on others—remember the old woman who kissed the cow.

Don't change patterns for mere personal preferences of design—the next man may change them back again.

Don't think you are the whole show—there are others who have trouble before the design is working.

Don't put all dimensions on, then all arrow heads; you are sure to miss some of the latter by this method.

Don't forget that natural functions are quicker to use than logarithmic when multiplying by even figures.

Don't make changes in a half-hearted, dispirited, sloppy manner. Make them as good as the rest of the job.

Don't make parts right and left when it can be avoided, even if some changes in the drawing are necessary.

Don't mix styles of printing; for instance, Italics and Roman, vertical and slanting, or backhand and vertical.

Don't forget that while you are young and single is the time to do your moving for a varied experience.

Don't lead ropes off the bottom of a drum when it can be avoided; they lead much better from the top.

Don't try to smoke and draw simultaneously—you don't enjoy the smoke and it interferes with your work.

Don't ask a tracer to do a job for you which takes longer to explain to him than it would to do it yourself.

Don't wait until the tracing is made before writing the bill of material; there are many good reasons for this.

Don't, unless an expert, attempt to dictate a proposal or specification without first roughly blocking it out.

Don't forget the value of free-hand sketching; it is a great aid towards securing a mental picture of what is required.

Don't waste time rubbing and redrawing which could be avoided by roughly sketching out the scheme first.

Don't commence a layout blindly when it is possible to secure a good mental picture of the requirements.

Don't forget the value of sections or little true plane projections of parts which are at an angle to the main body.

Don't put a ⅜-inch bolt or set-screw where a ⅝-inch or ¾-inch one would remove all doubt as to security.

Don't be industrious only when the chief is around, but plug away faithfully and you will some day be discovered.

Don't scoff at theory; theory is crystallized fact. There is a wide divergence between theory and hypothesis.

Don't forget to allow for the efficiency of various mechanisms; friction is often a very important factor.

Don't perform extended trigonometrical calculations when scaling a layout is sufficiently accurate and quicker.

Don't let a stop strike a moving part at a great distance from its center of percussion if it can be avoided.

Don't use abbreviations no one understands but yourself; *you* may even forget what they mean in a year or so.

Don't draw two arcs tangent for a reverse curve—they give a hump-backed appearance. Connect them by a straight line.

Don't forget the Lord did not make man with ribs on the outside of his body, and that smooth contours are pleasing.

Don't draw a moving part in a dozen different positions for clearance—trace it and shift the tracing over the layout.

Don't say, "Bore 6-inch diameter" or "6-inch diameter bored"—say bore 6-inch. (Any fool knows it is not square.)

Don't put little undercuts on castings; they seldom save much metal and cause the pattern-maker and molder lots of trouble.

Don't send a solid wheel out as a repair or additional part when it would save money in erection by having the wheel split.

Don't forget that the draftsman should be a designer, and to reach that stage he must study outside of working hours—life is short.

Don't undervalue the process of elimination when attempting to arrive at a decision where numerous factors are apparent.

Don't copy other concerns' designs; you may get your employer into trouble, and besides it is poor policy. Study designs, but don't copy.

Don't treat the shop man with contempt or disrespect; he knows a thing or two and dollars to doughnuts he's as much a man as you.

Don't destroy mechanical publications; save, at least, the articles you are interested in and file them in some way so that you can find what you are looking for.

Don't think that you know more than the chief; maybe you do on some things, but it is bad to look through glasses of that color.

Don't make shrouded pinions just a little wider than the gear; leave plenty of room, say (3/16 × pitch) + 1/4 inch on each side of gear.

Don't try to draw all of one view first, work your different views up together, thus seeing the relation of parts; this is very important.

Don't use long compound names like "Second Intermediate Shaft Bearing"—call it "bearing." Assembly drawing should show where it goes.

Don't, when given a scheme to work out, immediately try to work in something else, but make the scheme given you work if possible.

Don't use gold where clay will do; for instance, if machinery steel case-hardened answers the purpose, what is the use of using tool steel?

Don't give up in despair when ideas will not come; take a little walk out into the shop, come back and try again. It helps wonderfully sometimes.

Don't imagine a shroud has to be thick for strength; it is entirely a matter of casting. Thickness = (¼ × pitch) + ¼ inch is writer's rule.

Don't repose explicit faith in figures when things look out of proportion—you may have made an error in calculating or a wrong assumption somewhere.

Don't leave a thing just good enough, or on the ragged edge, when opportunity exists for making it positively and absolutely adequate to all requirements.

Don't spoil the entire appearance of a machine by one or two cheap details; for instance, an unsightly rough lever, or an old bent flat for a bracket.

Don't waste too much time in explaining the mental processes whereby you fell in error; although if they can quickly and clearly be shown, it lets you down easier.

Don't imagine the workman only needs measurements from the pitch line for cut bevel gears. Give outside diameter, face and pitch angle, and backing from point of tooth.

Don't be ignorant of structural design because you are in a mechanical line; many of the principles are valuable in machine design.

Don't, if a boss, imagine your men will stay just to help you out when they can do better elsewhere; if you want to keep your men make it profitable for them to stay.

Don't prohibit the use of 2- and 4-inch scales; they are as readily scaled as the 1-inch-to-the-foot drawings and are often better in every way than 1½, 3, or 6-inch scales.

Don't forget that the stub tooth, of higher angle of obliquity than the present standard, is going to be the coming thing. (It is here now, but too few persons recognize it.)

Don't go to war without arms; for instance, don't tackle a job without preparation (especially a new line of work), or go out to measure up a job without a steel scale and calipers.

Don't run an old men's home or a kindergarten; either extreme is liable to require excessive philanthropy, for the old ones die and leave you, and the young ones leave of their own account.

Don't forget that multiplication of parts costs in clerical work on orders, cost accounts, etc., besides being more parts for the erector to handle and to carry in stock, and for the user to replace.

Don't be helpless if required to do a simple mechanical job just because you are a structural man—acquire a certain amount of general knowledge; it will be very helpful even in your special line.

Don't use thin nuts where standard ones will do just as well; for thin nuts are generally made from standard ones, therefore cost more; and standard nuts avoid all doubt as to the old check-nut argument.

Don't imagine thought grooves can be readily obliterated; it is doubtful if they can ever be filled up entirely. Start a new and better groove; wear it deeper by using it oftener and thus short circuit the old path.

Don't imagine an idea to be valueless, or a man incompetent, on account of being old; old is but a comparative term, and age is a condition, not a quality. The condition may indicate certain qualities, but they vary with the individual.

Don't forget that kinetic energy varies as the square of the velocity; this fact sometimes changes the complexion of things.

Don't forget that weight varies as the cube of like dimensions and that a part twice as large as another therefore weighs eight times as much, and if rotating at the same angular velocity has $2^3 \times 2^2 = 32$ times the energy of the part one-half as large.

* * *

GOOD AND BAD DESIGNS OF OFFSET LEVERS

JOHN S. MYERS[*]

Don't make levers like Figs. 1 and 3; make them like Figs. 2 and 4, and thus avoid excessive torsional stresses and resultant deflections. The reason is as follows: On section AA, Fig. 1, the bending moment equals Pl and the torsional moment equals Pl_1; on section BB the bending moment equals Pl_2, and the torsional moment equals Pl_3. Thin rectangular pieces are not suitable for torsion, hence the form illustrated in Fig. 1 will be subject to excessive deflection as compared with Fig. 2 in which the weight of the lever is the same or even less.

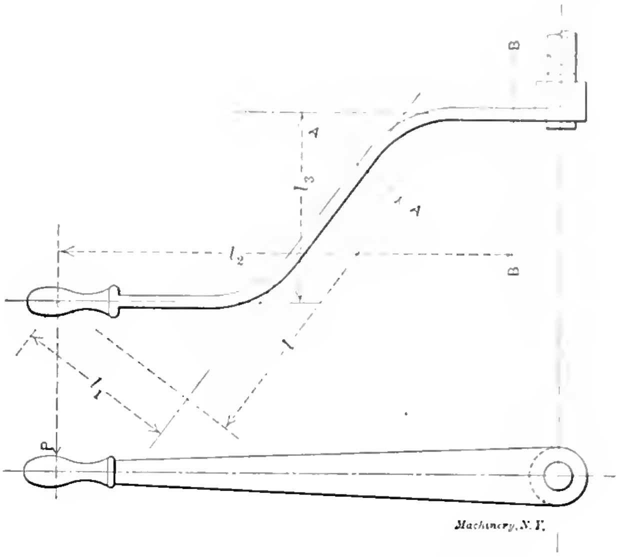

Fig. 1. Poor Design of Offset Lever; Torsional Moment High

In Fig. 2 the bending moment on section BB equals Pl, and the torsional moment equals Pl_1. The reduction in torsion in comparison with Fig. 1 is evident. With the same rectangular section Fig. 2 will not suffer the same torsional deflection as is shown in Fig. 1.

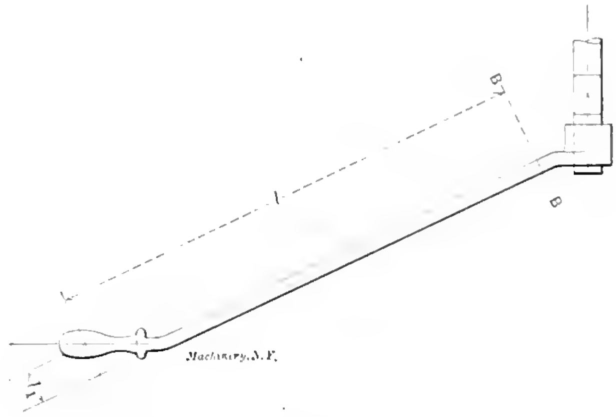

Fig. 2. Good Design of Offset Lever. Torsional Moment Low

The same principle is illustrated in the clutch lever in Figs. 3 and 4. The sections AA and A_1A_1 are each subjected to a torsional moment equal to ½ Pl in addition to a bending moment equal to ½ Wl_1. The torsional deformation causes excessive deflection and much higher fiber stresses than

---

[*] Address: 2456 Almond St., Philadelphia, Pa.

the designer is likely to anticipate, if he has not given the matter consideration.

The preferable form is that shown in Fig. 4. The sections AA and A_1A_1 are subjected to bending only, the moment on each being equal to ½ Pl. The tension in the top fibers t and t_1 in consequence requires a thrust T to balance it. This puts the top fibers of the cross-piece C in compression, and the lower fibers in tension. (See section BB.) To determine the value of T, calculate the unit stress t_1 and lay out as shown to the right. Scale off T and multiply by $b \div b_1$. The product is the unit stress in C.

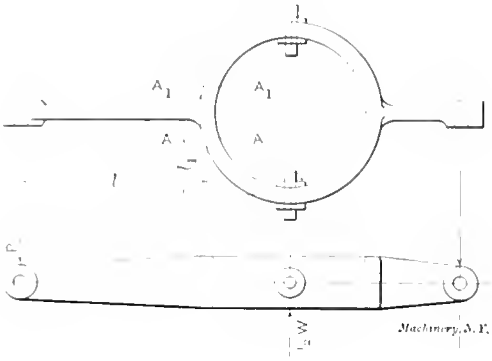

Fig. 3 Poor Design of Clutch Lever

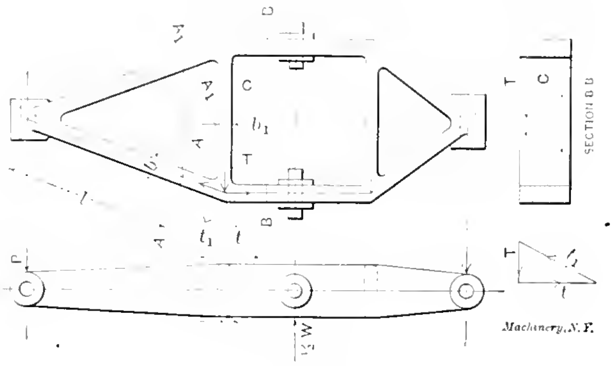

Fig. 4. Preferred Form of Clutch Lever Design

* * *

An ingenious camera has been devised for recording the speed of automobile speed violators and furnishing the evidence to convict them in court. The camera is the invention of Professors D. F. Comstock and H. T. Kalmus of the Massachusetts Institute of Technology. It comprises two plate holders and a stop watch, and is so constructed that a picture of the stop watch appears in each exposure, thus giving an automatic record of the time elapsed between each exposure. The operator takes his place on the highway where speed violators pass, within focusing distance of the road. When a speeding automobile passes a certain point, the upper plate in the camera is exposed, and the second plate is exposed at another angle as soon as possible thereafter. A simple mathematical calculation enables the exact distance traveled to be deduced, and the watch face pictures record the exact time elapsed between the two points, thus making irrefutable evidence of the speed.

* * *

No sooner had flying machines of various types become successful enough to command the attention of military experts than the latter began to busy themselves to invent means of destruction of dirigible balloons and aeroplanes. The Krupp firm has a special department devoted to the construction of guns intended for disabling air ships, and two models have been brought out, one for discharging explosive shells and another for throwing a burning projectile, and it is, perhaps, no exaggeration to say that as much genius and energy is expended on these means of destruction as is expended on the constructive work in perfecting the flying machines. This is the price great nations pay for being world powers.

EXPERIENCES OF A YOUNG TOOLMAKER

T. COVEY

After an experience of about two years in a machine shop Jim the apprentice boy had proved that there was material in him for a first class mechanic. He was able to do good work on many of the machines, and had also spent some time in the erecting room. Jim was anxious to become proficient in every branch of the trade, and therefore he hailed with delight an order to report to the toolroom foreman. From this point we will follow him for a while and see how he and the average apprentice obtains his knowledge of the trade.

Mr. Corbin, the foreman of the toolroom in which Jim was to work, was also in charge of the blacksmith shop, storehouse, and the oil room, and consequently his time was so taken up with matters that the firm considered more important, that he really was unable to devote the time and personal attention to training his apprentice boys that he would have liked to. These conditions exist in a great many of our shops throughout the country, and the natural consequence is that boys are thrown on their own resources and left to "pick up" the business as best they can; and it is a fact that they get their training mostly from the journeymen with whom they work, whose instructions are sometimes good and sometimes bad. Mr. Corbin realized this condition, and the advice that he gave to Jim could be summed up in these words: "Keep your eyes open and think for yourself; if you get stuck don't be afraid to ask questions."

Jim's first job was to make a dozen 1½-inch novo steel end-mills, with straight flutes, or teeth. He was given the stock and a finished end-mill in good condition as a sample, and was told that he could get a gage for the shanks from one of the boys that passed out tools. He was also instructed to leave the straight portion 1/32 inch large, and to allow the shanks to project 3/16 of an inch through the gage. Jim carried the stock to a vacant place on the bench and proceeded to center it. When this was done he asked the foreman what lathe he was to use, and was told to use any idle machine that was suitable for his work. He found a Hendey-Norton lathe with a taper attachment that was not in use, and went ahead with his work on that. After getting the gage out of the tool department, he tried it on the shank of the sample mill that he had been given and found that the shank projected ⅜-inch; turning to the man working next to him he remarked that he guessed that the foreman was afraid to let him turn his work to size.

"How is that?" the man asked.

"Why he told me to leave the straight portion of these mills about 1/32 inch large, and to allow the shanks to project 3/16 inch through this gage; this sample projects ⅜ inch."

"Well that is all right—we all turn them that way. It is done to leave stock for grinding after the mills are hardened. You will notice that the gage you have is marked plainly 'No. 9 Brown & Sharpe taper. Tang to project ⅜ inch.' These gages were made up to insure uniform results in making taper shanks. This is a female gage (B Fig. 1) and is made ⅛ inch longer on the large end than the standard taper; this is done to make sure that the socket will not strike on any shoulder that may be left on the shank before the taper fits properly. The male gage (A Fig. 1) of this size is made the proper length and size except that the small end is about 1/16 inch longer than the standard. If you were to try gages of this size together, you would find that the male gage was apparently too small (or the female gage too large) as it would project 1/16 inch through the small end of the female gage, and the large end of the latter would overlap the large end of the male gage ⅛ inch. But you will readily see that if a shank fitted to the female gage be placed in a socket fitted to a male gage, the small end will not go home by 1/16 inch, and there will be a portion of the shank at least ⅛ inch long extending out of the socket. (See Fig. 2.) This allows for driving the shanks in until they fit tight, and also for wear to a certain extent. I don't think you will find gages like these in every tool-room, but there should be."

"Yes, I should think they were a good thing," Jim replied. "By the way, what should the taper be for a No. 9 Brown & Sharpe shank?"

"All Brown & Sharpe tapers, except No. 10, are ½ inch to the foot. No. 10 has 0.5161 inch to the foot. Morse tapers vary from 0.600 to 0.630 inch per foot. There is a blue-print over there mounted on a board giving all the dimensions in detail for both Brown & Sharpe and Morse tapers of all sizes."

"Thank you," said Jim, "I begin to see that there is more to this job than I thought"; and he proceeded to turn up his mills without any trouble until he wanted to recess the ends. Then he went to the man again and asked: "How would you put this recess in the ends of the mills? Chuck one end and run the other in the steady-rest?"

"Well, of course you could do it that way, but there is an easier and much quicker way. All of our lathes in here are fitted with half centers (Fig. 3), and to cut out that recess you should replace the regular center with one of these half centers, placing the cut out portion toward the front of the lathe, and then use a regular boring, or hook tool to make the recess. Of course you will be cutting out the center, but when it gets too small to hold the work safely the mill can be removed and the center drilled deeper with a combination center drill and reamer. I usually face the ends of my mills and put the recess in first, because if the drill runs off a little in re-centering it is less liable to do damage."

Jim followed instructions and completed his work in the lathe. Upon looking for a milling machine in which to complete his job, he found them all in use. One man named George was nearly through and Jim asked him how much longer he would be in the machine.

"About ten minutes," said George.

"How many teeth are you cutting in that reamer?"

"Twelve."

"Good! Just what I want. I'll clean up the lathe I was using and you will be through by that time," and he was.

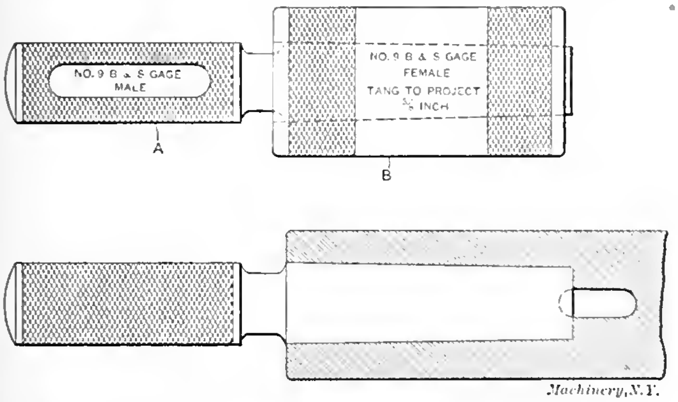

Fig. 1. The Way in which Male and Female Gages for End Mills should fit together, and Male Gage properly fitted into Socket

Jim put one of the mills in the machine, and was starting to mill the teeth when Mr. Corbin came up and said, "You should mill the tangs first then you can put the shanks in a collet, place it in the index head and mill the teeth. You would have to hold them in a collet to mill the ends, and if the tangs are not milled the shanks will not fit."

While Jim was milling the tangs he noticed that the index pin of the dividing head was in the 21-hole circle, and looking at the table he saw that for twelve divisions it gave 3 turns and 13 holes in the 39-hole circle. Going over to George, he said: "How is this? You said that you were cutting 12 teeth in that machine and the index pin is in the 21-hole circle."

"The machine is set up for twelve divisions, and I just cut twelve teeth on this reamer," said George.

"But for twelve divisions the table gives 3 turns and 13 holes in the 39-hole circle."

"Well I seldom use the table. I index in the quickest way and I don't change the index plates unless it is necessary."

"Then there must be other circles you can use instead of the ones given in the table?"

"Yes, in most cases there are."

"But how do you tell which ones they are?"

"I figure it out."

"You must be good at figures if you can do that quicker than you can look it up in the table, or change the index plates either. How do you do it?"

"Well it's simple enough when you understand it. You know that the ordinary index head is in the ratio of 40 to 1, that is, it takes 40 turns of the index handle to make one turn of the spindle. Now I'll give you the little rule I use. It will work on any index head of any ratio. You take the ratio, to 1, of the index head and put it down as the numerator of a fraction, and use the number of divisions you wish to make as the denominator, like this: 40/12. Now reduce this to a mixed number and you have 3 and 4/12. There it is, the whole number represents the number of turns; the numerator of the fraction, the number of holes and the denominator the circle. You learned at school that you could multiply or divide both terms of a fraction by the same number without changing its value. Now we will divide both terms of this fraction by 4 which reduces it to its lowest terms, or 1/3. So to get 12 divisions the index handle must be turned three and one-third times, no matter what circle you use; and it is plain that any circle having a number of holes that can be evenly divided by 3 may be used. For instance, 18 ÷ 3 = 6, or 6 holes in the 18-hole circle; 21 ÷ 3 = 7, or 7 holes in the 21-hole circle, and so on."

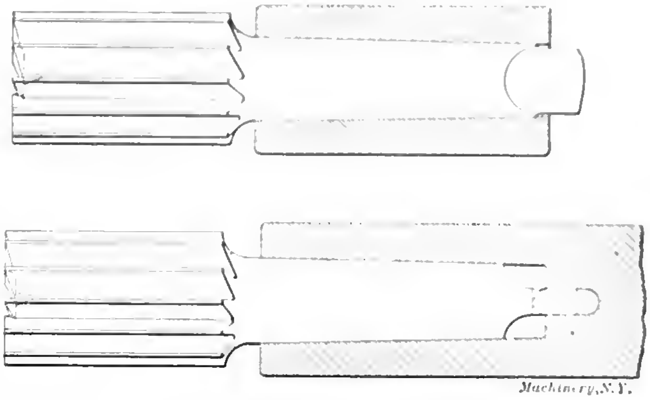

Fig. 2. Shank of an End Mill properly fitted to the Gage and Socket

"That looks easy," said Jim.

"Yes, and it is easy," replied George. "You try it every time you have a job of indexing to do, and you will soon find that you can do it without pencil and paper, and it will save you lots of time hunting up tables and changing index plates."

Jim got on fairly well in milling the teeth; only making one mistake in indexing by failing to move the marker the one-third turn. He told the foreman about it, and Mr. Corbin replied that that would not spoil the mill entirely, but he should be careful about such things. As Jim was finishing up this operation he began to think about how the machine was to be set up for milling the teeth on the ends, but could reach no satisfactory conclusion. Going over to George he said: "Say, I am a little puzzled as to how to mill the teeth on the ends of these mills. Will you kindly give me a few suggestions?"

"I'll help you all I can," said George. "What is the angle of the cutter that you used on the flutes?"

Fig. 3. Half-center for the Lathe

"I don't know," said Jim. "I took the sample mill to the window and asked for a cutter like the one used in making it."

"Well it should be 60 degrees, as that is what we use on the flutes or side teeth of practically all mills, and for cutting the teeth on the ends we generally use 70-degree cutters. The reason for this is that the teeth on the ends do not want to be as deep as they do on the sides, as the chip room would not be in proportion to the work the teeth are to do; the teeth would also be weak on the corner where the most work is done. First tip the index head up to about 75 degrees from the horizontal, but don't be particular about the setting, as you will have to make changes after taking a couple of trial cuts in order to get the lands of equal width from the outside

to the center. Tables have been figured out that will give you the angle to which the head should be set for a certain number of teeth and for a cutter of specified angle, but there are so many varying conditions affecting this angle that it would have to be a pretty elaborate table to cover them all, and even then the errors in the angles of the cutters due to grinding would be sufficient to make at least one trial cut necessary to get the correct angle. As you are cutting a right-hand mill you should get a left-hand 70-degree cutter and place it on the arbor with the side that is at right angles to the hole next to or facing the spindle of the machine. Set the saddle of the machine so that this side of the cutter is in line with the index centers. Move the table over until the index head is at the right hand side of the cutter or spindle, or loosen the head and move it along the table if necessary; then place the mill in the collet, bring it up to the cutter and revolve the index head until the edge of a tooth just comes in line with the edge of the cutter. Then move the saddle in four or five thousandths so that you will not score the teeth on the side of the mill, and take a cut, being careful not to go too deep. When one tooth is finished index for the next and take another cut. This will give you one land; if it is wider at the center than at the outer edge, tip the head up a little more and take another cut. If the index is turned so that the work revolves in the opposite direction to the hands of a watch, as you are looking down upon it, each new cut you make will give you a land true with the last change you made in the angle of the head, but if you turn it in the opposite direction, two cuts will be necessary after each change to secure a true land. After you get the land perfect note what angle the head is set to, and remember it, as you will have to swing the head back to a horizontal position each time you wish to remove a mill before you can drive it out. After the ends are milled take a file and smooth off the face of the teeth, so that they will have the appearance of matching perfectly, as it is practically impossible to match the two cuts so perfectly that no difference can be noticed, and the error always appears greater than it really is. I guess you will be able to get on all right now, and if you don't I am always willing to help you to the extent of my ability."

"Thank you," said Jim. "I think I understand it much better now."

On getting the teeth all milled and the faces smoothed off Jim took them to Mr. Corbin for his inspection.

"They are all right except that you have not marked them," said Mr. Corbin. They should be marked $1\frac{1}{2}$ inch on the large end of the shank, and the brand of steel underneath the size. Never make up a tool without marking on it plainly the brand of steel of which it is made. There are a great many different kinds of tool steel, and they are nearly all treated differently in tempering. No tool hardener can be sure of results unless he knows what steel he is handling. When you get your mills marked, turn them in and I will send them over to the blacksmith shop to be hardened."

* * *

An interesting method for producing an internal thread in castings while in the mold is referred to in a recent issue of the *Brass World*. This method can be used in cases where a good fit between the screw and the internal thread is not required and it obviates the need of tapping out the hole in the usual manner. Wire of about the same diameter as the pitch of the thread of the screw is bent in the form of a helix or spiral, with the coils closed up and inserted in the mold. The metal is cast around it and holds it firmly in place. The wire then forms a thread which will fairly well fit the screw. While this method would not answer the requirements for high-class work, it gives satisfactory service for many classes of low-grade machinery.

* * *

A fuel testing plant is being established by the Canadian government for investigating the natural fuel supplies of Canada. An important field of investigation will be that of peat, which is found in immense quantities in both Ontario and Quebec, and an attempt will be made to discover a method of using it successfully in gas producers.

DETERMINING THE ACTUAL COMPRESSION IN A SMALL GAS ENGINE

GEORGE M. STROMBECK*

Upon the proper compression of the explosive mixture in a gas engine depends the power and economy of the machine. This, together with the rapidly increasing number of gas (and gasoline) engines in the small and medium sizes, gives importance to methods of determining the compression. The simplest and most satisfactory way is by the use of a gas engine indicator which not only gives the compression, but also the force of the explosion. The compression alone can be obtained by the use of an ordinary steam gage, attached in the following manner: Next to the engine is placed a steam valve, opening into a check valve beyond which is a small air-tight chamber holding the gage. To determine the compression, run the engine, with the steam valve closed, until it is thoroughly warmed; then cut out the ignition and immediately after explosions have ceased open the valve. A few strokes of the piston will produce compression pressure in the small equalizing chamber holding the gage. The check valve serves to keep this pressure constant.

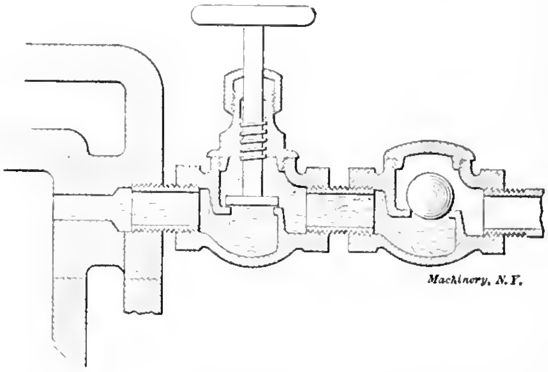

Fig. 1. When determining Compression by the Use of a Gage, Allowance should be made for the Increased Space indicated by the Shaded Portion

If neither indicator nor steam gage is at hand, a very close estimate of the compression can be made by filling the compression space (the space beyond the piston when it is nearest the head) with water, care being taken that no pockets are left containing air. The most convenient way is to either weigh or measure a quantity of water, then fill the engine and determine how much remains. The difference will give the volume of the compression space (one cubic inch of water weighs 0.577 ounce.) After thus filling an engine with water it should be run a while to prevent rusting. Gasoline may be used in place of water. To the volume of the compression space thus found add the piston displacement (the product of the area of the bore of the cylinder and the stroke). This gives the volume of the fresh charge.

It has been found that the relation between pressure and volume of a charge that is being compressed in a gas engine is very closely represented by

$$P\,V\,\sqrt[3]{V} = \text{a constant},$$

where P is absolute pressure in pounds per square inch and V is the corresponding volume. In gasoline engines the inflowing air must have a certain velocity to vaporize the gasoline. To produce this velocity requires a vacuum of two or three pounds per square inch. For this reason the pressure at the end of the suction stroke may be taken at 12 pounds above absolute vacuum. Knowing the volume and pressure at the beginning, and the volume at the end of the stroke the compression is found by use of the following equation:

$$P_1\,V_1\,\sqrt[3]{V_1} = P_2\,V_2\,\sqrt[3]{V_2}$$

$$P_2 = \frac{P_1\,V_1\,\sqrt[3]{V_1}}{V_2\,\sqrt[3]{V_2}}$$

The cube roots of the volume may be taken from a table of cube roots. From the value of P_2 thus obtained subtract 15 pounds for atmospheric pressure, and the remainder will be the compression of the engine.

---

* Address: 333 Third Ave., East Moline, Ill.

If the compression is obtained with the gas engine indicator, or steam gage, allowance must be made for the increase in the compression space due to the volume in the indicator and fittings, in one case, and steam valve and check valve as far as to the valve seat in the other case. The space beyond the check valve being sealed from the engine need not be considered. The spaces in question are shown shaded in the illustrations. That even a very little addition to the compression space will cause serious error in indicating small engines, will be shown by an example from actual practice. An engine having a bore of 4⅜ inches and a stroke of 5½ inches had a compression of 78 pounds when indicated. What was the compression with the indicator removed?

The volume of the air space in the indicator and fittings was measured with gasoline and found to be 2.3 cubic inches, which ought therefore to be added to the compression space.

Knowing the compression space in the indicator and fittings, that in the engine is readily computed as follows:

The piston displacement is

15.03 sq. in. (area of bore) × 5.5 in. (stroke) = 82.7 cu. in.

$P_1 = 12$ pounds absolute = pressure at beginning of stroke,

$P_2 = 15$ pounds (atmospheric) + 78 pounds (gage) = 93 pounds absolute = pressure at end of stroke.

Determine first the original volume of the gases compressed into the indicator. In the equation

$P_1\, v_1 \sqrt[3]{v_1} = P_2\, v_2 \sqrt[3]{v_2}$ all but v_1 are known. $v_2 = 2.3$ cubic inches = volume in indicator.

$$v_1 \sqrt[3]{v_1} = \tfrac{93}{12} \times 2.3 \sqrt[3]{2.3} = 23.5$$

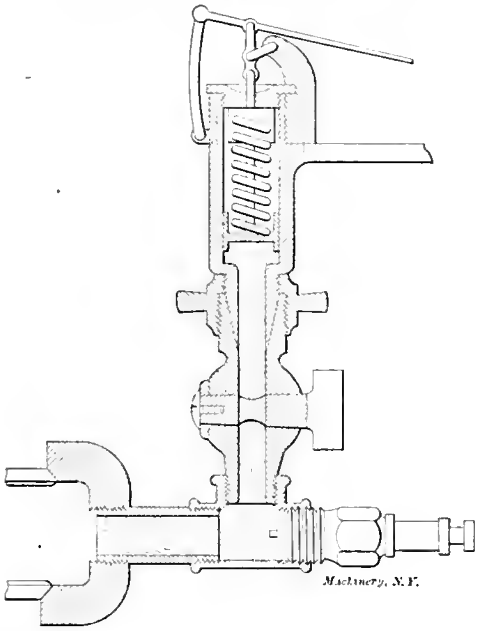

Fig. 2. When determining Compression by the Use of an Indicator, Allowance should be made for the Increased Space indicated by the Shaded Portion

From a table of cube roots pick out the number which when multiplied by its cube root will give 23.5, or

$$\sqrt[3]{v_1^4} = 23.5 \quad v_1^4 = 23.5^3 = 12{,}980$$

Extracting the square root twice $v_1 = 10.67$ cubic inches. Or solve with the aid of logarithms.

Of these 10.67 cubic inches, 10.67 — 2.3 = 8.37 cubic inches, originally occupied part of the space swept through by the piston. The rest of the gases displaced by the piston (82.7 — 8.37 = 74.33 cubic inches) must have been compressed into the normal compression space of the engine, which is the space to be determined. Since the pressure was the same in the engine as in the indicator, the relative size of the two parts of the compression space, in the engine and in the indicator, was proportional to the amount of additional gas forced into each, or

$$V_2 : v_2\ (= 2.3 \text{ cubic inches}) :: 74.33 : 8.37$$
$$V_2 = 20.4 \text{ cubic inches.}$$

By actual measurement with water and computation the compression space was placed at 20.57 cubic inches, a difference of less than one per cent from value above deduced. Having determined the normal compression space in the engine, the true compression is easily obtained:

Let $P_1 = 12$ pounds = absolute pressure at beginning.

$V_1 = 20.4$ (compression space) + 82.7 (piston displacement) = 103.1 cubic inches,

$V_2 = 20.4$ (compression space) cubic inches

Find P_2:

$$P_1 V_1 \sqrt[3]{V_1} = P_2 V_2 \sqrt[3]{V_2}$$

$$P_2 = \frac{12 \times 103.1 \sqrt[3]{103.1}}{20.4 \sqrt[3]{20.4}} = 104 \text{ pounds absolute}$$

104 — 15 = 89 pounds = true compression, which is 11 pounds higher than shown by indicator.

Fig. 1. Attachment for Automatically Starting and Stopping Bench Lathes

From this it is clear that in determining the compression by the use of an indicator or steam gage, one may be led to very erroneous conclusions unless the proper correction is made. The error will be larger, the smaller the engine or the larger the space in the indicator.

* * *

SOME INTERESTING SHOP APPLIANCES

When bench lathes are being used for turning small parts that have to be put in and taken out of the chuck by hand, the usual method of starting and stopping is by operating a belt shifter, or switch by a foot-lever. A method of starting and stopping these machines is employed in the shops of Adolph Muehlmatt of Cincinnati, whereby the control is entirely automatic. When on a job such as just outlined, the switch wires of the motor are connected at *A* and *B*, Fig. 1. As the tool carriage is pushed forward to the work, the circuit is closed at *C* and the motor starts. When the cut is finished and the carriage is drawn back, the circuit is broken and the motor stops. The long screw *D* which is adjusted by the knurled thumb-nut shown, allows the circuit to be opened or closed at any point desired.

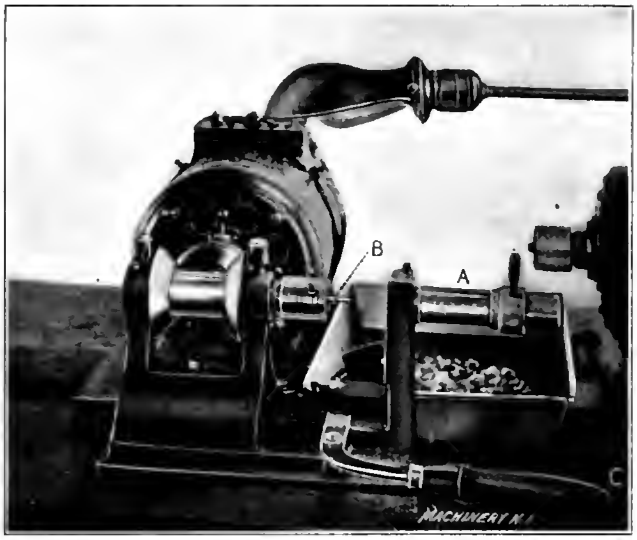

Fig. 2. Simple Form of Electrically-driven Tapping Machine

The engraving Fig. 2 shows a motor-driven tapping machine employed in these shops which will doubtless be of

interest. *A* carries a split chuck for holding the work and *C* is the lever which moves the work up to the tap. The spindle which carries the tap *B* is loose endwise so that it will not revolve either way when not in use; but, with the motor running right hand, as soon as the work is pressed against the tap, the end play of the spindle allows it to move over far enough to engage the pulley on the motor shaft and the tap is then fed into the work. By retarding the carriage the other pulley is caused to turn, and the tap is backed out. A girl can work this tool with great rapidity.

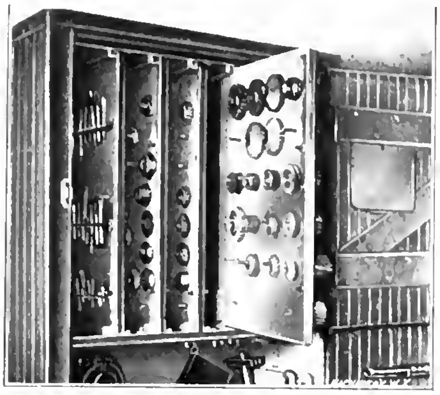

Fig. 3. A Compact Form of Cutter Cupboard

A very compact closet for milling-cutters is shown in Fig. 3. This closet has upright board partitions that slide in and out and they are hinged so that when they are pulled out against the stops they can be swung either way.

Fig. 4 shows one of the most compact batteries of small punch presses that I have ever seen. The motors and presses are all easily accessible, which is a point sometimes lost sight of in attempts to crowd a number of machines in a small space. E. V.

* * *

BOB'S BALKY PUMP

C. TUELLS

Bob was a good-natured, curly-headed apprentice boy in the best and largest machine shop in town. He had passed the days when the men used to send him to the blacksmith shop to get the teeth of a file drawn out a little longer, or to the stock room for a half-inch counterbore with a five-eighths pilot. As he was in his second year, he got fairly good work —compared with turning pulleys and snagging castings, or running errands and "chasing the broom."

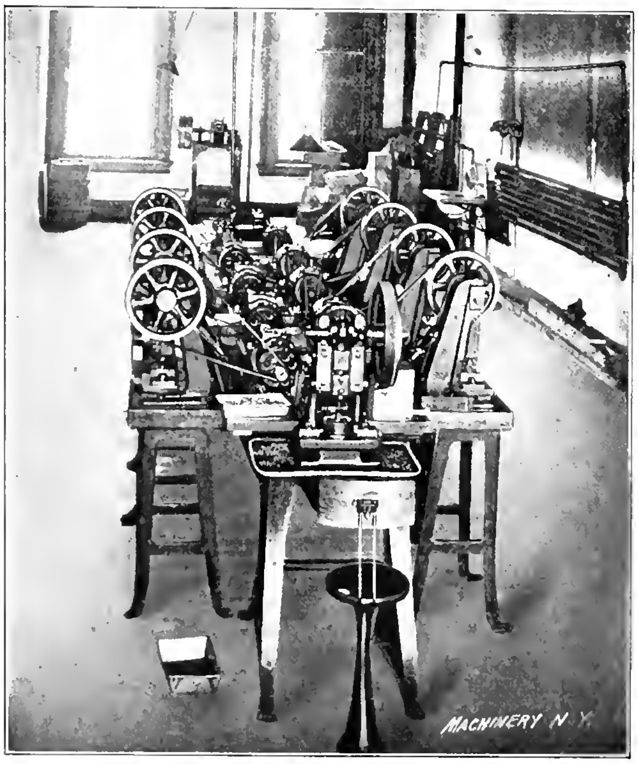

Fig. 4. A Compact Battery of Punch Presses

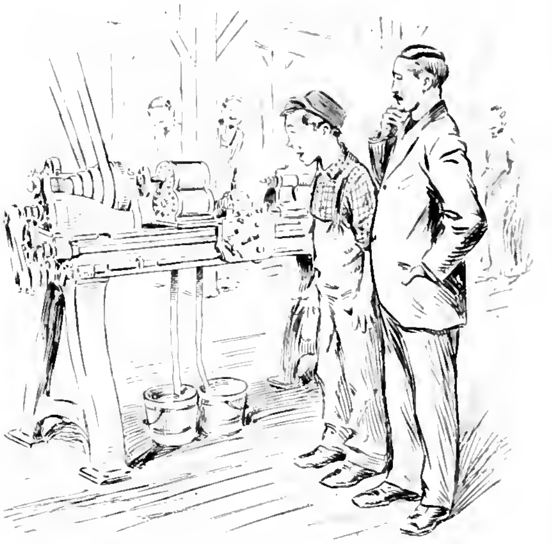
He was now at that stage of the trade where he was commencing to earn a little money for the company, for he could make a simple machine or a plain jig as well as most of the journeymen, and there was quite a difference between his thirteen cents an hour and the journeyman's thirty, which went on the right side of the books.

One day the boss brought around the blue-prints and castings for a rotary pump and gave Bob instructions how to make it. It was his first pump, so with all the vigor of ambitious youth he "waded into his job." He bored out his casting for the pump casing, turned up his gear blanks, and made his union as good and as quickly as the best of the men could do. True, he slipped up cutting one of the gears, but he hustled out a new blank, and this time his gears were cut the right number of teeth and the proper pitch.

After three or four days of interesting work his pump was completed and ready to be tested before being sent out of the shop. In "trying out" a rotary pump, it was customary to set it up on the ways of an old lathe, with the pump spindle in the chuck and the inlet and outlet pipes reaching to the floor into buckets; in this way, by starting the lathe, a bucketful of water was pumped from one bucket to the other, when everything went right.

Well, Bob got his pump set up all right, and it pumped, and pumped good, too. After pumping a few bucketfuls he shut off the power and went to get the boss to inspect the pump and see it work—his mind in that harmonious state that always accompanies a successful job.



"There was nothing doing at the outlet end, and all attempts to make it pump were in vain"

In the meantime, two of Bob's brother apprentices conceived the brilliant idea of inserting a large cork stopper in the end of the inlet pipe and pushing it up out of sight.

Bob soon came back with the boss, who, after looking it all over, ordered him to start the pump. The pump started all right, but, strange to say, there was "nothing doing" at the outlet end, much to Bob's astonishment, and all attempts to make it pump were in vain.

The boss looked dubious and Bob looked worse, but the sly glances his fellow apprentices cast in his direction were full of fiendish glee. After telling Bob to "pull her to pieces and see what's the matter" the boss left Bob to work out his own salvation. Although he took the pump apart and examined every inch of it thoroughly, he could find nothing wrong, until he tried to look through the inlet pipe—he couldn't see light. Then Bob knew what the trouble was, and another leaf was added to his book of experience.

Back together went that pump in double-quick order, and this time it worked fine and to the satisfaction of the boss. Bob's detective abilities traced the stopper to the empty bottle in his shop-mate's dinner box, and it wasn't long before he was paid back in his own coin—but that's another story.

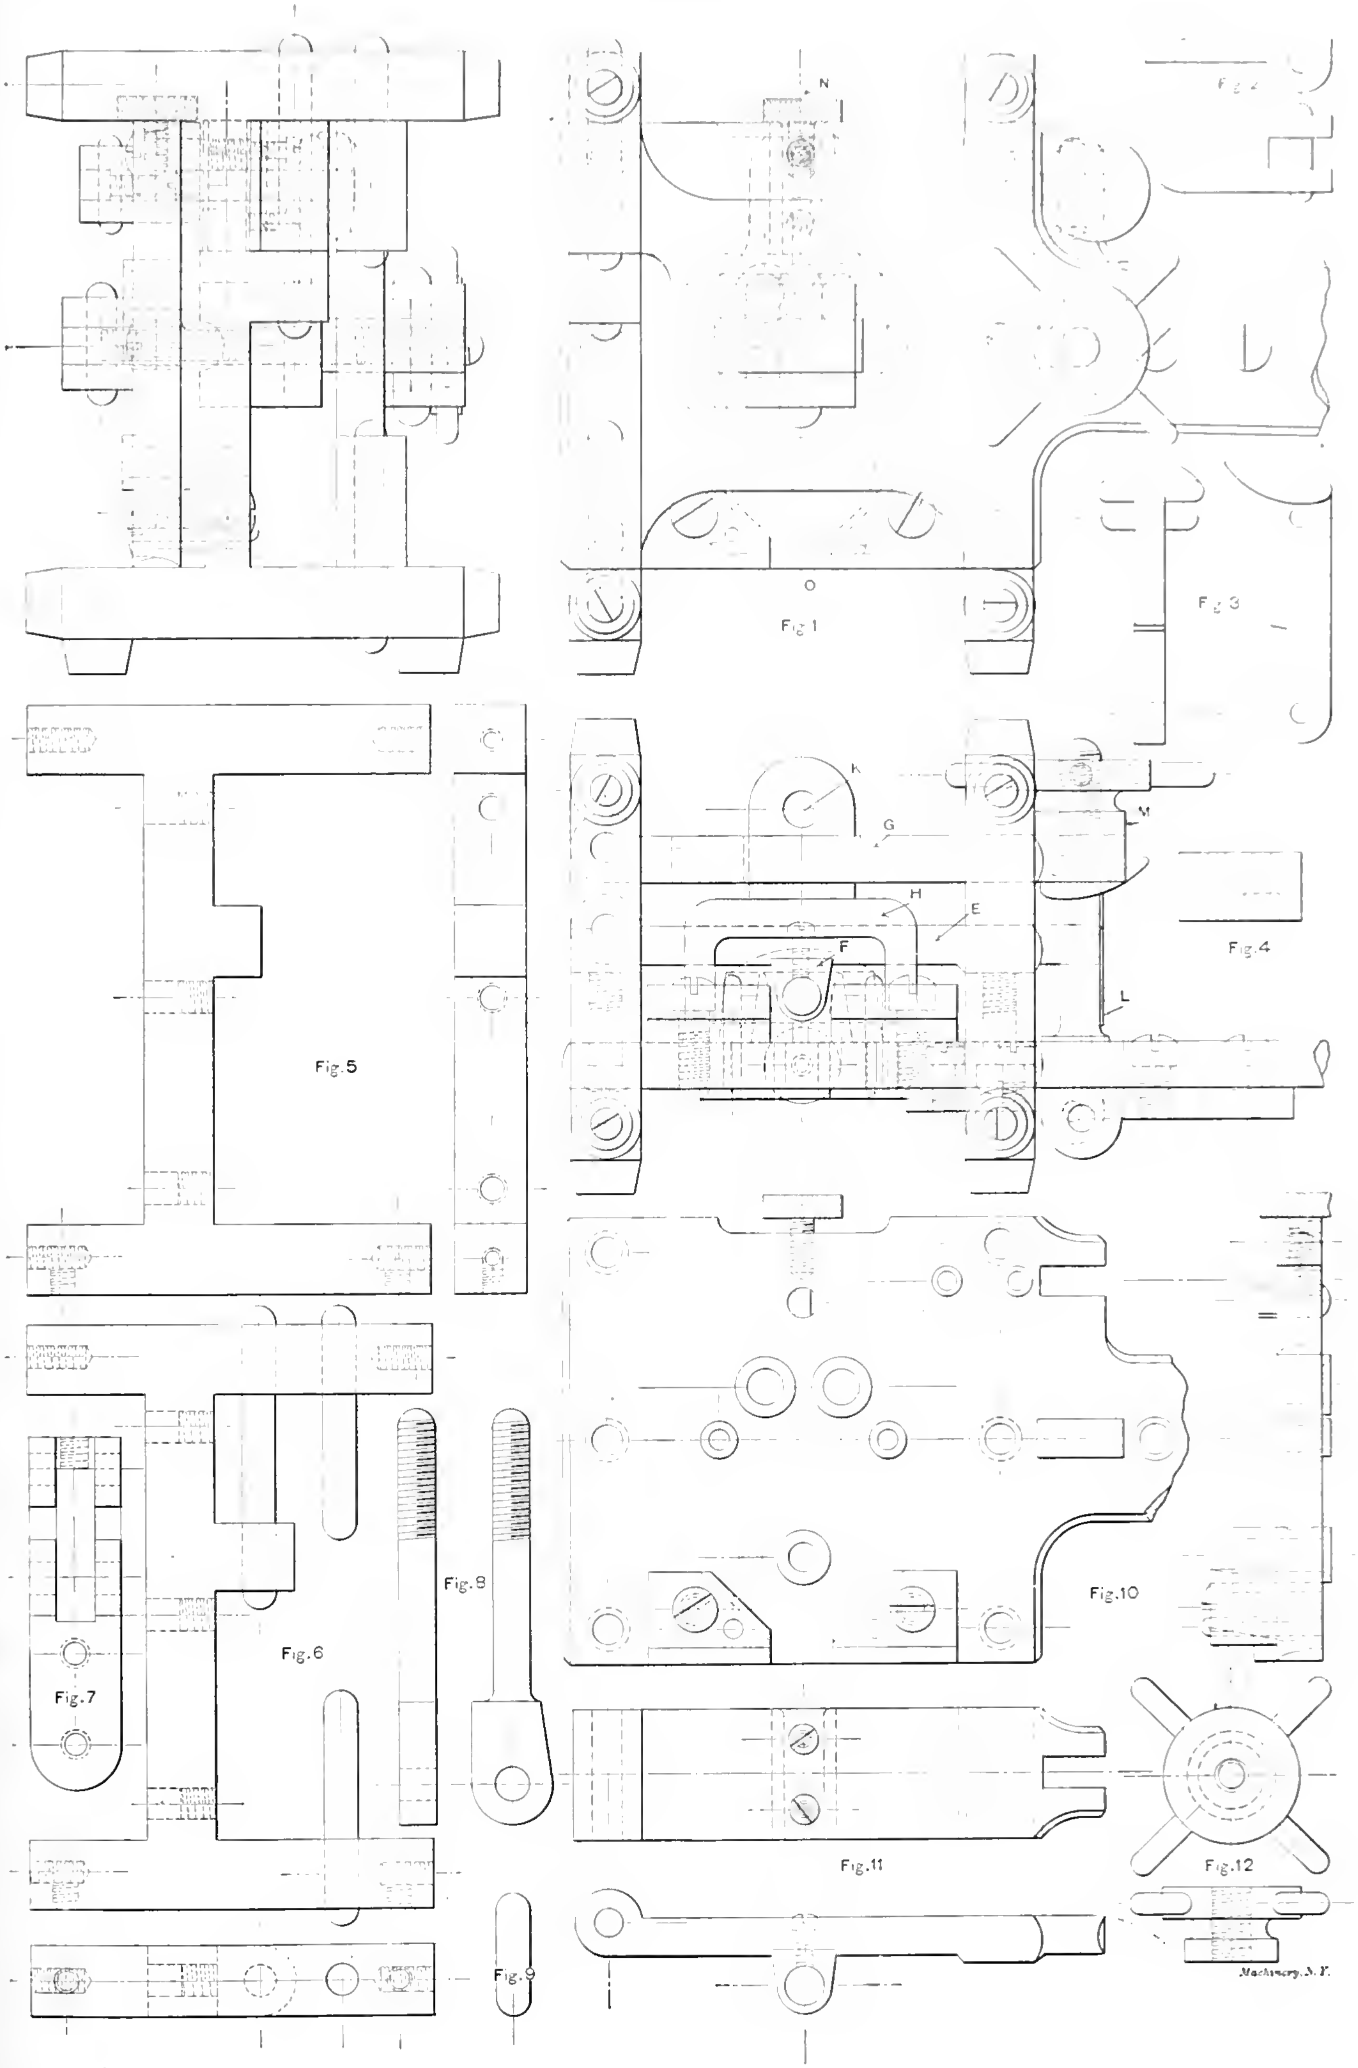
Aluminum paint is made by blowing air or gas through molten aluminum while it is setting, and at the same time stirring violently. This forms a spongy or granulated metal that is easily pulverized. The powdered metal is sized and polished in polishing mills.—*Mechanical World.*

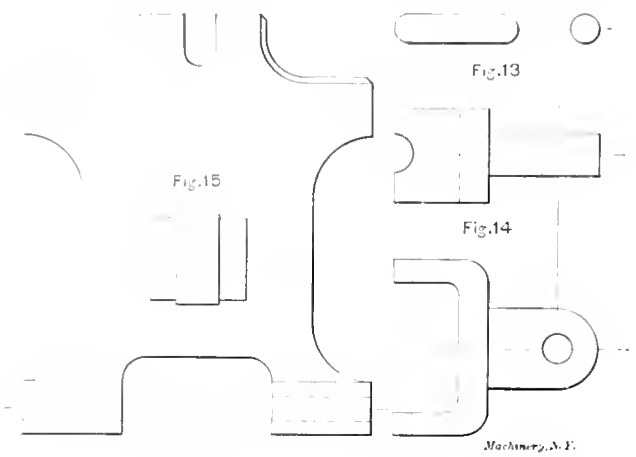


Standard Jig Design No. 4 for Manufacturing Small Interchangeable Parts. See next page

STANDARD DESIGNS OF JIGS AND FIXTURES FOR THE MANUFACTURE OF SMALL INTERCHANGEABLE PARTS—2

FRANK P. CROSBY*

In the July issue three designs of drill jigs were shown, indicating the possibility of standardizing the design of tools of this kind. In the accompanying illustrations are shown two additional jig designs, and dimensions are given for standard jig parts.

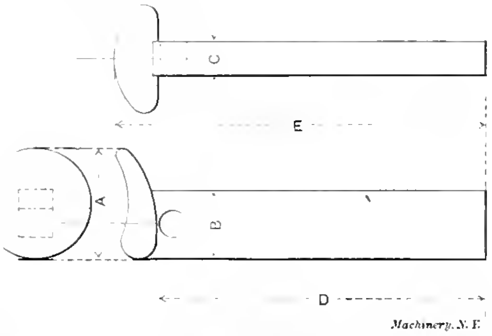


Detail of Upper Leaf and Equalizing Clamp, Jig Design No. 4

Design No. 4

The jig designated as Design No. 4 is used for drilling and hollow milling the piece shown in detail in Fig. 16. The holes *A*, *B* and *C* are drilled, and the projections *D* are hollow milled. Fig. 1 shows the assembled jig with the work in place. The work is of such a form that it necessitates an extra swinging plate *E* to hold the drill guide *F*. The top plate *G* holds the equalizing clamp *H* in position. This clamp is hinged at *K* to allow for any inequality in the castings. The lower swinging plate *E* is held in place by the latch *L*. The work is held in place by the pressure brought to bear upon it by the upper plate *G*, which is held in place by a latch which at its upper end is provided with a nut *M*. The head of a binding screw *N* forces the works against the V-block *O*, previous to closing the upper plate.

TABLE I. DIMENSIONS OF THUMB LATCHES FOR JIGS



No.	1	2	3	4	5
A	1/2	5/8	3/4	7/8	1
B	5/16	3/8	7/16	1/2	5/8
C	1/8	5/32	3/16	1/4	5/16
D	1 1/2	1 3/4	2	2 1/2	3
E	1 11/16	2	2 1/4	2 3/4	3 3/8

The various parts are plainly shown in detail. Fig. 4 is an end view of a half of the V-block showing the screw and dowel pin holes. Fig. 10 shows the lower plate with bushings, V-blocks and adjusting screw in position. Fig. 11 shows the lower leaf with its drill guide, and Fig. 15 shows the upper leaf to which the equalizing clamp is attached.

Design No. 5

The design of a drill jig for drilling and hollow milling the piece Fig. 11, Design No. 5 is shown in Fig. 1. This jig has double swinging plates the same as the previous one, but these plates both swing on the same pin. The equalizer *C* is mounted on the top of the top plate, and, as shown in Fig. 3, is provided with pins which run down and clamp the work at *D*, Fig. 1. The locating screw *E* brings the work into contact with the wall *A*, Fig. 7, and the screw *F* brings it into contact with the stop at *G*. The shoulder screw *H* prevents the lower plate from remaining down when the jig is open; the upper and lower leaves both must open simultaneously. The thumb screw *M* forces the lower plate firmly against the stop plugs *N*, Fig. 6, and prevents it from lifting during the operation of the mill. The upper leaf is finally clamped down by the swinging bolt *J*, provided with a knurled nut *K*. Fig. 7 shows the lower plate with its bushings and holding plugs in place, while Figs. 8 and 13 show the upper and lower plates or leaves. The other details are of the same standard form as used for the jig designs previously described.

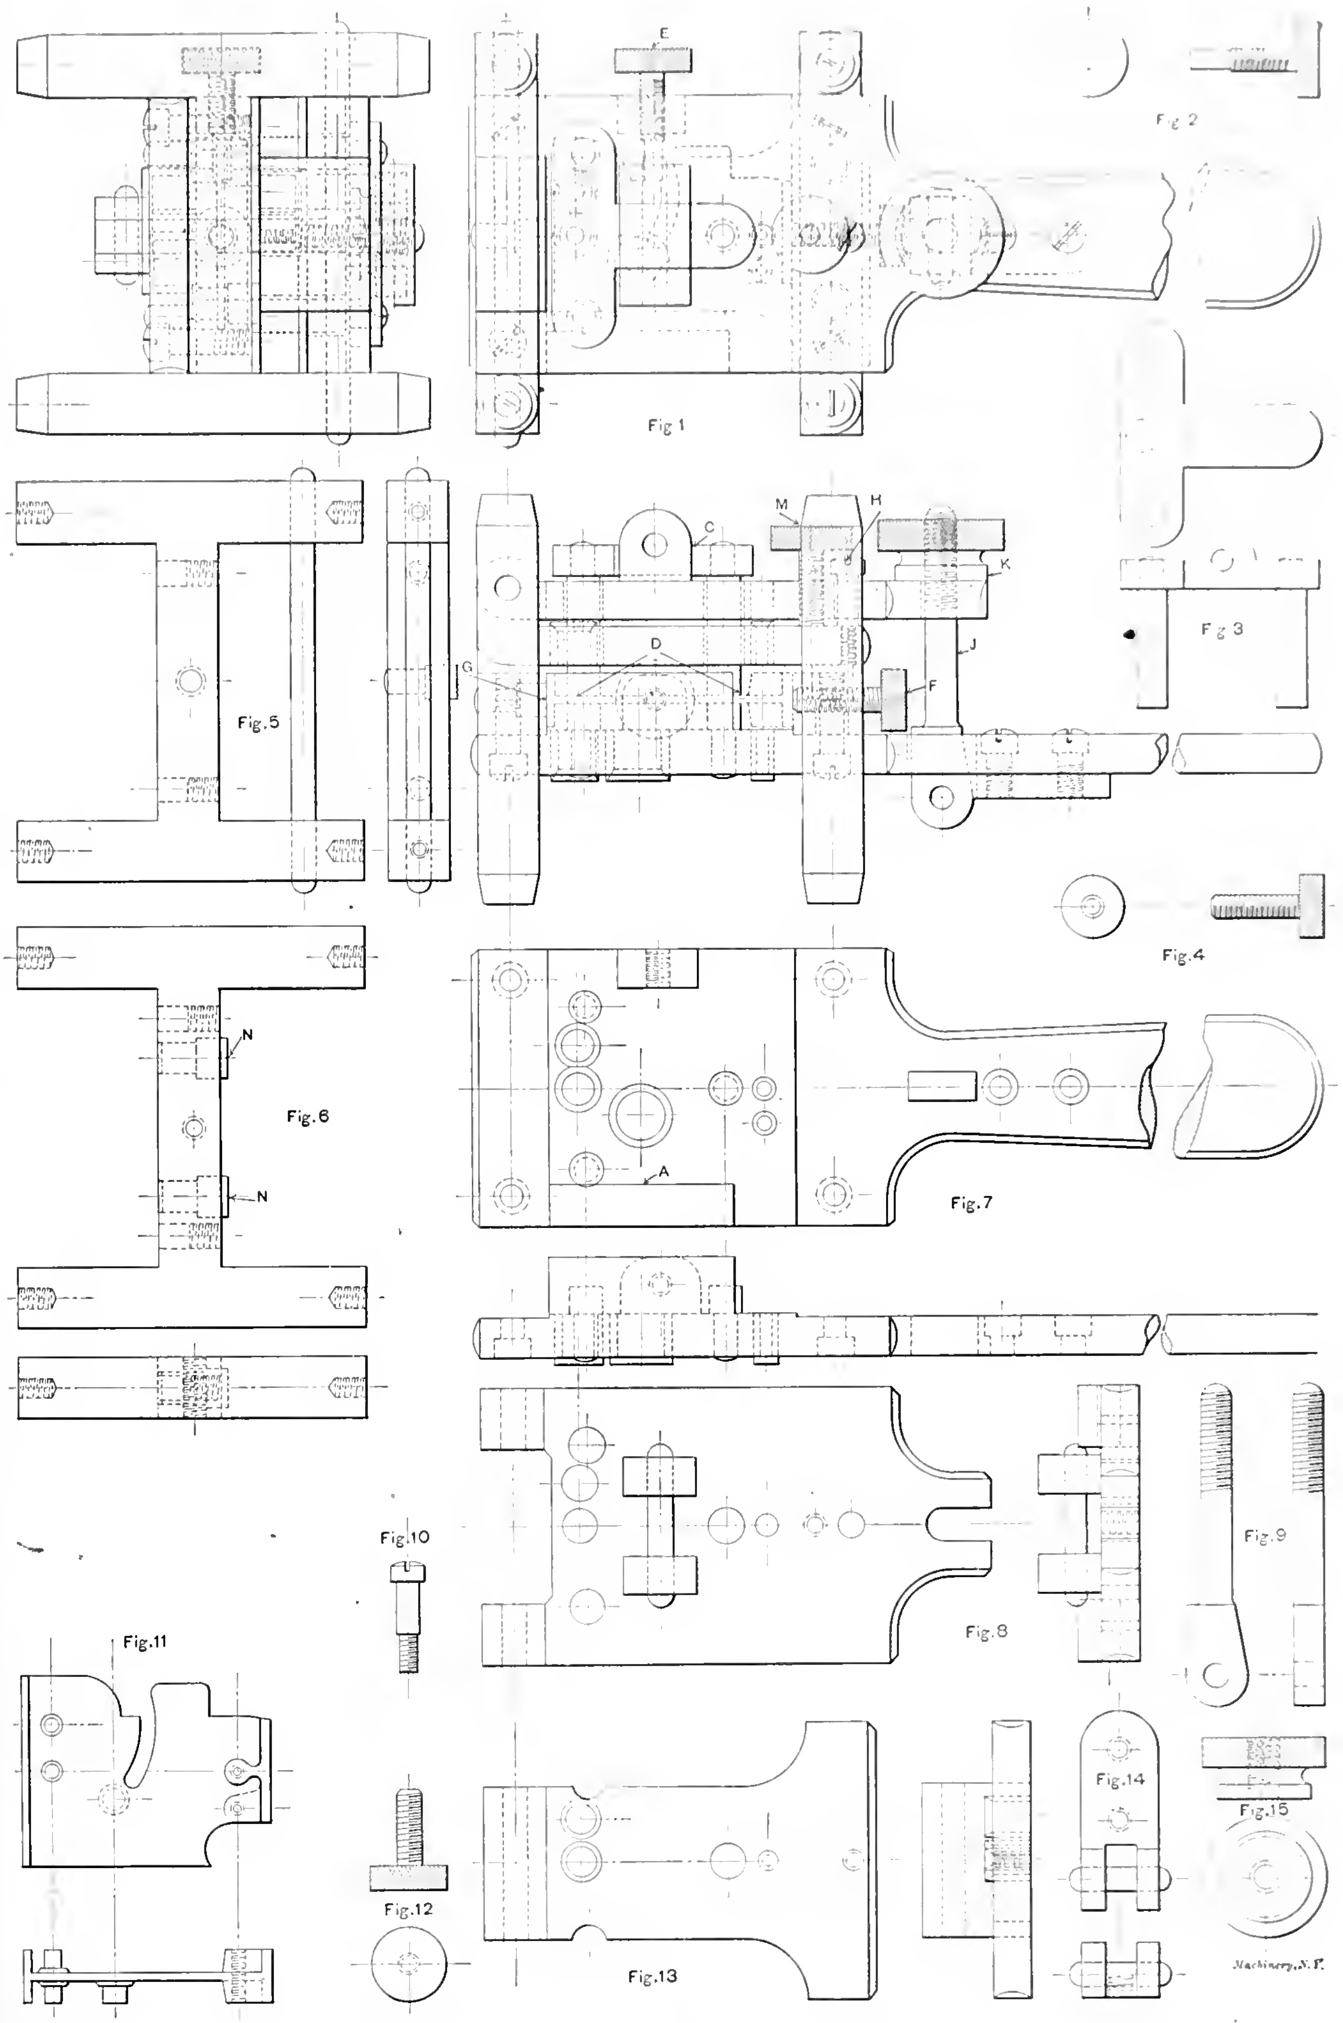
Standard Parts for Jigs

The accompanying tables give dimensions for a number of standard jig parts which can advantageously be kept in stock

---

* Address: 43 North State Street, Chicago, Ill.



Standard Jig Design No. 5 for Manufacturing Small Interchangeable Parts

ready for use. A great saving in the expense for jigs and fixtures will result if jigs are made up along the lines of the standard designs shown, and standard parts kept on hand, these parts being made up in quantities. Of course, it is understood that it may not be possible to adapt the jig details tabulated to all classes of work. The designer must make his own standard to suit the work on which he is employed, but the dimensions given have been found to work well on small interchangeable work, and the main point to be impressed upon the jig designer is that a system can be devised for standardizing the general design of jigs, as well as the details used.

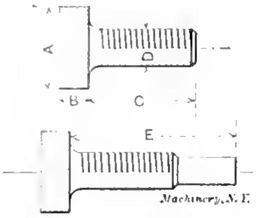


TABLE V. KNURLED HEAD THUMB SCREWS

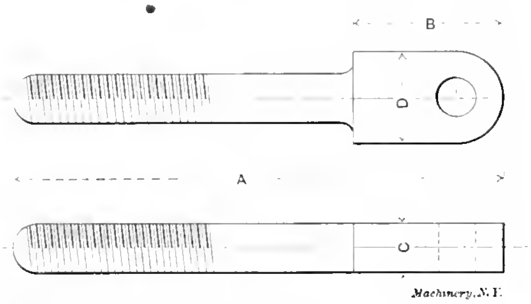
No.	1	2	3	4	5	6
A	$\frac{1}{2}$	$\frac{9}{16}$	$\frac{5}{8}$	$\frac{11}{16}$	$\frac{3}{4}$	$\frac{7}{8}$
B	$\frac{3}{32}$	$\frac{5}{32}$	$\frac{3}{16}$	$\frac{7}{32}$	$\frac{1}{4}$	$\frac{5}{16}$
C	$\frac{1}{2}$	$\frac{5}{8}$	$\frac{3}{4}$	$\frac{7}{8}$	1	$1\frac{1}{8}$
D	$\frac{1}{8}$	$\frac{5}{32}$	$\frac{3}{16}$	$\frac{1}{4}$	$\frac{5}{16}$	$\frac{3}{8}$
E	$\frac{3}{4}$	$\frac{15}{16}$	$1\frac{1}{8}$	$1\frac{5}{16}$	$1\frac{1}{2}$	$1\frac{3}{4}$

TABLE VI. DIMENSIONS OF JIG SCREW LATCHES



No.	1	2	3	4	5	6
A	$1\frac{1}{4}$	$1\frac{3}{4}$	$2\frac{3}{8}$	$2\frac{7}{8}$	$3\frac{1}{2}$	$4\frac{1}{8}$
B	$\frac{3}{8}$	$\frac{1}{2}$	$\frac{3}{4}$	$\frac{7}{8}$	1	$1\frac{1}{4}$
C	$\frac{1}{8}$	$\frac{5}{32}$	$\frac{3}{16}$	$\frac{1}{4}$	$\frac{5}{16}$	$\frac{3}{8}$
D	$\frac{5}{16}$	$\frac{3}{8}$	$\frac{7}{16}$	$\frac{1}{2}$	$\frac{5}{8}$	$\frac{3}{4}$

But little is necessary to say in explanation of the tables. The latch holders in Table II should be made of machine steel, case-hardened and the pin hole lapped to fit the pin with a close sliding fit. The latch holder pins and the latch pins in Tables III and IV are made of tool steel and hardened. The knurled head thumb screws in Table V should only be used for clamping when a light pressure is required. The latch nuts in Table VII are made of machine steel and case-hardened. The pins in Table VIII are made of machine steel and left soft. The screws for the jig feet, Table X, are not standard screws. The diameter *A* is smaller than regular, and the length of the head is also less.

* * *

A correspondent to the *Pittsburg Dispatch* states that Hankow, China, possesses a large modern steel plant, employing, in all, 20,000 people, only twenty of whom are Europeans. The latter largely do the designing and engineering work, while the Chinese carry on the work in the steel mills and the shops entirely by themselves. The wages are very low; steel mill rollers are paid from $4 to $6 per month and helpers from $4 to $5. Blacksmiths are better paid, and receive up to $20 per month if exceptionally skilled, while boiler-makers may get up to $10. Common unskilled labor is paid 7½ cents a day. Unskilled men are paid off in full each night, and are hired anew each morning.

EFFECTIVE FLOATING REAMER HOLDER USED BY THE LANDIS TOOL CO.

Only in recent years has it been considered practicable to finish ream holes in the machine on which the hole is roughed out. It has always been the customary practice to bore and rough ream in the machine and finish ream by hand, holding the work in a vise or a special reaming stand. The difficulty in machine reaming has been that of properly holding the reamer so that it will cut from the side of the hole the infinitesimal amount desired. If the reamer is not held properly, either it will not finish the hole out, leaving the marks of the roughing reamer on one side, or it will dig in and break the blades or cause other damage.

The problem of machine reaming is then one of devising a suitable reamer holder. This must be of the "floating type," so that the cutting edge is guided by the hole itself, otherwise it will not center itself properly with the rough reamed surface. About the best thing in this line the writer has previously seen is the holder used by the Bullard Machine Tool Co., in which the reamer is fed through the hole by a loose joint connection with the arbor near the front end of the body. The arbor itself is provided with a loose drive at the rear end, where it is connected with the holder in the turret. By pivoting the reamer body at the front end in this way, it is in effect *drawn* through the hole, which thus guides it in a way superior even to the best hand reaming. The holder

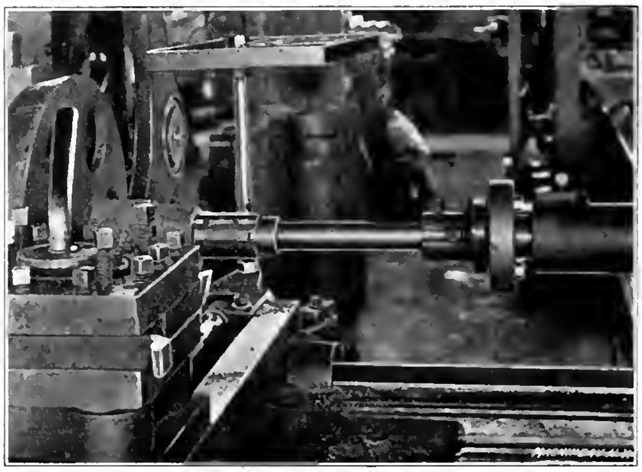

Fig. 1. Floating Reamer Holder for Turret Lathe Use, Guided by Adjustable Center

shown herewith was developed by Mr. Steiner, superintendent of the Landis Tool Co., of Waynesboro, Pa.; besides being of the floating type, it is so arranged that it can be used with reamers much smaller than in the design just described, adapting it to all kinds of work, both large and small.

The tool is shown at work in a Gisholt turret lathe in Fig. 1, while Fig. 2 shows a section of the holder and plainly illustrates its construction. The reamer at *A* is held in the taper socket *B*, which is, in turn, firmly threaded into the flange *C*. The body of the tool *D* is carried in a taper tool holder *E*, mounted in the turret of the machine. In a recess in *D* is contained the floating center holder *F*. Two screws *G* (only one of them is shown) are tapped into *F* from the back side of *D*, passing through holes large enough to allow a slight adjustment in any direction. With this provision center *H* may be accurately lined up with a similar, truly-ground center, mounted in the spindle of the machine. Four screws, of which one is shown at *K*, assist in this centering operation.

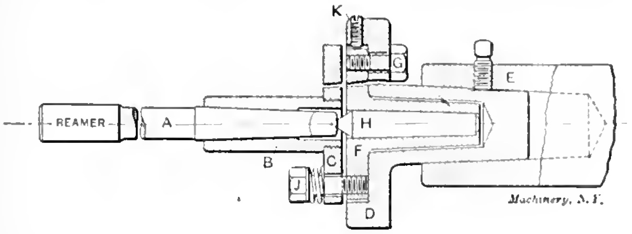

Fig 2 Section through Reamer Holder, showing Details of Construction

When the two points are in line, screws *G* are tightened down, thus holding the adjustment. Reamer *A* has its center hole supported on the point of center *H*, being drawn onto it by two screws, of which one is shown at *J*. These screws pass through clearance holes in *C* and press upon it, through the medium of springs as shown, thus allowing reamer *A* to find its own center without interference.

Besides using reamers from the largest to the smallest sizes, as previously mentioned, this arrangement has the added advantage of straightening out the holes it reams, at the same time that it follows them. It is supported at the back on a center which has been adjusted concentric with the axis of the spindle, about which the work revolves and is supported. If the hole, in spite of the boring and rough reaming operations, is not quite parallel with the axis of rotation, the tendency of this reamer, supported on center *H* as it is, is to correct such slight errors, and bring the bore back into the proper center line. HOW TO FIND INCLUDED ANGLE OF INLET AND EXHAUST CAMS

A. F. M.

Much has been written about the laying out of cams, but one reads little about the mathematical calculation of cams. The simple formula given below saves the designer the work of laying out the included angle of inlet and exhaust cams of gas engines. In laying out this angle some small inaccuracies very often occur, and it is, therefore, of special advantage to be able to calculate this angle; when desired, a layout can be used to check the result. The angle in question, shown at c in the illustration, necessarily must be correct, or a more or less incorrect opening and closing of the valves will result. Angle a represents the angle on the cam shaft, during which the valve is open. R and R_1 are the radii of the cam base circle and the cam roller, respectively, while C is the clearance between the plunger and valve stem. Then the distance between the center of the cam and the center of the roller at the moment of the opening of the valve equals $R + R_1 + C$. Assuming a line drawn from N parallel to AB, and extending MB, we get the right triangle MNP, in which

$$MN = R + R_1 + C \text{ and } MP = R + R_1.$$

Then,

$$\cos b = \frac{R + R_1}{R + R_1 + C} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

But $d = 90° - \frac{1}{2}a - b$, and $d = \frac{1}{2}c$; therefore $\frac{1}{2}c = 90° - \frac{1}{2}a - b$, and

$$c = 180 - a - 2b \quad \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

In case no clearance between cam and roller is allowed, Then $C = 0$, and

$$\cos b = \frac{R + R_1}{R + R_1 + 0} = 1, \text{ and } b = 0$$

This value of b substituted in formula (2) gives

$$c = 180 - a$$

Suppose we want to find the value of angle c for an exhaust cam which should keep the valve open during 240 degrees, measured on the crank-shaft. This corresponds to 120 degrees on the cam circle. Let the base circle of said cam be 2 inches and the roller $1\frac{1}{2}$ inch in diameter. The clearance is 1/16 inch. Then $a = 120$ degrees, $R = 1$ inch, $R_1 = \frac{3}{4}$ inch, $C = 1/16$ inch.

Substituting these values in formula (1) we get:

$$\cos b = \frac{1 + \frac{3}{4}}{1 + \frac{3}{4} + 1/16} = \frac{28}{29} = 0.9655; \quad b = 15 \text{ degrees } 5 \text{ minutes.}$$

Substituting this value of b in formula (2)

$$c = 180 - 120° - 30° 10' = 29 \text{ degrees } 50 \text{ minutes.}$$

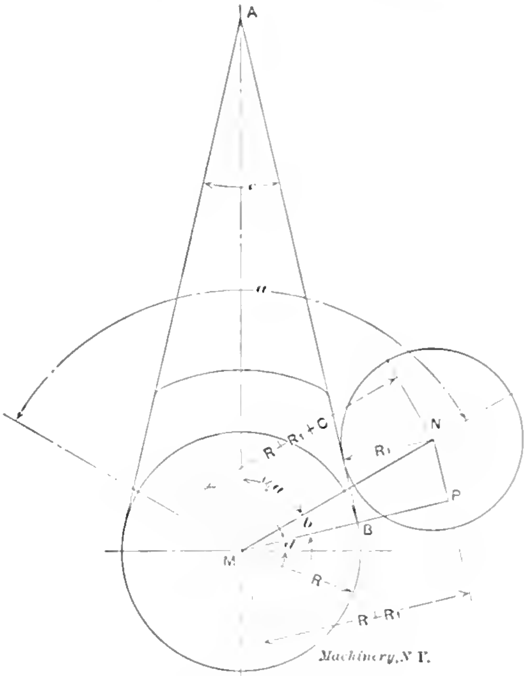

Diagram illustrating the Method of Calculating Included Angle of Inlet and Exhaust Cams

These formulas are correct only for a valve mechanism in which the center line of the valve plunger passes through the center of the cam shaft. In case the valve plunger is offset (to diminish side thrust), an irregular cam will result. This is mentioned only to avoid any possible misapplication of the formula.

* * *

As has been previously stated in these columns, extensive use will be made of blast furnace gases for power production at the new steel works at Gary, Ind. With the sixteen furnaces in operation it is estimated that 44,800,000 cubic feet of gas will be produced daily, and of this over one-half will be used for power generating purposes. Part of this will be required for the blowing engines and about 45 per cent of the total available gas will be used for power. With the sixteen furnaces in blast, it will be possible to generate in this way over 200,000 H. P.

* * *

According to the *Scientific American*, a new form of arc lamp has been devised in which carbon disks are used instead of carbon rods. The disks are constantly rotated, and the arc takes place between their peripheries; owing to the continuous rotation, the disks are consumed uniformly. The lamps are small as compared to the ordinary type of arc lamps, and it is claimed that a lamp of this type will burn fifty per cent longer than lamps of the rod type.

MACHINERY

DESIGN CONSTRUCTION- OPERATION.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,

49-55 LAFAYETTE STREET, CORNER OF LEONARD,
NEW YORK CITY.

Alexander Luchars, President and Treasurer.
Matthew J. O'Neill, Secretary.

Fred E. Rogers, Editor.
Ralph E. Flanders, Erik Oberg, Franklin D. Jones, Ethan Viall,
Associate Editors.

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit exclusive contributions from practical men on subjects pertaining to machine shop practice and machine design. All accepted matter is paid for at our regular space rates unless other terms are agreed on. All copy must reach us by the 5th of the month preceding publication.

AUGUST, 1909

PAID CIRCULATION FOR JULY, 1909, 20,499 COPIES

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 650 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

CURVES VS. TABLES

The presentation of certain data in the form of curve diagrams, of the Cartesian coordinate form, is advantageous for several reasons. First, in a curve there may be an infinite number of intersections of ordinates and abscissae, and therefore of values within the limits of the diagram; whereas a table is limited to the precise values given, and interpolation in any but tables agreeing with straight line curves must of necessity be inaccurate unless calculated by the curve formula. Again, plotted curves clearly indicate the rate of change, and values plotted outside the limits of the diagram can be estimated or calculated with precision when the curve can be expressed by an equation. Hence, it is not strange that the plotting of curves is a common and generally acceptable method of graphically showing a great and varied mass of engineering data.

But we find curves used for data when they are not properly applicable to the case. When certain exact data have been determined and accepted, the use of curves for the drafting room or shop is not so desirable as ordinary tables. For example, take the case of pipe thread dimensions: these data were recently submitted to us in a diagram of curves, the contributor being under the impression, evidently, that the curves possess some advantages over the usual pipe thread table. Obviously, the reading of precise values, that is, to thousandths of an inch, is impossible on an ordinary diagram. A toolmaker given the job of making gages for pipe fittings would have absolutely no use for the diagram; what he needs is the table of precise values reading to thousandths. So it is with all screw tables and much other data in which all values of a series between limits have been precisely determined.

Curves have their use in the derivation of such data when a series of values are being tentatively determined. Having given the dimensions of the largest and smallest sizes, and perhaps of one or more intermediate sizes, a curve may be drawn and the other values approximately found without calculation. For illustration, suppose that a special list of thread pitches is to be laid out for certain fittings ranging in size from one inch to ten inches diameter, the sizes varying by half inches. Having given the data for the largest and smallest and one or more intermediate sizes, the curves drawn through the intersections with the ordinates and abscissae will express the intermediate pitches for each desired size. The approximate values will be changed, of course, in most cases to make them read to the nearest even figures. The values once having been determined and crystallized, so to speak, the use for the curves disappears.

THE PSYCHOLOGY OF MAGNIFIED DIMENSIONS

Not many years ago the micrometer was an unknown instrument of measurement, and is still comparatively unused outside of manufacturing plants producing parts on the interchangeable plan. The steel scale graduated in sixty-fourths of an inch is a gage by which the large majority of mechanics make all their measurements from the coarsest to the finest, and for most of them measurements made with the steel scale generally answer practical purposes. The machinist who is able to fit a locomotive axle or crank-pin, making the proper estimate for a press fit of 50 to 100 tons, depending on the diameter, by the use of outside and inside calipers, and gaging the allowances by the difference on a steel scale, has a "good eye" and good judgment.

While these measurements may vary slightly day by day, the average is surprisingly accurate and leaves little to be desired. But ordinarily it takes the common man several years before his fingers and eyes acquire the sensitiveness that makes his estimates uniformly reliable. Give the same man a micrometer, and under proper direction he will learn to make more accurate measurements in a few months than is possible with years of experience with the calipers and scale. The reason is simply magnification of differences. The ratio on the ordinary micrometer barrel is about sixty to one, thousandths of an inch between the anvils being about one-sixteenth inch on the barrel. An apparent difference of one-sixteenth inch from the measurement desired is an amount that even a tyro will not ignore when he knows how to use the micrometer, and realizes that it is an instrument of touch rather than a C-clamp.

The principle of magnification of small dimensions is common in the apparatus used in scientific and mechanical work, and is accepted by all users as a matter of course, but we suspect that most users of such instruments never quite realize the extent of the impression made by small values through this principle of magnifying them. A new pyrometer recently described in these columns carries the principle to an extreme, fractions of a degree of temperature difference being expressed by the needle swinging over a large portion of the visible arc of action. The effect of minute differences of temperature indications on the attendant when shown by so great a movement of the pointer is very marked. He cannot ignore, if he would by reason of ordinary slothfulness, differences that on an ordinary indicator would be almost imperceptible, and therefore negligible.

* * *

An interesting observation has been made in connection with tempering of hardened tools in electrically heated baths. It was found that the obtaining of a certain tempering color is not a function of the temperature only, but that time also is an important factor. As an example it may be mentioned that a dark blue was produced by heating an object either to 200 degrees C. (392 degrees F.) for four minutes, or to 350 degrees C. (662 degrees F.) for one minute. This statement was made in an exhaustive paper on electric hardening and tempering by Messrs. E. Sabersky and E. Adler, read before the Faraday Society (Great Britain), and if correct practically upsets the generally accepted idea that tempering colors are dependent solely on temperatures. Whether the color determines the degree of temper of the tool or not is not stated; most likely it does, but it might be conceived that the time factor influences the degree of temper also. Experiments along this line should be of great value, and may lead to a new conception of the tempering process.

CARRIAGE-BOLT SCREW THREADS

On the "How and Why" page of this number are certain data on carriage bolt screw threads, shanks, and heads, that doubtless will be of interest and value to a considerable number of tool- and die-makers, but for the screw thread part, we feel an apology is required. We do not mean an apology for our presentation of the matter, but for the existence of such an anomalous form. Carriage and loom bolts are used in great quantities, but strange to say, the screw threads as made by the largest concerns are bastard forms, not easily reproduced, and for which there is no commonly recognized standard. A few concerns using large quantities of carriage bolts specify the United States standard thread and pitches, and one maker at least recommends them, but why the demand for the recognized standard has not become universal is somewhat of a mystery. Perhaps the approximately square carriage-bolt thread has an advantage over the United States standard thread when driven through a closely fitted hole in wood, in not having so great a tendency to tear and damage the wood, but it is easily damaged and hard to repair. Other disadvantages outweigh the feature named, and it should have been discarded long ago.

The vogue of the carriage-bolt threads may be largely due to the conservative policy of manufacturers who have maintained them because of the mistaken belief that the obscure forms tend to discourage competition. Such a petty business principle is out of place in modern manufacturing, and is of little avail. A screw thread, gear tooth or profile of any description, no matter how irregular, can be copied by an expert tool-maker; such work is done daily, and an odd screw thread offers little discouragement to the copyist if there is assurance of profit. Let the irregular and difficult carriage screw threads be relegated to the limbo of forgotten things; and when they are discarded we shall score another triumph for standardization.

* * *

LOCATING DEFECTS IN MECHANISM

The ability to quickly locate defects in machinery is possessed by comparatively few men. Competent engineers and mechanics, having years of experience, often, when trouble is encountered, find it necessary to send for an "expert" to solve what appears to be a great mystery. In many instances, the real reason why engineers and others are unable to locate simple mechanical defects is because they at once jump at the conclusion that the trouble is due to something complex and mysterious. As every mechanic knows, the disarrangement of some small part will often render a piece of mechanism inoperative or greatly impair its efficiency; but as a rule the seat of the trouble can be located by a careful and systematic inspection. Such inspection however is often not made because of a sort of superstitious belief that any trouble which is unusual must be the result of something mysterious, and this belief is always augmented when attempts are made to locate the defect by haphazard methods. It is a common experience of men sent out by manufacturers to locate and remedy trouble in machinery to find simple causes —so simple sometimes as to make the call for help ridiculous.

The chief engineer of a large plant discovered, upon starting an air compressor which had been idle for some time, that it would only compress to twenty pounds, which was sixty pounds below the required pressure. After a few futile attempts had been made to remedy the trouble, the manufacturer was notified by wire to send an "expert." In order to appreciate the situation a brief description of the construction of the compressor is necessary. This machine had two single-acting air cylinders, the plungers of which were connected to the ends of a piston-rod common to both, which passed through the steam cylinder located midway between the two air cylinders. The inner ends of the air cylinders were open, exposing the plungers. One suction and one discharge valve was used for each cylinder. The suction valves were located in the centers of the plungers, and the discharge valves, which were slightly larger in diameter than the bore of the cylinders, covered the outer ends of the latter. The counterbore into the bottom of which each discharge valve seated, was sealed by the cylinder head. A cylindrical projection on the back of each discharge valve, was a sliding fit in the head, and served to keep the valve in position as it moved back and forth. In order to insure a pressure of one atmosphere in the cylinder at the beginning of the compression stroke, three small holes were drilled through the cylinder wall, just ahead of the plunger when it was in this position. As these holes were uncovered just before the end of the suction stroke, an inrush of air occurred, the magnitude of which depended largely upon the stiffness of the closing springs for the suction valves. When the manufacturer's "expert" arrived and the compressor was started, it was very noticeable that instead of an inrush of air through the holes of one cylinder, there was a strong discharge to which attention was attracted by the sound emitted. This indicated at once that the cylinder was in communication with the receiver, and it was also evident that the discharge valve was either broken or displaced. When examined it was found to be rusted fast to the head in an open position. Less than a thimble of oil jumped the pressure to eighty pounds, much to the discomfort of the chief engineer.

Still another incident from the log-book of a "trouble man" will be given to show how easy it is to overcome the cause of a defect when the search is conducted along intelligent lines. The suction valves of a high-pressure pump, working under a pressure of about 2,000 pounds per square inch, had given considerable trouble, evidently due to a leak through the valves on the discharge stroke, as then a sibilant sound could be heard, which was pretty good evidence. The leak, however, had not occurred until after a new set of valves made by one of the chief engineer's assistants had been installed, which added to the mystery, as the valves were carefully ground to a perfect bearing in their seats. These valves were of the poppet type, and on the top of each there was a guiding stem that was a sliding fit in a cap above. On the original valves the stems were fluted so that air would be admitted to the space above them. On the new valves these flutes were omitted, with the result that they closed so slowly, owing to the partial vacuum formed above the stems during their descent, that there was considerable discharge through them during the early part of the discharge stroke. In this particular instance a little elementary knowledge of physics was a greater help in discovering the trouble than practical mechanical training, and the incident teaches the value of acquiring knowledge other than that necessary to hold a position, for such knowledge is often the key to the door of opportunity. Of course the causes of defects in mechanism are not always so easily located, nor of such a simple nature as those mentioned in the foregoing, but experience teaches that work of this kind may be greatly facilitated by a careful and systematic inspection, after having observed any abnormal action.

* * *

In a paper on the preservation of iron and steel by Mr. Allerton S. Cushman, assistant director, office of public roads, United States Department of Agriculture, presented before the May meeting of the Iron and Steel Institute, the author refers to the fact that iron containing 20 per cent of silicon is not attacked by acids and, therefore, such material should theoretically be non-rustable. He has found that iron containing 10 per cent of silicon is almost incorrodible, but unfortunately is not easily worked, and has peculiar properties. He suggests that inasmuch as silicon is similar to carbon in its characteristics, chemically speaking, it might be worked into the surface of steel by modifying some of the well-known casehardening processes used for impregnating iron and steel with carbon. If a method for applying a coating of silicon on metals should be discovered, it would be a valuable contribution to the art of metallurgy and the world at large.

* * *

According to the *Engineering Record*, an interesting means of heating a building will be tried at Detroit, Mich. The hot water from the jackets of a 1,400-horse-power gas engine now being built for the Ford Motor Co. will be utilized for this purpose.

THE TRANSMISSION OF POWER BY ROPES*

When compared with belts, ropes have some very distinct advantages, the most important being that they slip less and that the drive is more positive. As the rope acts in a groove, the loss due to the centrifugal force is lessened as compared with belt driving, and ropes can therefore be run at a higher velocity than belts. While few cases of rope transmission exceed a velocity of 5,000 feet per minute, there are cases of ropes running satisfactorily on specially constructed pulleys at a speed of over 7,000 feet per minute. The accompanying table gives the horse-power which may be safely transmitted by cotton ropes of different diameters at various speeds. Ample, though not extravagant, margins of safety against breakage of individual ropes are provided, and the table applies to the average good quality of rope, giving to superior makes the benefit of greater durability. With regard to the relative cost of ropes and belts, experience has shown the former to be cheaper; this advantage is more marked in the case of small ropes than in the case of larger sizes.

Rope driving may be divided into two systems, known as the American or continuous system, and the English or multiple rope system.

The Continuous Rope System.—The continuous or American rope system consists of winding one long rope as many times around the driving and driven pulleys as there are grooves to fill, carrying the rope across the whole width of both pulleys and then carrying the rope from the last groove back again to the first groove by means of an idler pulley held at the required angle. This system possesses certain advantages under special conditions, as, for instance, when driving paper-making machinery by a series of expanding rope pulleys so arranged as to permit a variation of a few inches in the respective diameters. Under ordinary conditions, however, the comparative imperfections of the method are so pronounced that numerous installations have been transformed to multiple rope drive. A great disadvantage of continuous driving is that of having to depend upon one rope for the entire drive, and the resulting stoppage of the machine in the event of breakage. In case of multiple driving, an accident to one of the ropes means only running without it for the remainder of the day, as a good reserve of power is generally allowed in the remaining ropes.

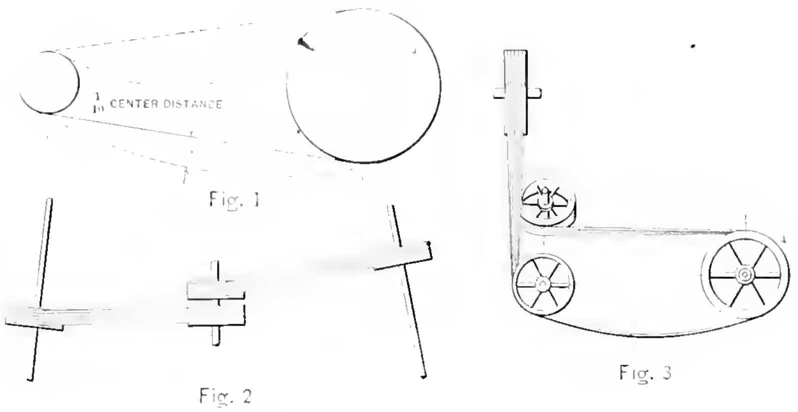

Fig. 1

Fig. 2

Fig. 3

Figs 1 to 3. Power Transmission by Ropes.

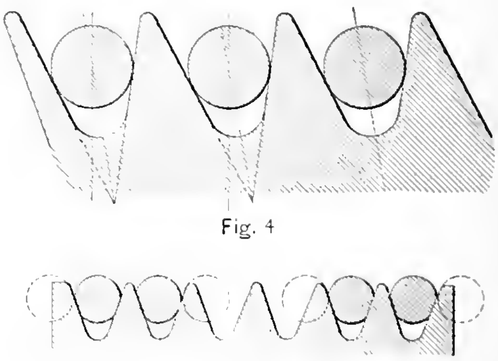

Fig. 4

Fig. 5

Figs. 4 and 5. Tilted Grooves for Angular Drives and Arrangement of Drive for Crossed Ropes

Another objectionable feature of continuous driving is the irregular rope tension. The trailing span reaches its highest tension immediately after leaving the idler pulley and gradually slackens down with each successive lap of the pulleys.

Casing of Pulleys.—It is important when arranging for rope driving to encase the sides of the pulleys with sheet metal or boards, as otherwise the displacement of air by the arms of large high-speed pulleys adds materially to the load. It has been stated that a saving of five per cent of the power may be thus effected. Some firms advocate the casing of all pulleys, large or small, while others do not consider casing necessary unless the pulleys be at least seven feet in diameter and run at a peripheral velocity of 4,000 feet and over.

Minimum Diameter of Smallest Pulley.—For ordinary cotton ropes used as main driving ropes the smallest pulley diameter should be thirty times the diameter of the rope. If this rule is adhered to the rope will cling firmly to the pulley.

Durability of Ropes on Large and Small Circumferences.—Too much importance cannot be attached to the question of relative proportion of pulleys and ropes, and great losses in driving power are caused by non-observance of the "thirty-diameter" rule. Instead of adding a number of heavy ropes to make up for the loss of power transmitted, when large pulleys are impractical, it is far better to divide the total power nominally required between the necessary number of smaller ropes.

Arc of Contact.—When the pulleys are of equal size the arc of contact of each is practically 180 degrees, but when the pulleys are of an unequal size the arc of contact of the smaller pulley is less than 180 degrees. Long center distances, however, are conducive to a greater degree of contact for the smaller pulley, and whenever short center distances can be avoided it is advisable to do so. When short centers are required, the disadvantages can be overcome by adding a sufficient number of ropes to make up for the deficient contact, and a case is on record where spur gears were removed from two shafts and rope pulleys fixed upon the same centers, permitting a clearance of only eight inches between the rims, 360 horse-power being thus easily transmitted with sixteen ropes, 1¾ inch in diameter. In another case two rope pulleys were placed so close together that there was less than an inch distance between the outside of the rims.

The arc of contact is also affected by the position occupied by the trailing span of the ropes which, when above the pulleys, gives the maximum bearing surface. This position, however, is not always obtainable, as sometimes a variable load may set up oscillations in the rope of such violence as to fling it off the pulley. In this case, if the trailing span is below the pulleys, any tendency on the part of the rope to wander from its appointed track is held in check by the pull at the tight side.

Long Center Distances.—Referring to Fig. 1, it will be observed that in under-driven installations, center distances are governed by the size of pulleys employed, which should allow sufficient clearance between the slack of the trailing span, (which should be not more than 1/10 of the distance between the centers) and the tight portion of the ropes. Over-driven installations permit a greater latitude, and center distances are successfully extended to distances of over 100 feet without intermediate support. In drives of this kind, however, it is necessary to provide against the extra strain imposed on shafts and bearing by the weight of the ropes. Center distances in ordinary mill driving seldom exceed 90 feet. As a rule, it is preferable to divide distances which are too great for one span into two drives, rather than merely to support the ropes between the pulleys by idlers. In cases where supporting pulleys are necessary, it is advisable to distribute them along the drive at unequal intervals. The possibility of continued oscillations along the whole track

---

* Abstract of paper read by Mr. Edwin Kenyon before the South Wales Institute of Engineers. For additional information on this and kindred subjects see the following articles previously published in MACHINERY: Rope Drive for Machine Tools, October, 1907, engineering edition; Notes on Rope Drives, January, 1908, engineering edition; Experiments with Rope and Belt Drives, February, 1909.

is thereby obviated, so that initial wave-like movements quickly diminish to small oscillations. This prevents the ropes from leaping out of the grooves.

Angular Driving.—No class of power transmission lends itself better to angular driving and drives around corners than does rope driving. When transmitting power to shafts set in an angular position, the tight side of the rope should be directed by a pulley deflected to a suitable angle, while the slack side of the rope should be carried over an idler revolving on a horizontal axis, as indicated in Fig. 3. The grooves in guide pulleys require to be turned deeper than in the regular pulleys, to prevent the ropes from falling away. As a rule, guide pulleys are made too small for the ropes passing over them, and as a result the ropes suffer considerably from over-straining in passing over sharp bends. The wear of ropes is due more to the bending than to the driving strain, and the "thirty-diameter" rule should be applied to idler pulleys as well as to the driving and driven pulleys.

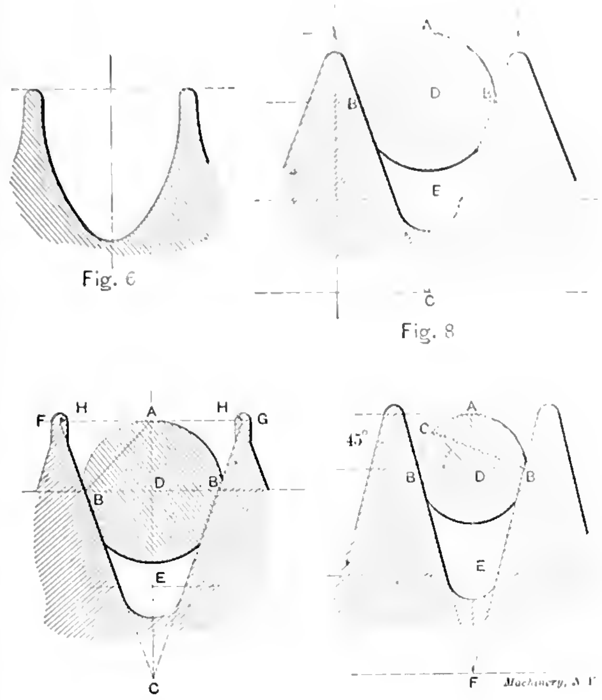

Fig. 6

Fig. 8

Fig. 7

Fig. 9

Figs. 6 to 9. Grooves for Rope Pulleys

Shafts Slightly Out of Alignment.—When shafts are only slightly out of alignment, the ropes will direct themselves without the aid of guide pulleys, but the extent to which the angularity may be carried depends largely upon the center distances and the pulley diameters. With center distances not less than three times the average diameter of the pulleys, a deflection of seven degrees is safe. Sometimes an angle too large for direct drive may be divided up into two drives by the introduction of an intermediate shaft and pulleys, as shown in Fig. 2. Tilted grooves, as shown in Fig. 4, are advantageous for out-of-parallel driving because of aiding the rope to "catch on" and slide down the side having the greatest inclination from the vertical until it reaches the true driving position. The tilted groove, however, has its disadvantages; the pressure becomes one-sided and even impact is impossible. Wide-angled and highly finished grooves appear to be the best solution for this class of driving. Long keyways cut on both shafts are a decided advantage in the arrangement of angle drives, as they permit the movement of the pulleys to their most effective working position, which may be discovered only by practical tests.

Driving with Crossed Ropes.—When it is necessary to transmit power between shafts revolving in opposite directions by crossed ropes, the friction at the crossing point can be materially lessened by running the ropes in pairs, the two tight portions running together while the slack portions pass with slight pressure on the outside as indicated diagrammatically in Fig. 5, where the full circles show the tight parts and the dotted circles indicate the slack parts of the rope passing on the outside of the tight parts at the crossing point. If more than two ropes are employed, it is, of course, necessary to allow sufficient space between the various pairs of ropes to permit free passage of their trailing spans. Therefore, a crossed drive with four ropes will require six grooves, as shown in Fig. 5. One-half crossed rope drives are arranged on practically the same lines as one-half crossed belt drives; that is, the leading side follows a straight line from pulley to pulley, while the other side is drawn away at an angle governed by the relation of the center distances to the pulley diameters.

Vertical Drives. In vertical drives it is advisable to have the ropes running without much slack, particularly if the bottom pulley happens to be the smallest, and to use fairly acute angles not exceeding 40 degrees for the grooves.

Grooves.—Grooves with curved sides, as shown in Fig. 6, have proved to be of no advantage, but on the contrary to result in loss of power, and should, therefore, be discouraged. These grooves are conducive to a rolling action of the rope in the groove, which is not always avoided even in straight-sided grooves, except if their angle is fairly acute. For this reason an included angle of not more than 40 degrees is recommended. It is estimated that the life of a rope is reduced by at least one-third when revolving in the groove.

In general, it may be said that the groove with a 40-degree included angle, as shown in Fig. 7, is the best for ropes above 1¼ inch in diameter, and a 30-degree groove, as shown in Fig. 9, is preferable for ropes below that size. However, for ropes of very small diameter, say ½ inch in diameter and less, used for driving cotton machinery, the included angle may be as acute as 15 degrees. Care should be used never to make the grooves too shallow, remembering the rope will not merely be tangent to the sides of the groove, but will take a wedge-shaped form and thus press itself down toward the bottom of the groove. In Fig. 7 flanges are shown at *F* and *G*, but as flanges of this character do not contribute in any way to facilitate but rather to prevent the rope falling directly in its working position when the driving is unsteady, many rope pulleys are laid out with flangeless grooves, as shown in Fig. 8. Grooves for idler pulleys, having no power to transmit, may be so constructed that the rope rests at the bottom of the groove so that as small an amount of power as possible is lost in passing over the pulley.

TABLE OF HORSE-POWER TRANSMITTED BY THREE-STRAND COTTON DRIVINO-ROPES RUNNING ON PULLEYS NOT LESS THAN THIRTY TIMES THE ROPE DIAMETERS

Laying out a Groove of Approximately 40-degree Included Angle.—In Fig. 7 a circle is shown representing a section of the rope pressed into the groove so that the points *BB* of the

half circle *BAB* touch the sides of the groove. When laying out the groove, draw first the center line *BB*, and then the center line *AC* at right angles to *BB*. Then connect *A* and *B* and set off the length *AB* from the center *D* to *E*, which is the center of the circular section at the bottom of the groove. From *E* set off *EC* equal to *AB*, and draw lines from *C* through the points *BB*. These lines indicate the sides of the groove; their intersections with the line *FAG*, which is tangent to the top of the rope, mark the centers *HH* of the top of the flanges. The flangeless grooves shown in Fig. 8 are laid out in the same manner as the flanged grooves in Fig. 7, except that the sides of the groove are continued to sharp corners at the top, and then slightly rounded off as shown.

The 30-degree groove in Fig. 9 is laid out approximately in the following manner: Draw from the center *D* a line at forty-five degrees angle to the line *BB*, until it intersects the periphery at *C*. Connect *C* and *B* and set off the distance *BC* from *D* to *E* and the same distance from *E* to *F*. The point *E* is the center of the circular section at the bottom of the groove, and the lines *FB* give the sides of the groove.

Cotton Versus Manila Ropes.—In selecting the ropes for the drives, too much stress should not be laid upon initial cost, for although cotton is more expensive than manila, its superior qualities as a driving rope make it possible to transmit at least one-third more power with cotton ropes of the same diameter; besides, cotton ropes will wear approximately three times as long as manila ropes, and in some case considerably longer. The life of cotton ropes, of course, depends upon their size and the conditions under which they work. The most economical diameters range from 1½ inch to 1¾ inch, the last size being most commonly used for transmitting large powers. In a specific case twenty-four cotton ropes, 1¾ inch in diameter, are employed to transmit 820 horse-power at a velocity of 4,400 feet direct from the engine flywheel, which is twenty-eight feet in diameter, to the various rooms in a cotton mill. This installation was completed in September, 1878, and all the ropes driving one of the departments have been running until the present time, a period of over thirty years, without any attention more than tightening two of the ropes which accidently were saturated with water. Another set of cotton ropes has been working an average of twenty hours a day since April, 1885, and appears almost as good as new.

The three-strand rope is superior to the four-strand rope, and it is possible to transmit the same power with a fewer number of ropes when the three-strand rope is used.

Lubrication of Driving Ropes.—The chief function of lubricating material, as supplied to cotton driving ropes, is that of providing a smooth, filmy coating to prevent friction between the twisted surfaces of the strands in contact with each other. Re-lubrication is seldom necessary unless the ropes are working in an unusually dry atmosphere, and should even then be only sparingly used at long intervals. The most serviceable lubricant is compounded from saponified tallow, wax and plumbago, which sets hard like domestic soap. Greasy compounds likely to penetrate the fibers should be avoided as they increase the tendency to slipping. If ropes have been so treated, a liberal application of whiting is usually recommended, which absorbs the grease and falls away in flakes.

EFFICIENCY OF WATER WHEELS

Speaking of the methods employed in his practice, Mr. Charles T. Main, mill engineer and architect of Boston, says: "Some tests of water wheels show a maximum efficiency of about 85 per cent. It is probable that over 80 per cent is rarely realized in practice after wheels have been installed for a short time, and this is for three-quarters to full-gate opening. When the gate opening is less than about three-quarters, the efficiency begins to drop. After wheels have been run for some time the buckets and guides are not as smooth as when they are new, and the efficiency drops off. For these reasons I usually allow an average efficiency, for wheels running under ordinary conditions of age, repair, and variable gate opening, of about 75 per cent. Under exceptionally good conditions and where there are several wheels this could be increased."

SIMPLE METHOD OF STACK DESIGN[*]

A. J. HAIRE, JR.[†]

The engineer with a chimney or stack to erect, knowing the conditions he must meet with regard to boiler horse-power, draft, coal consumption, etc., usually turns to the hand-books, boilermaker's catalogues, and similar literature, rather than to one of the many exhaustive treatises we have on the subject of stack design. These catalogues and hand-books are often inadequate, treating the subject either so simply as to be incomplete, or so technically as to be practically useless. Matter that is found in one is often repeated in the others, and nine out of ten reproduce the familiar table that Kent worked out originally for his hand-book on mechanical engineering. All of these catalogues, however, are of some value, but nearly all fail in one respect or another to satisfy the needs of the busy engineer, who is not interested in learning the whole theory of the design, but wants definite information on how to build his stack with the conditions he has, so that it will work out as he wants it to after it is built. Ninety-nine times out of a hundred such an engineer decides on Kent's rule, and lets it go at that. Any values between those given in the table, he disregards, and, for any rate of coal combustion, or for any draft conditions other than those in the table, his percentage of errors is more or less great. He may overlook the fact that the values given by the table are based on a coal consumption of five pounds per hour, which is rather a high figure, and a figure that the average power plant should cut down materially with even a fair grade of coal and boilers loaded economically. He may also overlook, and generally does, that the draft figured in reaching the values of the table is presumed to be the best, a state of affairs not always found in the average station. If he does not use this table, making allowances for the differences between his conditions and those for which the table was drawn, he has to resort to the literature on stack design, and make a lengthy computation, and the chances for error will be twice as great as if he used the table.

The diagrams in the Data Sheet Supplement represent the medium between relying solely on a table drawn up for an arbitrary set of conditions, and making a separate design with great waste of time and possibility of error for each stack. Exact results can be obtained from them with ease and quickness. Every element that would come in any computation is met in these diagrams, as a glance will show, and there is absolutely no guesswork in any decision, no necessity for interpolation of values as in the case of the table, and no need of using constants to correct the final answer to suit your own case.

Use of the Diagrams

Diagram No. I, in the accompanying Supplement, gives a double set of curves which are plotted between temperatures of flue gas, or inside and outside air, with varying heights of stacks, and the draft pressure in inches of water. By it we can determine the relation of the height to the draft pressure desired with the different temperature changes. This diagram can also be used in determining the draft if we know the height of the stack and the temperatures of the inside and outside air.

Diagrams Nos. II and III show the relation between the height of stack, the amount of boiler horse-power, and the cross-sectional area. Diagram No. II provides for boiler horse-power up to 850, and No. III for values beyond that. Knowing the height, from Diagram No. I, and knowing the horse-power, we use these curves to get the effective cross-sectional area necessary for the stack.

Diagram No. IV makes it possible to determine at a glance the side of square stack having the necessary cross-sectional area, or the corresponding diameter of a round stack.

For example, we will design a stack for 2,000 boiler horse-power, stack temperature to be 550 degrees F. and outside temperature 80 degrees F., the maximum summer temperature. The pressure on the stack is to be one inch pressure of water. From Diagram No. I, starting at 550 degrees F. at the right of the sheet, run over to the curve representing 80 degrees F.,

---

[*] With Data Sheet Supplement.

[†] Address: 8638 Twentieth Ave., Brooklyn, N. Y.

temperature of outside air. From this point drop down to the horizontal line representing one inch pressure for the desired stack, in inches of water. The point found here gives us 160 feet for the stack height. Refer to Diagram No. III to find the cross-sectional area, since the boiler horse-power equals 2 000. Where the vertical line at 2,000 boiler horse-power crosses the line of the 160-foot stack, we get a point which, projected to the left of the sheet, gives a cross-sectional area of about 47 square feet. From Diagram No IV we find the value of 47 square feet cross-sectional area on the curve, and running to the left we get the diameter of the stack corresponding to that area, which is 96 inches, or 8 feet. The side of the square stack with corresponding area as shown to the right of the diagram would be slightly less than 7 feet square. Hence, from the curves we have a stack 160 feet high, effective cross-sectional area of 47 square feet, and either 8 feet in diameter or 7 feet square.

These curves have been carefully worked out, and are exact. They are now in use by some of the largest engineering concerns in New York, and several universities have adopted them in their courses of instruction for power station work. The engineer who gives them a fair trial will undoubtedly find them of great value and superior to all general tables or arbitrary rules in the current literature or catalogues of the day.

* * *

METHODS OF TESTING THE HARDNESS OF METALS*

Few properties of iron and steel are of more importance than that of hardness. In some cases, as with a cutting tool or a pressure die, the metal is practically valueless unless it can retain a sharp edge; while in other instances, where the material has to be machined or cut and trued to shape, even a relatively slight increase of hardness is the cause of much inconvenience and expense. In a third class of material a good wearing surface is of prime importance; while, lastly, hardness may often serve as an indication of a degree of brittleness and untrustworthiness which might perhaps be otherwise unsuspected.

Hardness may be defined as the property of resisting penetration, and, conversely, a hard body is one which, under suitable conditions, readily penetrates a softer material. There are, however, in metals various kinds or manifestations of hardness according to the form of stress to which the metal may be subjected. These include tensile hardness, cutting hardness, abrasion hardness, and elastic hardness; doubtless other varieties could also be recognized when the experimental conditions are modified so as to bring into operation properties of the material in addition to that of simple, or what may be conveniently called mineralogical hardness. This has been defined by Dana as "the resistance offered by a smooth surface to abrasion." The usual quantitative tests for hardness are static in character, but the conditions are profoundly modified when the penetrating body is moving with greater or less velocity. The resistance to the action of running water, to the effect of a sand-blast, or to the result of the pounding of a heavy locomotive on a steel rail, afford examples of what might perhaps for purposes of distinction be called dynamic hardness, which is a branch of the subject which has received little examination.

Comparison will be made in the following of four typical methods of measuring hardness. Those selected include the sclerometer, introduced by the author in 1886; the scleroscope, recently invented by Shore; the form of indentation test adopted by Brinell about ten years ago; and the drill test introduced by Keep a few years earlier. Each of these methods has been used in actual works practice, and by various persons other than the inventor, and may thus be regarded as being typical of the particular class of test to which it belongs. Among the many other forms of test the microsclerometer and wearing tests call for special mention, though to these only incidental reference can be made.

The principles underlying the four methods selected for comparison may be briefly described as follows.

Turner's Sclerometer

In this form of test a weighted diamond point is drawn once forward and once backward over the smooth surface of the material to be tested. The hardness number is the weight in grammes required to produce a standard scratch. The scratch selected is one which is just visible to the naked eye as a dark line on a bright reflecting surface. It is also the scratch which can just be felt with the edge of a quill when the latter is drawn over the smooth surface at right angles to a series of such scratches produced by regularly increasing weights.

Shore's Scleroscope

In this instrument a small cylinder of steel, with a hardened point, is allowed to fall upon the smooth surface of the metal to be tested, and the height of the rebound of the hammer is taken as the measure of hardness. The hammer weighs slightly over 2 grammes, the height of the rebound of hardened steel is in the neighborhood of 100 on the scale, or about 160 millimeters, while the total fall is about 10 inches or 255 millimeters.

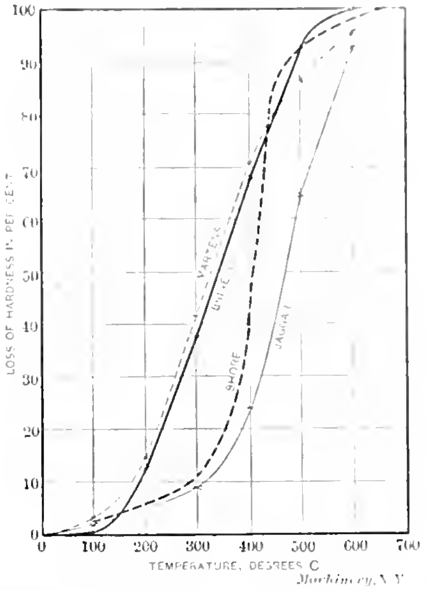

Diagram showing Percentage of Loss of Hardness of Hardened Steel when tempered to Various Temperatures, as measured by Different Hardness Testing Apparatus

Brinell's Test

In this method a hardened steel ball is pressed into the smooth surface of the metal so as to make an indentation of a size such as can be conveniently measured under the microscope. The spherical area of the indentation being calculated, and the weight being known, the stress per unit of area when the ball came to rest is calculated, and this gives the hardness number. Within certain limits the value obtained is independent of the size of the ball, and of the amount of pressure. In the original tests the steel ball was 10 millimeters in diameter, and the pressure was equal to a weight of 3,000 kilogrammes; but a more convenient form of apparatus is now supplied by Mr. Brinell for works tests, while Mr. Stead has introduced a small and portable instrument.

Keep's Test

In this form of apparatus a standard steel drill is caused to make a definite number of revolutions while it is pressed with standard force against the specimen to be tested. The hardness is automatically recorded on a diagram on which a dead soft material gives a horizontal line, while a material as hard as the drill itself gives a vertical line, intermediate hardness being represented by the corresponding angle between 0 and 90 degrees.

Each form of test has its advantages and its limitations. The sclerometer is cheap, portable, and easily applied, but it is not applicable to materials which do not possess a fairly smooth reflecting surface, and the standard scratch is only definitely recognized after some experience. The Shore test is simple, rapid, and definite for materials for which it is

---

* Abstract of paper read before the Iron and Steel Institute (Great Britain), May 14, 1909, by Prof. Thomas Turner, of the University of Birmingham. For additional articles previously published in MACHINERY see "The Brinell Method of Testing the Hardness of Metals," September, 1908, engineering edition; "A New Mechanical Test for Hardness," October, 1908, engineering edition.

suited, and appears likely to have an important future. But further information is yet needed as to the exact property which is measured by this form of test. As shown by De Fréminville, the result obtained varies somewhat with the size and thickness of the sample, while if the test-piece is supported on a soft material, such as a plasticine, the results are valueless. It should also be pointed out that india-rubber gives a rebound of 23, which is equal to that of mild steel, while light soft pine wood gives a rebound of 40, which is nearly twice as great as that of gray cast iron. Curiously enough, hard wood, like teak, gives a rebound of about 12, while some samples are considerably lower than this. As illustrating the influence of the support, a sample of exceptionally hard rolled copper, about 1/25 inch in thickness, when supported on a block of hard steel, and tested with the blunt or "magnified" hammer supplied, gave a value of 30, which was increased to 34 when the copper was supported on wood. A sample of brass only gave a value of 17, and yet this brass would scratch the copper, while the copper would not scratch the brass. From these results it is evident that the Shore test is only applicable to a certain class of substances. It appears to test what may be termed the "elastic hardness," and gives high results with metals in the "worked hard" condition. Tests appear to show that good results are, however, obtained with glass and with porcelain, as well, of course, as with most metals.

The Brinell test is specially useful for constructive material; it is easily applied and definite, and is now of all hardness tests the one most employed. It appears to give satisfactory results with wood, but cannot be applied to very brittle materials, such as glass, or to hard minerals; Keep's test is specially suited for castings of all kinds, as it records not merely the surface hardness, but also that of the whole thickness, and gives indications of blowholes, hard streaks, and spongy places. Obviously, it can only be applied to materials the hardness of which is less than that of hardened steel.

A very important question arises in connection with these various tests—namely, as to whether there is any observed agreement between the results which are arrived at by such entirely different methods. It will be noticed that in each case an arbitrary scale is adopted. If the weights used on the sclerometer had been ounces instead of grammes, the hardness numbers would naturally have been different. Similarly, Brinell's tests might have been expressed in tons and inches, or a different weight of hammer and height of scale adopted by Shore. Hence all that can be expected is a proportionality in the results, and if this is ascertained it should be possible to convert values on one scale into results on another.

TABLE I. HARDNESS SCALES COMPARED

Metal	Sclerometer	Scleroscope	Brinell
Lead	1.0	1.0	1.0
Tin	2.5	3.0	2.5
Zinc	6.0	7.0	7.5
Copper, soft	8.0	8.0	....
Copper, hard	..	12.0	12.0
Softest iron	15.0	....	14.5
Mild steel	21.0	22.0	16–24
Soft cast iron	21–24	24.0	24.0
Rail steel	24.0	27.0	26–35
Hard cast iron	36.0	40.0	35.0
Hard white iron	72.0	70.0	75.0
Hardened steel	....	95.0	93.0

An examination of results obtained by the four methods dealt with shows that, for relatively pure metals in their cast or normal condition, there is a general agreement which must be regarded as remarkable. In Table I will be found, in the first column, results which were published in the author's original paper on the hardness of metals in 1886. In the second column are the author's results with the Shore scleroscope, and these figures are in good agreement with those supplied by the maker of the instrument. In the third column are values taken from published results by Mr. Brinell and by Mr. Stead, but the numbers given have been divided by 6, as this figure has been found to suitably reduce the Brinell hardness values for purposes of comparison. It will be observed that either by accident or design the scale adopted for the scleroscope is, for practical purposes, identical with that of the sclerometer, while Mr. Brinell's values are proportional. The angles in Keep's tests are, or could easily be made, in pretty close agreement with the other values. It would therefore appear that each instrument, with simple and homogeneous substances, must measure one and the same physical property and gives results which are either in actual agreement with, or proportional to, the results obtained by the other forms of test.

In practice, however, the use of relatively pure metals in the unworked or annealed condition is comparatively rare, unless we include in this category wrought iron and mild steel. Carbon steels and special steels consist largely of alloys, the complexity of which is profoundly modified by heat treatment; while copper, zinc, and their alloys are frequently hardened by rolling, drawing, or other mechanical treatment. The very important question therefore arises as to the extent to which the different methods of testing agree in their values for the hardening and tempering of steel, and for the hardness caused by mechanical treatment. From preliminary observations on the latter point the author is inclined to believe that metal which has been mechanically treated, as with hard-drawn rods or rolled sheets, has its tenacity increased out of proportion to its hardness as measured by a file or cutting tool. The sclerometer shows relatively little difference, for example, between hard-drawn and annealed copper, while the scleroscope shows an exaggerated effect, at all events in some cases. As the Brinell test closely follows the tenacity, it too may be expected to show marked difference between worked and annealed samples. The result in some cases is likely to be a confusion between elasticity or tenacity on the one hand, and true or mineralogical hardness on the other. For example, a piece of hard-rolled copper may give a greater hardness number than one of mild steel. Yet a tool made of mild steel will always cut copper, and no amount of cold-rolling will make copper cut steel. Hence great care is required when hardness values for different materials are compared and further information in this direction is desirable.

TABLE II. PERCENTAOE OF LOSS OF HARDNESS OF HARDENED STEEL WHEN TEMPERED TO VARIOUS TEMPERATURES, AS MEASURED BY DIFFERENT HARDNESS TESTING APPARATUSES

Temperature of Heating, Degrees C	Brinell Method (0.83 per cent Carbon)	Martens Sclerometer (0.95 per cent Carbon)	Jaggar Micro-sclerometer (0.86 per cent Carbon)	Shore's Method (0.88 per cent Carbon)
160	..	2.5	1.8	3.7
200	13	14.0	5.4	2.7
300	38	41.0	9.1	11.1
400	68	70.6	23.6	33.0*

Hardness of Steel in Hardened, Tempered or Annealed Condition

The question of agreement in reference to the true hardness of a sample of steel in the normal, hardened, tempered, or annealed condition is perhaps of even greater importance. To illustrate the kind of difficulty which arises, reference may be made to some recently published results by E. Maurer, in which samples of steel with varying content of carbon were heated to ascertained temperatures, quenched, and afterward tempered or annealed at given temperatures. The hardness of the samples was then determined. When the tempering heat was 300 degrees C., the loss of hardness in a sample containing 0.83 per cent of carbon was 11.1 per cent by the Shore method, and 38.0 per cent by the Brinell test. A steel with 0.95 per cent carbon tested in a similar manner by Heyn and Bauer with a Marten's sclerometer gave a loss of hardness of 41.0 per cent; while lastly Boynton, with a Jaggar sclerometer, using a steel with 0.86 per cent carbon, has recorded a loss of hardness on tempering at 300 degrees of only 9.0 per cent. The question may be put in this way: The steel is suited for making wood-working tools, if properly hardened and tempered. Is 300 degrees C. a proper tempering heat? According to the Shore test and the Jaggar test the tool should be hard and cut well; but according to the Brinell test and the Martens sclerometer it has lost nearly half its original hardness, and should rapidly lose its cutting edge. Maurer states that every-day experience shows that with this class of tool steel a tem-

pering heat of 300 degrees renders the metal useless for woodworking.

The results of the four sets of experiments are given in Table II.

The values are graphically represented in the accompanying illustration, from which it will be seen that the greatest difference occurs at about 300 degrees C., the loss of quenching hardness due to tempering being about four times as great when tested by the two first methods as compared with the results obtained when the steel is tested by the two latter methods given in the table.

Further, Martens and Heyn have recently pointed out that in the ball test for hardness the indentations are frequently not circular, and are therefore difficult to measure, and that when testing hard materials the ball itself is appreciably flattened while under load. To diminish these sources of error Martens has introduced a special form of apparatus for measuring the depth of the indentation.

It is evident, therefore, that further research and comparison is required before agreement in principle can be arrived at with hardness tests for hardened, tempered, or mechanically treated metals.

ALLOY STEELS FOR MOTOR CAR CONSTRUCTION*

The cost of the materials used in automobile construction amounts to about sixty per cent of the total cost of production. In view of this fact, the kind of material best suited for the more vital parts is highly important. In the following the composition and treatmnt of some of the most commonly used alloy steels are reviewed.

TABLE I. NICKEL STEELS

Carbon	Manganese	Nickel	Elastic Limit, tons	Tensile Strength, tons	Elongation in 2 inches, per cent	Reduction in Area, per cent	Treatment

Nickel Steel

Nickel steel is the most generally used of the alloy steels. The best quality contains 0.20 to 0.25 per cent carbon, 3.50 per cent nickel, 0.60 to 0.90 per cent manganese, and not over 0.04 per cent sulphur and phosphorus. With carbon and nickel as given above, the manganese content ought never to exceed the limits mentioned. A slightly lower carbon content is sometimes used for case-hardening purposes, and a higher carbon percentage is much used for crank-shafts. Nickel steel is usually made in the basic open-hearth furnace. It is an excellent steel for case-hardening, and is easier to machine than other alloy steels.

Chrome-Vanadium Steel

The chrome-vanadium alloy steels are preferably made in the crucible or electric furnace, although the open-hearth process is also much used for the purpose. The open-hearth product, however, is somewhat uncertain, and while springs of steel made by this process may be better than those made from ordinary crucible steel, they cannot be compared with springs made of crucible chrome-vanadium steel. For excellent quality the latter product constitutes the highest attainment of the steel makers' art.

Chrome-vanadium steel made with high carbon content is suitable for oil-hardened gears and springs. When made with a low carbon content it is used for case-hardened gears, and, when oil quenched and annealed, for axles, shafts and steering knuckles. When a better material than the best nickel steel is needed, the various kinds of chrome-vanadium steel are to be recommended. They can be easily forged and can be machined more readily than chrome-nickel steels of corresponding carbon percentages.

Chrome-Nickel Steels

Chrome-nickel steels are made either with a high carbon content, and used for oil-hardened gears and springs, or with a low carbon content, in which case the steel is used for axles, shafts, forged parts, and case-hardened gears. The high carbon steel carries about 0.5 per cent of carbon, while the low carbon alloy carries 0.25 per cent. The nickel content is from 2 to 3.5 per cent, while the chromium varies from 1 to 1.5 per cent. A special nickel-chrome-tungsten steel is sometimes used for springs. Nickel-chrome steels possess excellent static qualities, but present difficulties in heat treatment, forging and machining.

Silico-manganese and silico-chrome steels with medium and low carbon contents are used to a considerable extent abroad for springs and gears. Their relatively low cost favors their use, but they do not stand up well when subjected to shocks, and are too sensitive to heat treatment. When handled with great care they give good results where the temperatures for the heat treatmeat can be accurately gaged. Chrome steels with high carbon content are used to a considerable extent for balls and ball races. Tungsten steels are universally used for making magneto magnets.

Heat Treatment of Alloy Steels

While the best alloy steels are none too good for most of the parts in automobile construction, their qualities will not become pronounced unless they receive proper heat treatment. It is waste of money to buy good alloy steels without knowing how to properly treat them to bring forth their exceptional qualities. For gaging the heat a pyrometer is necessary, but it is too often supposed to take care of itself. The best pyrometer of the thermo-couple type should be regularly inspected. The protecting tubes should be frequently examined and renewed, and the electrical contacts looked over.

The heat treatment operations depend upon established scientific facts, and a lack of appreciation of this causes many people to buy high-priced alloy steels from which they get no better results than from carbon steel properly handled. As an example of the effect of heat treatment may be mentioned a chrome steel which in its rolled condition had an elastic limit of 158,000 pounds, 5 per cent elongation, and 9.4 per cent reduction in area. The same steel, oil tempered and annealed, had an elastic limit of 153,000 pounds, 14 per cent elongation and 52 per cent reduction in area. In other words, the material was transformed from brittle to tough without appreciably affecting its elastic limit. Nickel steel similarly treated will have the elastic limit raised twenty per cent, with its elongation unchanged and its reduction in area improved.

The accompanying tables show typical analyses, treatment and tensile strength of nickel, nickel-vanadium, chrome-vana-

---

* Abstract of paper by Mr. John A. Mathews, read before the Franklin Institute, Mining and Metallurgical Section, April 1, 1909.

dium and chrome-nickel steels. Many sources of information have been drawn upon in the compilation of these tables, as, for instance, the data published by the American Vanadium Co., experimental data obtained by tests made by the writer, and the commercial tests made on the steels of many makers. The elastic limit and tensile strength are given in tons per square inch, and the elongations are measured on 2-inch test specimens, ½ inch in diameter. It should be noted that the figures given must be used with some caution. Because a ½-inch test piece, oil tempered and annealed, gives an elastic limit of 75 tons per square inch, it does not follow that a 1½-inch bar similarly treated will have the same elastic limit. The hardening action in quenching does not penetrate very deeply in the large bar, while in a small one it may penetrate to the center.

In the column marked "Treatment" is given the temperature to which the steel is heated before quenching, followed by the liquid in which it is quenched; where a third temperature is given it indicates the temperature to which the steel is reheated to draw the temper or anneal. This will make clear such terms as "1,600 F. oil 600 F."

For springs it seems that no material is better than crucible chrome-vanadium steel. The tempering of this steel is quite simple. The springs made from it should be heated to from 1,675 to 1,700 degrees F. and quenched in oil. The temper is then drawn according to the nature of the spring, and the duty expected. The drawing range is very wide, varying from 600 to about 1,000 degrees F.

Case-hardened versus Oil-hardened Gears

Both case-hardened and oil-hardened gears are largely used in automobile construction. As previously mentioned, the chrome-vanadium, chrome-nickel and silico-manganese alloys are made with both high and low carbon contents. The former contains about 0.45 to 0.60 per cent carbon and enough other hardening elements so that by merely quenching the steel in oil from a bright red heat, surface hardening is produced sufficient for ordinary wearing purposes, while the hardness does not penetrate deeply into the gear, but leaves a tough and strong core. The low carbon alloy steels, with about 0.20 per cent carbon, require to be case-hardened in order to produce sufficiently hard surface for wearing purposes. The writer's observations lead him to prefer the case-hardening gear, the following conclusions being based on the results of direct tests on thousands of gears.

TABLE III. CHROME-VANADIUM STEELS

0.45	0.58	2.37	0.30	88	94	13.2	46	1600 F. oil 1125 F.
0.45	0.58	2.37	0.30	138	146	6.0	16	1600 F. oil 430 F.
0.36	0.21	2.78	0.24	60	101	4.1	88	Natural as rolled.
0.36	0.21	2.78	0.24	65	72	20	56	1500 F. oil 1150 F.
0.36	0.21	2.78	0.24	98	104	13	45	1500 F. oil 600 F.

1. The static strength of case-hardened gears is equal to that of oil-hardened gears, assuming that in both cases steel of the same class of appropriate composition has been used, and the respective heat treatments have been equally well and properly conducted.

2. Direct experiments prove that case-hardened gears resist shocks better than oil-hardened.

3. The case-hardened gear resists wear incomparably better, although it is perhaps not as silent in action.

The strong objection to the case-hardening is in nine cases out of ten doubtless due to the fact that the case-hardening operation is not properly understood. The depth of the hard case or covering, the time and temperature required to produce certain results, and the exact control of the conditions, together with an accurate knowledge of the material to be treated, are factors which enter into successful case-hardening.

To obtain the best results in case-hardening ordinary carbon steel, the following rules should be observed. Steel containing less than 0.12 per cent of carbon, and with a low percentage of manganese (less than 0.30 per cent) should be used; the case-hardening should be accomplished by a chemically definite material, such as a mixture of 60 per cent charcoal and 40 per cent barium carbonate, and at a temperature between 1,560 to 1,920 degrees F. The higher the temperature, the more rapid will be the case-hardening. After the case-hardening operation, allow the steel to cool down to about 1,100 degrees F. Then re-heat the work to be case-hardened, and quench it at 1,650 degrees F. This heating and quenching has the effect of toughening the center, but the outside will be coarse-grained and brittle; therefore heat the material a second time to 1,470 degrees F. to render the outside non-brittle.

TABLE IV. CHROME-NICKEL STEELS

0.40	0.18	2.1	0.80	58	66	17.5	40	1500 F. oil 1150 F.
0.40	0.18	2.1	0.80	106	118	10.0	34	1500 F. oil 600 F.
0.40	0.18	2.1	0.80	70	79	15.5	48	Annealed 1150 F.

This procedure is more elaborate than that most commonly used, where pieces are dumped directly from the case-hardening boxes into water. The process, however, can be somewhat modified if one uses a good grade of nickel steel, low in carbon, and after having case-hardened it at the appropriate temperature, permits the material to cool off in the boxes before re-heating and quenching. In this case, if the material is re-heated but once to 1,470 degrees F. the result will be fully equal to or better than those obtained by the most careful annealing and double quenching of ordinary carbon steels. It is, however, better to give a double quenching, as then extraordinary toughness and wearing qualities are obtained.

An ideal way of making a nickel steel gear consists in first annealing the blank than rough machining it approximately to size, and then re-annealing before taking the last finishing cut. The gears are then packed in a mixture as mentioned, heated to a temperature of about 1,625 to 1,650 degrees F., carbonizing to a depth of about 1/64 to 1/32 inch. The gears are then permitted to cool in the boxes, are heated to 1,500 degrees F., and quenched in a hot brine or calcium-chloride solution, and finally re-heated to 1,375 or 1,400 degrees F. and quenched in oil. The temper need not be drawn.

Another important point is that of drop forging small parts which can also be made from bars in automatic machines. No steel is improved by drop forging, although some steels are less susceptible to injury than others. In drop forging work, in order to give plasticity, the material must be heated very hot. An investigation of drop forging and bar cut gears, the former being the product of one of the foremost drop forging companies, showed that under static test the bar cut gears were fully 25 per cent stronger and their resistance to shock was also greater.

THE COMMERCIAL AIRSHIP

C. A. McCREADY*

Broadly stated, there are two distinct systems followed by inventors in their efforts to produce a vessel that can navigate the air. In the first, the vessel is heavier than air, with wings or supporting planes, and equipped with machinery light enough and powerful enough to force it upward and keep it in motion in the air; in the second, it is lighter than air, so that it can of itself rise and carry a definite load. The problem is purely a commercial one, as in transportation on the land and on the sea, and the proper gage of the success of any aerial vessel is its availability for commercial purposes. With commercial success achieved, all other needful purposes can readily be met. As yet we are in the experimental stage, the best results by either system falling far short of commercial requirements. It is well, therefore, to analyze the underlying principles with a view to determining which system offers the best assurance of final success.

The heavier-than-air machines, popularly known as flying-machines, have the advantage of cheaper cost of construction and operation. On the other hand, the construction of such machines is necessarily frail, the risk of being overturned by a sudden change of wind is ever present, they can only rise under favorable conditions, and even under favorable conditions can only remain a limited time in the air. Many improvements can, and doubtless will, be made that will reduce the force of these objections; but even if entirely removed, the further objection still holds that such vessels cannot remain at rest in the air even for a moment, so should any accident befall the propelling machinery, the vessel must descend, whether under control or not, and whether or not there is available a suitable place for landing. The carrying capacity is also limited, and any increase to commercial proportions seems doubtful, since the weight increases as the cube of the dimensions while the carrying capacity increases only as the square.

Of lighter-than-air machines the general public is as yet only familiar with those based on the balloon principle; which means that the air contained in the envelope is forced out and a lighter gas substituted, the difference between the weight of the air and the weight of the gas furnishing the ascensional force, after deducting the weight of the envelope and appurtenances. The advantages of the balloon over the flying-machine are important: it can remain longer in the air, it can ascend higher, and it can carry a greater load. However, the disadvantages are serious, although recent developments have tended to modify some of them. First, the gas—whatever gas is used—is an element of danger. It is also expensive, inasmuch as it must be renewed with each ascension. The process of inflation is likewise bothersome. In a limited sense, the balloon can rise to such altitude as may be desired, yet it can only do this by discarding the ballast it has taken along. It can also descend at will, yet to do so part of the gas which caused it to rise must be released. Neither the ballast nor the gas, once released, can be restored without coming to earth; so the possibilities of the balloon while in the air are limited, and its return to the air is made possible only after delay, inconvenience and extra cost.

The rigid construction of recent German balloons has removed some of the previous disadvantages of this system, and also has permitted making the balloon dirigible, in a modest way, even while carrying a load such as the flying machine could not support; yet little of practical value has so far resulted from the enormous sums spent in experiments. Still enough has been learned to make it clear that it is through the lighter-than-air principle alone that aerial transportation must come, even though balloons themselves, however modified in form, may be incapable of solving the problem.

As already stated, aerial transportation is a purely commercial problem, and to be a success the airship must be capable of meeting the every-day requirements of commercial transportation. It must be able to support and carry a substantial load for an indefinite time without coming to earth. It must be able of itself to rise to such altitude as may be desired, whether it be a few feet above the earth or ten thousand feet or more, and to remain at the chosen level, either at rest or in motion indefinitely. It must be equally able to descend at will, always under the absolute control of the pilot.

All this is possible only on the lighter-than-air principle, yet abundant experience has shown that it is hopeless to expect so much from any vessel which gets its ascensional force from inflation, as with the balloon. There only remains the principle of deflation,—that is, exhausting the air and leaving a vacuum,—and by the proper application of this principle it will be found that all of the above requirements of the commercial airship can be met.

Let us assume a thin steel cylinder of high tensile strength, say 26 B. W. G.,* (0.018 inch) so as to permit of the lightest construction consistent with safety; the diameter to be about 150 feet, and (including cones at either end to facilitate passage through the air) of an extreme length of say 750 feet from apex to apex of the cones; the cylinder and cones to be supported internally by a system of bracing, light in weight but so constructed as to prevent collapse or buckling when the air is exhausted. The natural objection that such construction is impracticable must, for obvious reasons, be passed over for the present without further explanation than that the entire system has been worked out to the final detail, and attested by engineers of national reputation. Such an envelope would contain over 420 net tons weight of air. The weight of the steel cylinder with its internal bracing, including the weight of the attached car, with furnishings and all necessary machinery, would be, roughly, 270 net tons, leaving an extreme lifting force of about 150 net tons with the air entirely exhausted from the cylinder. Leaving say 50 tons of air in the cylinder as a reserve, there would still remain a lifting force of 100 net tons, or 200,000 pounds, the equivalent in weight of at least 1,000 men. If so much lifting force were not required, the surplus would remain as an extra reserve force of air in the cylinder. It is, of course, understood that where no strain appears, the lightest material available, as aluminum, would be used, particularly in the furnishings.

On a small scale the vacuum system is not now practicable; but it becomes proportionately more efficient as the size is increased, which is very important from the commercial point of view. It may be well to note how the vacuum principle as applied to airships will work out in practice. The lifting force itself is the weight of the air withdrawn from the cylinder, after deducting the weight of the cylinder, car and equipment. When the car is loaded ready to be transported, pumps are set to work to exhaust the air from the cylinder, and when the weight of the air exhausted overbalances the weight of the airship and its load, it will rise; and as more air is exhausted, the airship will rise higher until the desired height is reached, whether it be a few feet above the ground or high above the clouds. To descend, it is only necessary to open valves and allow air to enter until the added weight causes the airship to descend. This rising and descending can be adjusted at the will of the pilot, so as to take advantage of whatever atmospheric level is most favorable for navigation; and it is accomplished without difficulty and without cost, by using the very medium in which it floats to increase or decrease the weight of the airship.

The first requirement in aerial transportation, as elsewhere, is safety, and in all calculations concerning the vacuum airship this has first of all been provided for. It must, however, be remembered that while vessels on the sea must at times combat the combined fury of wind and waves, there is one less element of danger in the air; and this danger is minimized in the vacuum airship through its ability to change its specific gravity at will. If storms are raging near the earth, it can rise above them; if the upper air is violently disturbed, it can descend to the quieter level near the earth.

The speed at which this airship can travel must partly depend on the varying conditions met, but a minimum of 100 miles per hour is provided for. Bearing in mind the speed actually attained by the crude devices now on exhibition here and abroad, this estimate for a scientifically constructed air-

---

* Address: 301 Produce Exchange, New York.

* The dimension of $^1/_4$ inch, given in the note "Zeppelin's Last Record—The De Bausset Vacuum Airship," July, 1909 issue of MACHINERY, was erroneous.

ship capable of carrying the necessary machinery does not seem extreme. This would permit of a passage across the Atlantic within one and one-half days, or one-third of the time required for the fastest ocean passage yet made. The same rate of speed in a continued trip—which is well within the limits of possibility—would permit of circumnavigating the earth in ten days.

In various other ways the vacuum airship may exert an influence almost incalculable on human affairs. What better health resort can be imagined than the upper air for victims of tuberculosis and kindred ailments? What better method of exploring distant regions, now almost inaccessible, and searching out their hidden treasures? How better could relief be carried to famine-stricken districts, when each day's delay means the sacrifice of many lives?

Unlike the balloons and flying machines of the present, this airship was not designed for war purposes. That it would be useful in time of war is self-evident. But it is hoped that it may be more useful to the world by showing the futility of building and supporting warships and fortifications that could be so easily destroyed, and of maintaining large standing armies that could readily be put out of action by it, and thus relieve the nations of the world of the tremendous burdens they are now compelled to support in time of peace, and perhaps hasten the time when war shall be no more.

In conclusion, it is only proper to state that the vacuum principle as applied to airships is based on the researches and experiments of the late Dr. Arthur de Bausset, a physician by profession, and a scientist of very high attainments; and it is the earnest belief of those most familiar with his work, that when the history of aeronautics is finally written in the light of facts now known only to a few, to him will be given the credit for having made possible the commercial conquest of the air.

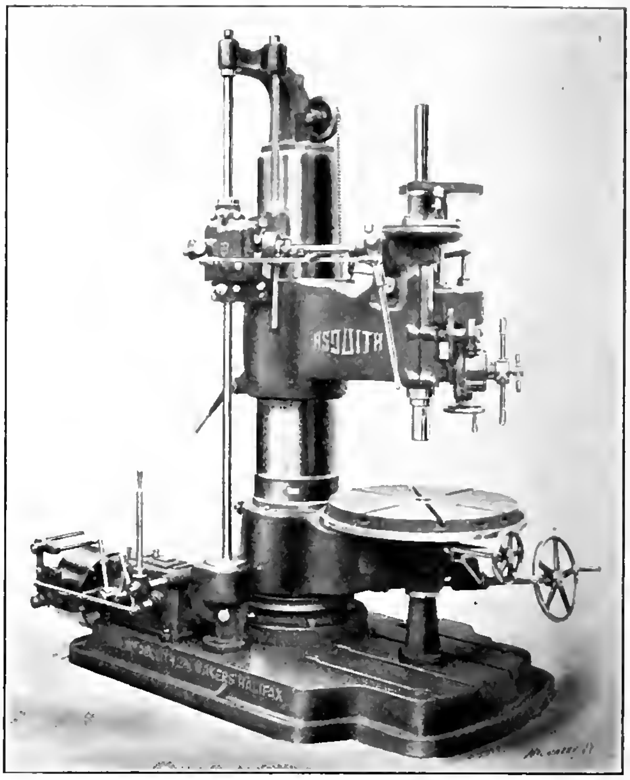
* * *

NEW ENGLISH UPRIGHT DRILL PRESS

JAMES VOSE[*]

The firm of Wm. Asquith, Ltd., Halifax, formerly built a wide range of machine tools in conformity with the then common English practice. During the last few years, however, they have specialized in the manufacture of medium and heavy drilling and boring machines, including the radial, upright and horizontal types, and have met with considerable success. We herewith illustrate their most recent design of vertical drill press.

The principal advantages claimed for these machines are an unusual degree of handiness of adjustment, coupled with extreme rigidity and freedom from deflection in the frame or table. They are built in three sizes to admit work up to 36, 48, and 60 inches diameter. The diameters of the driving parts of the spindles are $2\frac{1}{4}$, 3, and $3\frac{1}{2}$ inches respectively, and the vertical feeds for the three sizes are 11, 15, and 18 inches. The 36-inch machine has 8 speeds and 4 feeds, and the 48- and 60-inch sizes have 12 speeds with 4 and 6 feeds respectively. The coarsest feed provided is 1/32 inch and the finest 1/150 inch per revolution of spindle. The maximum distance from spindle nose to the table varies from $28\frac{1}{2}$ to 30 inches in the different sizes, and from spindle nose to the base-plate, from 53 to 57 inches. The heads may be raised or lowered by power within a range of 32 inches in the case of the 36-inch press, 34 inches on the middle size, and 36 inches on the 60-inch machine. As will be noticed, the main drive from the line shaft is through a gear box mounted on the base at the rear of the column. The constant-speed belt, which is 4 or 5 inches wide, runs at from 1,500 to 1,800 feet per minute. The work tables are surrounded by a trough which catches the surplus lubricant, and their working diameters are 30, 42, and 48 inches, respectively, for the different machines. The weights of the machines—which may, of course, be electrically driven if desired—range between 5,500 and 9,500 pounds. Some of the constructional features which may be mentioned are as follows: The high-carbon steel spindles are made larger in diameter where they bear in the sleeves than at the driving parts, and they are rigidly supported by the sleeves even when out at the full length of the traverse. Ball thrust bearings are used, and the spindles have quick up-and-down adjustment with fine hand- and power-feed motions and an automatic trip motion with index dial and safety stops for the prevention of over traverse. The powerful friction feed is also capable of being instantly stopped or applied. For tapping and stud fixing, the reversing motion is worked by the same lever which stops or starts the spindles and controls the vertical motion of the heads, the lever being brought to the front of the head, on which it is carried, for easy access from the operator's working position. The head has no radial adjustment, the present construction being considered more rigid. The standard carrying the head and table is in one piece down to the foundation plate, to which its unusually large base is bolted. Special stress is laid on the assurance thus obtained of practical absence of deflection. The arm carrying the table is very strong and it has a bearing of large diameter and considerable length on the lower portion of the standard. The table can be very easily and quickly adjusted radially by a large hand-wheel (seen in the illustration attached to an inclined shaft), worm and wheel. A fine, accurate and quick adjustment is thus available. The tables also have a rotary motion in the arm bearing through a hand-wheel, worm and wheel, and by this combination of motions any portion of the table can be rapidly brought under the drill spindle. The table, which can be swung entirely clear of the base when desired, is fitted with a foot, as shown, which prevents deflection under any cut which can be imposed. All the driving gears are of steel, and all bearings bushed with gun metal. Particular attention has been paid to the handy locating of locking and manipulating levers and also to lubrication. By way of taking advantage of the satisfactory support afforded the spindle, a very handy attachment is supplied for milling keyways in spindles or shafts. This takes the form of a fixture which is self-setting on the table. The top portion of the fixture can be screw-traversed by hand and it is arranged as a V-block with T-slots on each side for bolting down the work. Generally, the machines are considered by the builders to combine—within their range—the handiness of the best standard radial machines with the rigidity of the best type of vertical drill press. The engraving shows the 36-inch machine.



Rigid Design of English Drill Press

* * *

It is stated in the *Cement Age* that the Pullman Company has completed an all-steel sleeping car with concrete floor laid on steel girders. The new car consists entirely of steel and concrete, with the exception of the upholstery, making it as nearly wreck- and fire-proof as possible.

MACHINE SHOP PRACTICE*

LAYING OUT WORK 1

It is necessary prior to many machining operations to first lay out lines indicating just where the finished surfaces should be, so that when the work is completed all machined surfaces will be in proper relation to one another. Another purpose of such lines, providing they are properly located, is to enable the machinist to remove an average amount of metal from the various surfaces; this is important, for, by way of illustration, if too much metal were removed in facing a boss, it might not be possible to finish another surface to a certain required dimension from the first. In addition, the finished faces are in a more orderly relation with those parts which are left rough, and therefore the work presents a more pleasing appearance. At the present time there is less of this class of work done than formerly, as the numerous jigs and fixtures now used, so locate the work and guide the cutting tools that lines indicating finished surfaces are unnecessary. When the parts are not manufactured in quantity, however, and in small shops where there are few jigs, it is frequently necessary to lay out work.

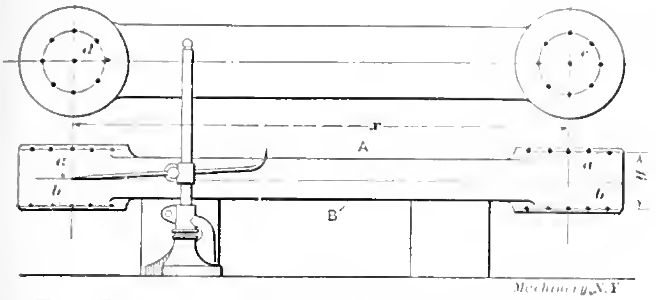

Fig. 1. Example of the kind of Work that is given a Preliminary and a Final Layout

With the exception of certain small parts, a surface plate or other flat surface, such as a planer platen, is almost indispensable for this operation. There are various styles and sizes of laying-out plates, the type depending largely upon the class of work for which it is intended. A table with a circular top which revolves on its base, is very convenient for general work of a light character, and by reason of the movement possible, all sides of the work being laid out may be easily turned toward the workman and also into the best position for light. Large rectangular plates are used in some shops for heavy work, which are sometimes bedded into a firm concrete foundation in order that the weight of the part being operated upon will not spring the surface of the plate. The advantage of placing work on a flat surface is that vertical dimensions, even when they are between points not in the same plane, may be easily laid off, and, in addition, both vertical and parallel lines may be drawn on any part of the work by the use of a square and surface gage. Among the more important tools for this class of work may be mentioned V-blocks, parallel pieces and height blocks of various sizes, surface gage, square, dividers, trammels, scriber, prick-punch and the hammer. As these tools are in common use in every shop, a description of them will not be given.

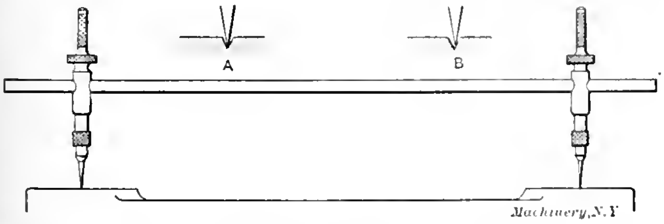

Fig. 2. Testing the Accuracy of the Distance between Centers with the Trammels

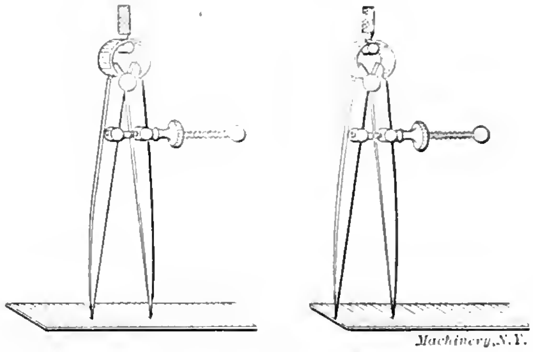
Some parts are laid out prior to any machining, but it is often advantageous to first finish some surface, so that lines may be accurately located in correct relation to one another, from this finished part. Upon some work it is not practicable to plane a surface without first laying out the work in a rough way, as it is necessary to secure average allowances in order that other surfaces may be properly trued. A finished surface facilitates lining out to such an extent, however, that this first or tentative lining is often advisable, so that some broad surface, as for example the base of a frame or bed, may first be planed. Furthermore, it is not practicable to lay out most work in one operation, as some of the lines can often be more conveniently and accurately located on previously finished surfaces and, besides, if every line finally required were laid out in the beginning some of these would be removed by the turning or planing tools. Therefore, the laying out of parts is often divided into a preliminary and a final operation.

A simple example of a preliminary and final layout, is shown in Fig. 1. First a center line is drawn central with the sides *A* and *B* and extended to the ends with the surface gage, as illustrated. The lines *a* and *b* are then drawn parallel to and central with this center line and a distance *y* apart equal to the dimension given on the drawing. The faces *a* and *b* are then ready to be machined, and after this operation the lines for the hole in each end of the link are laid out on the finished surface as shown in the plan view.

In order that the lines drawn upon metal surfaces may be plainly visible, some suitable preparation is applied to those surfaces upon which lines are to be drawn. Common chalk or a mixture of whiting and alcohol and water is often used on rough castings, while a solution of sulphate of copper ("blue stone") gives excellent results on finished surfaces. The thin film of copper which is deposited makes it possible to easily see fine lines, because of the difference of color between the copper and the metal beneath. When the latter method is employed it is essential that the surfaces be free from oil or grease. As the lines which are drawn are quite easily obliterated, especially when they are on a chalked surface, permanence is given them by marking their location with small punch marks, as shown in Fig. 1.



Figs. 3 and 4. Correct and Incorrect Methods of Setting Dividers by a Scale

When locating the centers of two circles a certain distance apart it is not advisable to lay off this distance from the edge of a scale, as this can be more easily and accurately done by the use of dividers or trammels. For instance, if the two centers *c* and *d* were to be located, one of them, say *c*, should first be marked lightly with a small center punch. The trammels should then be set to a distance *x* by placing their points directly against the divisions on a scale. Then with one trammel point in the center *c*, an arc could be scribed by the other point upon which center *d* would be located. The accuracy of the distance between two punch marks can be tested by placing the trammel points in them as shown in Fig. 2. If the bottom of each center coincides with each trammel point as shown enlarged at *A*, this will be evident by the "feel" of the trammel and also by the sound emitted as the point is made to strike the bottom. On the other hand, if the centers are, say, too close, one point will bear on the side as indicated at *B*, and the spring necessary to force it to the bottom can easily be felt.

When setting trammels or dividers, the end of the scale should not be used to set one of the points; that is, if a pair of dividers were to be set to say 1 inch, a more accurate setting would be obtained by placing one point in the 1-inch division and the other in the 2-inch division, as illustrated in Fig. 3, than by attempting to use the end of the scale, as shown in Fig. 4.

All parts to be laid out should first be inspected for blow holes or other defects that would render them useless, and

---

* With Shop Operation Sheet Supplement.

when a casting is the first made from a new pattern, a rough measurement of some of the more important dimensions is advisable. Then in case a core has shifted or insufficient metal is left at some important point, the casting may be discarded before much time has been expended upon it.

Of course, it is impossible to lay down any fixed rule or give any exact method of procedure for laying out machine parts. We shall, however, in a continuation of this article, endeavor as far as possible in the limited space, to teach some of the underlying principles governing this work by giving a detailed description of the way in which one or two typical parts are laid out.

* * *

MINIMIZING THE TIME OF DRILLING OPERATIONS—2

ALFRED SPANGENBERG[*]

In the previous installment the general requirements of drilling machines and the effect of high speed drills on reducing drilling cost are set forth. In the following the causes of lost time, the requirements of an efficient drilling department, the human element and the wage systems are treated, following which is a summary of the elements which enter into rapid drilling.

Causes of Lost Time

The causes of lost time in a drilling department are located so far back toward the fundamentals of production, and the individual units affording the causes are so seemingly unimportant, and such is the difficulty of recognizing these losses, buried as they are in a busy shop, that they are often overlooked or ignored. This is particularly the case in many large shops where the drilling is done in the various assembling departments. It is interesting to note that where this plan is followed, the drills in one department will be operating at such speeds and feeds as to show a loss of 25 per cent when compared with another department directly beside it but under another foreman; and, at that, both departments will be far below the standard of efficiency they should attain. This condition is due, of course, to the relative efficiency or inefficiency of the foremen. The foremen are not all to blame, however, as they seldom have the time to supervise this work and attend to the other important duties that usually require their attention. When the assembling department is sufficiently large to warrant it, the usual method is to appoint a drill boss who was formerly one of the drill hands, and his experience is limited to the routine practice of the shop. Another nullifying condition is that when the drilling machines are scattered, they cannot always be used to advantage. As an instance of this I recently noticed in one shop a large multiple-spindle drill that was standing idle because there was no work in the department where the machine was installed that could be handled to advantage on it. In the next department work was being drilled on a radial drill that could be handled 400 per cent faster on the multiple drill.

Fig. 2. Form of Jig Index Card

It may be objected that some of the holes in various machine elements cannot be drilled until part of the assembling operations are completed, and for this reason it is an advantage to have the drills in the assembling department. I contend, however, that with a proper system of laying out the work, or by the use of drill jigs, all holes that are drilled by a stationary machine can be drilled before any assembling operations are started. All other drilling will permit of being handled more economically by portable air or electric drills. This laying out never should be performed by the assemblers or the drill hands. The economy of having this work done by men set apart for that purpose is due to several reasons. Men become expert and quick at this kind of work; the drills are not idle while the drill hands stop the machine to do the laying out; besides, it can be done on a convenient plate with proper tools, to better advantage than otherwise. These men can also act as inspectors.

In brief, the worst "time wasters" may be classified as follows:

1. Waiting for a new job or because of lack of proper handling facilities. Result, the machine is idle.
2. Measuring up jig bushings to find out what tools are needed. Result, the machine is idle.
3. Getting tools, clamps, jigs, etc., from the tool supply room for a new job. Result, the machine is idle.
4. Excessive time in "setting up" a job, due to lack of suitable fixtures for holding the work, or lack of proper instructions as to the best method. Result, the machine is idle.

Add to these the tremendous loss through failure to use the very best speed and feed for the drills and the result is an output far below maximum efficiency. The important consideration is *time*. Time of the workmen running the drills continuously and efficiently—that is the vital point.

Having these usual defects in system and processes clearly in mind and logically grouped for study, we can easily see the advantages to be gained by having a separate department for the drilling, rigidly supervised by a competent foreman and assistants.

Requirements of an Efficient Drilling Department

The drilling department preferably should be located between the machine and the assembling departments for convenience in routing the work. A proper arrangement of the drilling machines will depend on the character of the work, type of drive, etc., so that no definite plan can be stated which would be generally applicable. It is the general practice to group the machines according to their size and type.

No mention has been made of boring machines for the reason that a proper discussion of them is not within the scope of this article. Before passing, however, it is well to state here that boring operations are so closely associated with those of drilling, that the boring machines are frequently placed in the drilling department. In fact, in many instances boring can profitably be performed on the less expensive drilling machines, especially when boring jigs are used.

The problem of running the drills at the proper speed and feed will be greatly simplified by providing each machine with brass speed and feed index plates. These furnish the drill hands with a standard guide and eliminate all guesswork. A judicious use of the data presented in Table II (July issue) will show surprising results.

The equipment for each drilling machine should consist of an abundance of bolts, straps, adjustable blocking, and other necessary fixtures for quickly "setting up" a job. Work chucks will enable the small work to be clamped very quickly. While this factor of "setting up" is far removed from the single problem of drilling, still it requires a most vital part of the time required to complete a job. The individual equipment should consist of the necessary sockets, bushings, tapping fixtures, wrenches and drifts. The machine number should be stamped on its equipment and a suitable cupboard provided in which to keep the outfit. Suitable work stands are needed for the smaller machines and these should be placed within easy reach of the workmen. For cleaning the chips out of deep holes, a small brass tube fitted with a valve and a dust shield and connected to the air line by a hose, is very useful to have by each machine.

The question of handling heavy work under a drilling machine often becomes quite a problem. For this class of work it will always pay to have good hoisting and handling facilities over each machine. These may take the form of compressed air hoists or an overhead single track carrying an electric hoist serving a number of machines—a very economical arrangement. Of course, where the size of work will war-

---

[*] Address: 951 W. 5th St., Plainfield, N. J.

rant it, an overhead electric traveling crane of the bridge type is to be preferred. For handling heavy work under a multiple spindle drill not provided with a work table on wheels, a specially designed jib crane is needed on account of not being able to reach the center of the table with an overhead crane. This arrangement will permit of handling a number of pieces by the jib crane after the work has been placed within its radius.

Drill and boring jigs will, of course, save the expense of having to lay out the work, but where these are not used it is necessary to provide suitable surface plates. Naturally, these will be located near the receiving point for the work so that the work will be laid out before it is sent to the drills. A surface plate with two surfaces, one at right angles to the other, is very convenient, and will enable center lines to be drawn from surfaces at right angles without having to move the work. It may be advantageous to have a style of plate that is not a permanent fixture in any one place, and hence can easily be moved from one part of the shop to another. Ample provision is needed for handling heavy work on these plates.

If the main tool supply room is not convenient to the drilling department, it will pay to institute a separate tool supply room in this department for the purpose of keeping all the tools, jigs, etc., used by the drill hands. A system should be established for taking care of the tools and jigs, keeping them in good condition, and checking up the workmen in regard to those tools in their possession. Some simple system of checking up the men when returning old or broken tools should be kept. This will enable the foreman to locate his careless workmen. The item of broken tools can become a very large one if the workmen find that little attention is paid to this matter.

It is the practice in some shops to supply and keep with each jig a separate outfit of tools. This is an excellent plan but one that cannot always be considered on account of the great expense involved. However, when the tools are in any sense special, such as boring-bars, cutters, special reamers or taps, they always should be kept with the jig to which they belong. A card index of the jigs will be found very convenient. The specimen card shown in Fig. 2 gives an idea of the data required. The cards are indexed according to the forging and pattern numbers. Jig numbers should appear on all detail drawings. The need for an automatic drill grinder already has been pointed out.

Finally, let me urge the necessity of bringing to each drill hand the work and tools for his next job, *before he is ready for it*, and this presupposes a method of removing the work and the tools when the job is completed. Thus will the workman's every duty be eliminated but that of running the drills continuously and efficiently.

The Human Element and Wage Systems

An article on the subject of "Minimizing the Cost of Drilling Operations" would not be complete unless mention were made of the human element and the effect of wage systems on the cost of production. Owing to the simple character of drilling operations and especially when drill jigs are used, it is the custom to have apprentice boys run the smaller machines and to employ drill hands who are handy men, to run the heavier machines. Any foreman who has "been through the mill" will at once recognize the difficulty of securing proper results from these "drill hands" who have been used to the gait of the average shop, especially if they have been accustomed to using the old carbon drills. I have found that the best results are obtained by securing "green men," who are intelligent and active, and train them properly for the work. In this connection the drilling tables and speed and feed index plates mentioned previously will be especially valuable.

The system of pay and character of the reward will depend upon the nature of the work and the method of pay already in use. The principle of extra bonus or the attainment of standard time can easily be applied to almost any system of pay. The determination of standard time should be made carefully, however. If the rates have to allow for the nullifying influences detailed under the subject of "Causes of Lost Time," the firm will be grossly deceived as to the proper output. A proper discussion of wage systems is too broad a subject to be fully outlined here; in fact, that has already been done by a number of able writers. Suffice it to say, however, that the workmen and the foremen should receive a very substantial increase in pay for accomplishing the very desirable results which can be secured.

Summary

Summarizing the elements that enter into the problem of rapid drilling we have:

1. The machine tools.

These must be of a type suitable for the work and must have ample driving power and possess sufficient rigidity; the best type of drive is with a direct-connected variable-speed motor located near the base; the bearings should be self-oiling, and ball thrust bearings should be provided for the spindle; provision should be made for using an abundant supply of lubricant on the drill when drilling steel; there should be a friction drive for rapid power traverse of head on multiple spindle machines and T-slots in the table of multiple spindle machines so as to permit clamping the work.

2. The cutting tools.

High-speed steel drills and cutters are necessary; these must be run so as to secure a maximum output with a minimum expense for grinding; cooling agents are necessary for steel; sockets for driving tools with broken or twisted tangs are valuable; safety tapping devices are needed; improvement in rose reamers to prolong life of reamer is desirable; drill jigs are an important factor in reducing drilling costs; the use of drill tables is recommended.

3. The drilling department.

There is an advantage in having a separate department; machines should be equipped with speed and feed plates; each machine should have its own equipment of fixtures; ample handling facilities are needed; suitable surface plates and men to lay out the work are necessary; it is essential to have a tool supply room in the drilling department and a system for keeping the tools and jigs and giving out the work is needed; the machines should be kept running continuously and efficiently.

4. The human element and the wage system.

The men properly trained are the most efficient; a system of pay is necessary that will reward the extra efforts of the workmen and the foremen.

* * *

A formula for welding cast iron, developed by Messrs. A. Beltzer and C. Delcampe and published in the *Iron and Coal Trade Review*, calls for a flux consisting of 15 per cent lithium chloride, 20 per cent potassium fluoride and 60 per cent potassium chloride. The cast iron surfaces to be welded are preheated, and then covered with the flux powder and heated to the melting point. Additional material is supplied from a rod of cast iron which is also dipped in the flux and presented to the joint where it melts and flows in, filling up the space and making a sound weld. It is claimed that blow-holes in castings may be filled by the addition of cast iron in the above manner and that metal may be added to defective castings to build them up where defective. In short, this can be made a "putting on" process where required. The means for heating are not given, but probably any non-oxidizing flame capable of raising the temperature to the melting point of cast iron, *i. e.*, 2,200 degrees F., can be employed.

* * *

It is expected that the Manhattan bridge over the East River connecting New York and Brooklyn will be ready for traffic about January 1, 1910. This bridge when completed will make the fourth great bridge spanning the East River and the third largest suspension bridge in the world. The contract for the tower on the Brooklyn side was made May, 1901, and the first caisson was put in place February 1, 1903. The first caisson for the New York tower was installed July, 1903, and the foundation was completed in March, 1904, following which the steel towers were soon erected. For further details, see the article on spinning the cables in the October, 1908, number of MACHINERY.

A TWENTY-FIVE DOLLAR TOOL-MAKING JOB

H. J. BACHMANN*

In order to convey somewhat of an accurate idea of the cost of toolmaking, I have here set down in detail the actual amount of money expended on an extension spindle for a drill press, and also the benefits derived from its use.

Having had an excellent demand for our exhaust fans in the smaller sizes ranging from 18 to 48 inches, we found it advisable to facilitate the manufacture of them as much as possible. After a suggested improvement was decided upon, the manager very thoroughly impressed upon the factory the fact that it was a bad time to spend much money, and that whatever was made must be very simple, etc., and the cost must be kept down to about 25 dollars. With this handicap, the fixture was designed with three objects in view, any one of which might ordinarily be considered of sufficient importance to justify the expense of construction. In the first place, it was desired to drill the set-screw holes in the hubs of large pulleys used on the fans, without drilling through the rim. We have a number of these pulleys on fans running at high speeds, in places where the belt must run noiselessly—something it will not do if there is a hole in the rim. Second, it was necessary to drill the holes *D*, Fig. 1, for the bearing adjusting screws in both the cast iron side frames. There are four of these screws on each fan, and, inasmuch as the screws, when adjusted, are held in position by lock-nuts, the former must be square to allow the nuts to set down flat. These holes had previously been drilled in the ordinary way with a long drill put through at a slight angle so that the shank of the drill would clear the edge of the frame as shown at *B*. While it is true that the inclination of the hole from the perpendicular position is very slight, it was found that the high speed of the fan and the consequent vibration would in a short time loosen the lock-nut unless it was properly seated. There was one other operation on these frames which gave us quite some trouble and that was the drilling of the holes *C* in the feet. On all sizes up to 3 feet, the drill press was large enough to allow the holes to be drilled in the direction *x*, but on the larger sizes we had to resort to the same makeshift of tilting the frame and using a long shank drill. With our extension spindle, however, we are now able to drill the foot holes, as shown by the arrow *y*, on all sizes of frames. Drilling in this direction also gives the additional advantage of being able to use a standard counterbore if the hole comes so close to the side of the frame that it is difficult to set down the fastening bolt.

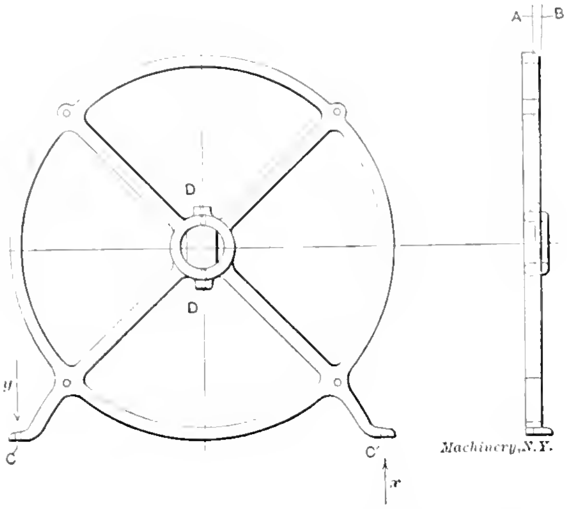

Fig. 1. The Exhaust Fan Frame, which is drilled as indicated by the Arrow y by the use of the Attachment shown in Figs 2 and 3

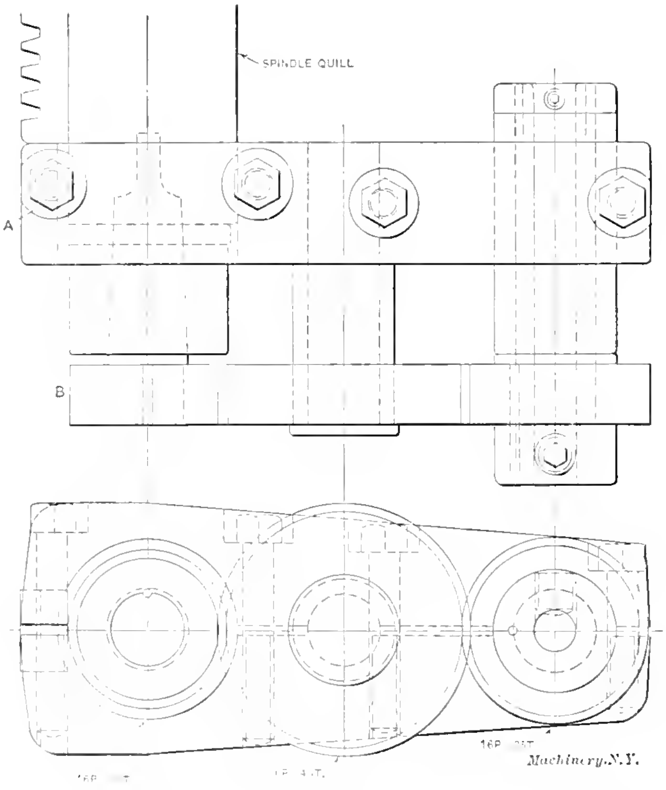

Fig. 2. Extension Spindle and Method of attaching it to the Drill Press

The illustration of the fixture, Fig. 2, will show how well we succeeded in "keeping down the cost." The extension arm was made of two pieces of 1½-inch square, cold-rolled steel clamped together with ⅜-inch cap-screws. A piece of ¼ x 1½-inch cold-rolled steel held between the two larger blocks made it a simple matter to lay out, indicate, bore and ream the three main holes in the arm. This method of making the arm was adopted in preference to using one piece of 1½ x 3-inch stock and splitting with a ⅛-inch saw after boring. By using 16-pitch gears, the center distances, being in sixteenths of an inch, were easily laid out with an ordinary rule and dividers. Finishing the two end holes first, facilitated clamping the work on the face-plate for boring the center hole because the bolts can be put right through the face-plate and the two end holes. The holes for the ⅜-inch cap-screws were counterbored with a ⅝-inch counterbore so as to make the heads come flush with the outside, thereby giving the fixture a very neat and tidy appearance. The heads of these screws fit a standard Williams drop-forged socket wrench, a much better arrangement, taken altogether, than fillister head screws and a screw driver. The outside of the two sections of the steel arm was finished off to the required shape as shown, not by planing or milling, but by standing it upright in the hack-saw vise and sawing a wedge-shaped piece from each side and grinding off the remaining metal on a disk grinder. The time for cutting off 5 inches of 1½-inch steel with the hack-saw running at 110 strokes per minute was

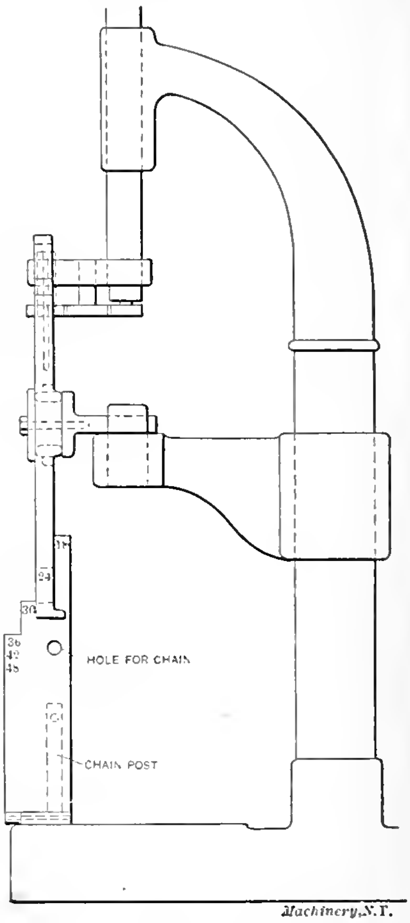

Fig. 3. Drill Prese equipped with Extension Spindle and other Auxiliary Attachments

---

* Address: 292 E. 169th St., New York.

25 minutes, or the total time for finishing the outside to size was 1 hour 10 minutes. When all work on the arm was completed the clamping-cap-screws were taken out and the pieces of ⅛-inch packing strip removed. Three of these clamping screws project into the bored holes of the arm, and are used not only to clamp the entire apparatus together, but two of them also act as pins to hold the intermediate gear shaft and the bearing for the outer spindle in position. The other cap-screw behind the quill of the drill press spindle, bears against a flat on the quill, thus holding the extension spindle rigidly in its proper position directly in front of the main spindle. This flat was made on the quill by cutting 1 inch off the blank end of the feed-rack to accommodate the extension.

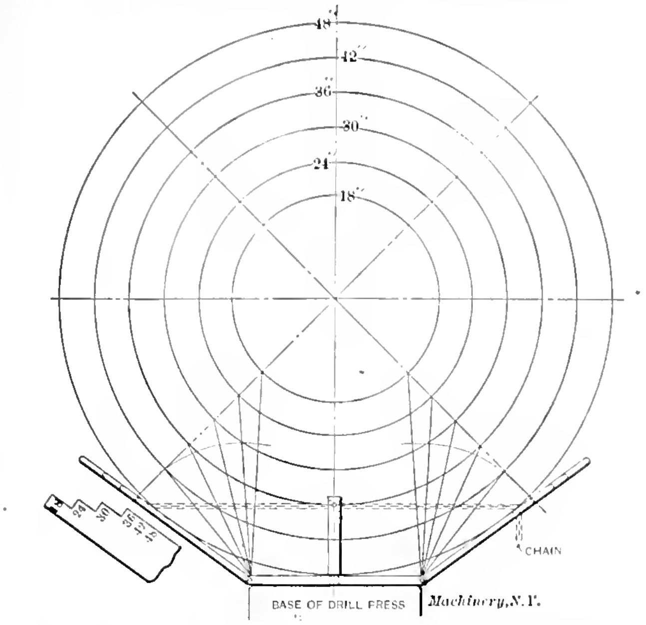

Fig. 4. Layout of a Large Adjustable V-block for Special Work

Not having any facilities for gear cutting it was necessary to buy stock gears. They were fastened to their respective shafts by means of ⅛-inch round pins driven in the ends. The driving gear is fitted to the live spindle with a taper plug in the usual way. The intermediate gear is bronze lined and runs on a shaft having a plain head for an end bearing. The extension spindle has its gear driven against a shoulder, and it runs in a bronze bearing clamped and held in place by the end cap-screw. It is fitted with a fiber washer to take the thrust and a threaded steel collar to take up the end play. A ½-inch reamed hole into which a ½-inch headless set-screw is tapped, serves to hold the drills, the small hexagon wrench furnished with these screws being just the proper thing to use as a key. The drills are the regular twist drills with ½-inch flatted shank, used extensively on blacksmiths' drill presses.

To use the fixture, the end cap-screw *A* is loosened, and the clamping arm is slipped over the driving gear *B* onto the quill, and is drawn into place by tightening the screw *A*. Fig. 3 shows the extension attached to a 20-inch Barnes drill, and also what might be called a few accessories. The fixture did its work so well, ordinarily, that we thought it would pay us to make a complete job of it by adding the two holding devices shown. It is hardly necessary to go into a detailed description of each of these devices, the lower one being simply a sort of a large adjustable V-block (the layout of which is shown in Fig. 4), while that part which is fitted to the table arm is an arrangement made of round cold rolled shafting and used to clamp the frame in an upright position while being drilled. The cost of these was not included with that of the extension spindle, of course.

The following table of the actual cost of the extension spindle alone is figured on the basis of adding 10 per cent of the entire cost to cover the fixed charges, and also on the assumption that none of the material used is kept in stock but must all be bought at retail.

COST OF EXTENSION SPINDLE

1 16-P., 30-T. cast iron gear	$ 0.85
1 16-P., 36-T. cast iron gear	0.90
1 16-P., 48-T. cast iron gear	0.95
11 pounds of square cold rolled steel	0.44
1 ⅜-inch cap screws	0.08
2¾ pounds of Tobin bronze	0.75
5½ pounds of round cold rolled steel	0.22
2 hollow set-screws	0.05
⅛-inch drill rod	0.05
Fiber washer	0.05
Cost of making drawing	5.00
Cost of machine work, 22 hours at 40 cents	8.80
Cost of hand work, 4 hours at 40 cents	1.60
Cost of power, 15 hours, 2 horse-power, at 20 cents	3.00
Total cost	$22.74
Add 10 per cent	2.27
Total cost	$25.01

SPECIAL DRAWINGS FOR THE PATTERN-MAKER

E. W. MILLER*

It is the practice of many shops in this country to make a working drawing of a casting, which suffices for both the pattern-maker and the machinist. The pattern-maker gets a blue-print and is told to go ahead with the work. From the maze of lines he picks out those meant for him, and makes the pattern, and usually he decides the amount of stock necessary for finish. At the outset, the pattern-maker loses time in distinguishing pattern dimensions from those necessary to the lathe or drill press hand. The time lost here, however, is small compared to that lost by the men who work repeatedly on this piece, and who are compelled to use a drawing bearing a lot of pattern dimensions which cannot fail to confuse. Very often, too, these drawings are made at a reduced scale. This necessitates various radii to insure the correct form for curved surfaces. All this adds to the confusion.

At the works of the Fellows Gear Shaper Company special drawings are made for the pattern-maker. These are full size and the amount of finish is decided in the drafting room. No blue-print is furnished, but a buff paper drawing is made, and when the pattern is completed, the drawing is indexed and placed on file. This method has the following advantages: The full-size drawing gives the draftsman a better idea of proportions. By making the pattern drawing first and using this together with the assembly drawing when making details for the shop, the chance of error is much reduced. This is because a pattern drawing must be more thoroughly developed than a shop drawing. The making of several sections and an elevation or two not necessary to the machinist, often brings to light interferences which would otherwise escape notice.

It might be said that the other method of making combined drawings would accomplish this. It is, however, impracticable to make such pattern drawings as complete as they should be. The difficulties of the machinist increase as those of the pattern-maker diminish, so at best it is a compromise. It is the lot of the pattern-maker to form many irregular curves. When the drawing is full size, he may prick through the paper and define a line on a thin board which, when cut to the line, is a correct templet for the curve. This is easily done, requires little time, and is more accurate than a curve formed by laying out parts of circles from radii given.

* * *

More than 56,000,000 gallons of creosote and nearly 19,000,000 pounds of zinc chloride were used in preserving timber in the United States last year. Small quantities of crude oil, corrosive sublimate, and other chemicals were also used. These figures are based upon reports to the United States Forest Service of forty-four firms which operated sixty-four timber treating plants. Assuming that on an average one gallon of creosote, or one-third of a pound of zinc chloride, will protect a cubic foot of timber from decay, more than 100,000,000 cubic feet of cross-ties, piling, poles, mine, and other timbers were given a treatment that will greatly increase their life and usefulness.

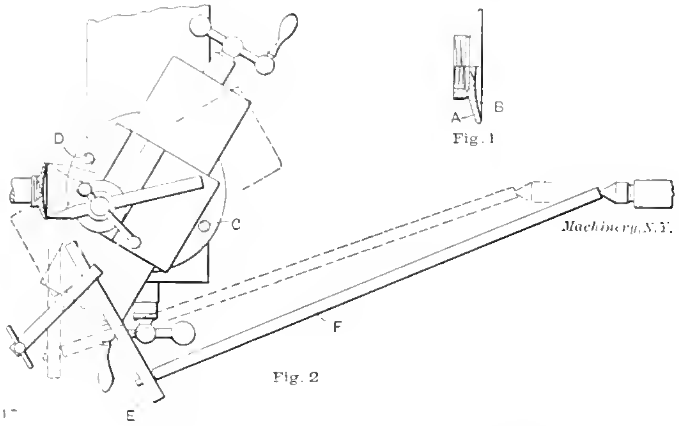
SPHERICAL TURNING WITH COMPOUND REST

The brass casting, Fig. 1, is part of an eyepiece for a small telescope, of which a number were to be made at one time. The curved surfaces, *A* and *B*, while not very particular as to shape and size, would look much better if smooth turned, so it was decided to turn these surfaces with a spherical turning rig and let them go with a good tool finish, rather than to turn them with a hand tool and polish with emery paper afterwards.

Fig. 2 shows how the concave spherical surface was turned. The cross-slide of the compound rest was so set that the swivel pin was directly under the line of centers of the lathe, and the rest was set at such a point on the bed that the distance, horizontally, between the swivel pin and the work, was equal to the desired radius of the surface *B*, Fig. 1. Then by slightly loosening the two screws, *C* and *D*, the top slide could be turned on the swivel pin, which would cause the point of the turning tool to travel in an arc of a circle. It was at first intended to simply grasp the top slide in the hands, and turn it that way, but it could not be moved steadily enough, as it would move by jumps, and leave ridges in the work. The square bar *E* was then clamped to the top slide, and the round bar *F* placed between the outer end of *E* and the tailstock center. Then, by turning the tailstock screw, a smooth, even motion could be given to make the point of the cutting tool travel in the arc of a circle, and produce a good finish on the work. The bar *F* has a shoulder turned on one end that fits loosely in a hole in the outer end of *E*, while the other end of *F* is centered in the ordinary manner. This leaves the top slide of the rest free to be used to feed in for the depth of cut.



Figs. 1 and 2. Eyepiece for Telescope, and Lathe arranged to turn its Spherical Surfaces

It is a comparatively easy matter to adjust the cross-slide so that the swivel pin is in line with the lathe centers. If it is too far forward, the tool will not touch the finished surface when moved around towards the back, as shown dotted in Fig. 2, or if the swivel pin is too far back, the tool will jam into the work when moved to the dotted position. A good way to make this adjustment, is to set the swivel pin at approximately its proper position, preferably a little too far back, and take a light spherical cut near the edge of the rim. Then by placing a test indicator in the tool-post, and swiveling the top slide so the test indicator point bears alternately at the front and back, the cross-slide can be adjusted so the test indicator reads the same in both its front and back positions, when the swivel pin will be properly located, crosswise of the lathe, to turn an accurate spherical surface.

The convex spherical surface *A*, Fig. 1, was turned in much the same manner, only a bent left-hand side tool was used, and the top slide of the rest was nearer to the end of its travel. In this case the bar *E* was not necessary, as *F* could then bear directly against the back end of the lathe tool.

As a matter of fact, two clamps were used to clamp *E* to the top slide, but only one is shown to avoid confusion, and also to make it a little easier for the draftsman and the engraver.

WALTER GRIBBEN.

STRIPPING CUP-SHAPED DRAWN PIECES AND BLANKS THAT ADHERE TO PUNCHES

Die work, as all enterprising mechanics are aware, is to-day playing one of the chief parts in the manufacturing business, and with all its broad possibilities we are continually striving to perfect the most minute, troublesome details to the fool-proof and break-proof basis, thereby bringing out the speed and output, for, as we all realize, every time a stroke of the press is halted there is time and output lost.

In the first place, it goes without saying that in the drawing of all punch pieces there must necessarily be a die-shedder to throw the drafted punchings out of the die, but this is by no means the complete solution of the proposition. Every diemaker or press hand is acquainted with the troublesome, disastrous effect of having the drawn and punched pieces cling long enough to the shedder for the press to come down on a new piece of stock and the punching just made. The outcome is generally a broken die. Of course many thousand may be drawn without any mishap, especially if none or little oil is used on the stock, but without oil the life of the drawing die is soon spent, or in the event of copper or brass being used, the metal amalgamates and necessitates taking down the die to remove the amalgamated stock. In our particular case nothing short of diamond powder would remove the stock from the die and, of course, the cost of this powder all added up in the expense account. When we undertook to put enough oil on the stock to keep the dies in condition, the cups or punchings would invariably adhere to the pushout shedder from oil contact; therefore, we were compelled to punch one at a time, pushing them loose from the shedder each time. After considerable figuring and experimenting, I arrived at a complete solution which has saved us many dollars in die repairs.

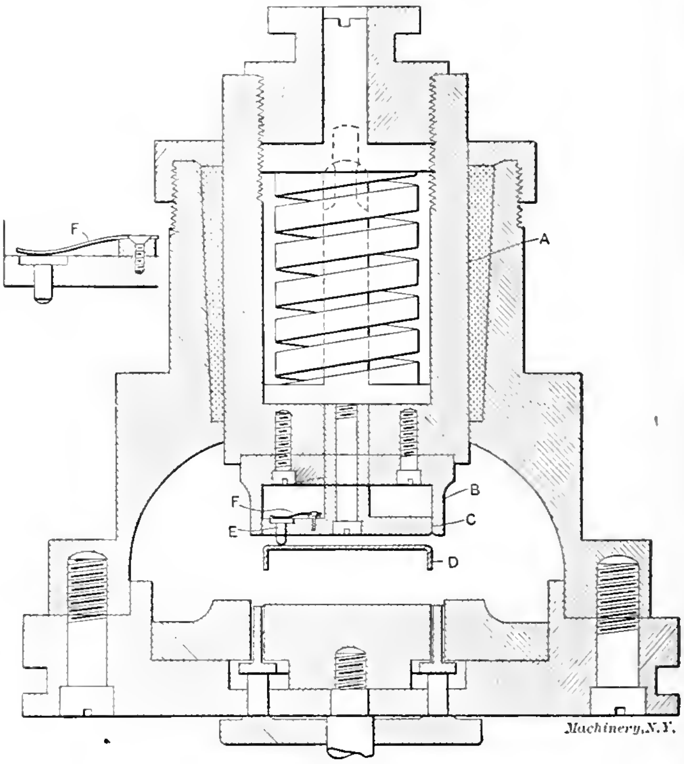

Fig. 1. Sub-press Die equipped with a Secondary Knock-off Pin E

The cast iron piston of a sub-press die is represented by *A* (Fig. 1), while *B* is the hardened drawing die, and *C* the internal die-shedder for pushing the drawn pieces from the die.

Now, as mentioned before, the cup D would cling by oil contact to the shedder C, but by means of the secondary knock-off pin E, with a flat spring F to operate it (see enlarged view), as soon as the cup is pushed from the drawing die the pin E has the tension supplied to it by the spring to break any oil contact that may exist, thereby causing the cup to drop immediately down into the punched hole in the running stock, to be drawn forward out of the way of the succeeding punching. By recessing a spring receptacle, the spring F and pin E consumed no additional space between the die and shedder. This scheme which has just been brought about by me and is truly original as far as we know, has enabled us to increase our speed from 1,500 to 4,500 an hour. The particular punchings in question are of brass and are $1\frac{3}{4}$ inch diameter, $\frac{3}{8}$ inch high, and 0.02 inch thick. We are now running from 25,000 to 35,000 without even touching the dies for repair.

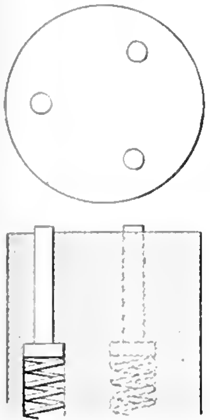

Fig. 2. Punch with Spring-actuated Push-pins to shed Blanks

This scheme has been applied to many flat compound punchings of copper when the center punching has a strong tendency to draw up and stick on the center punch. One instance is that of a copper washer 0.015 inch thick, 1 inch diameter, with $\frac{1}{2}$ inch hole. When blanking sheet copper the die does not seem to be able to shed the punching which invariably comes up after being punched; this, of course, puts two thicknesses of metal between the dies for the succeeding punching, then, by running both punchings, three deflecting pins in the punch with coil springs back of them, as shown in Fig. 2, end the trouble. Springfield, Ill.

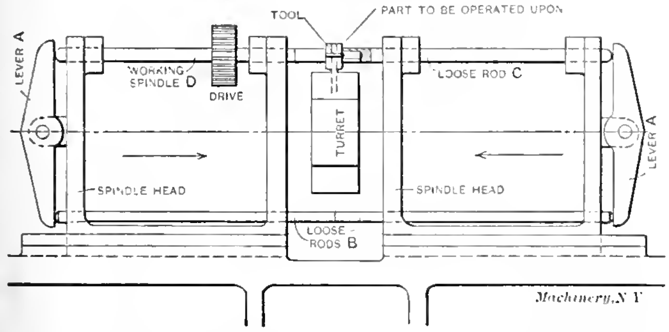
PRESSURE COMPENSATING DEVICE FOR AUTOMATIC MACHINE

When a fixture cannot be built strong enough to resist the pressure of the cutting tool, or when the surface of the part to be operated upon cannot be properly supported, the compensating device, shown diagrammatically in the engraving, may be used to advantage for equalizing the pressure on the part, due to the thrust of the cut. This illustration represents an unusual arrangement of an automatic turret machine. At either end there are levers A, fulcrumed in the center as shown, which can be put into any position. The levers A are so arranged that they are in line with the work-spindle D, the rod C, and the two lower rods B. As the spindle heads move toward the work, there is no appreciable pressure upon the latter when the spindle D or the rod C comes into contact with it, until rods B meet as shown in the illustration. Then the work is subjected to the pressure of the tool, but the former is supported on the other side by rod C with the same amount of pressure as that due to the thrust of the cut. There are doubtless a large number of cases in which this system of equalizing levers can be used to advantage, particularly when the same part is being manufactured in large quantities, such as small rods, links of threshing machines, small parts of sewing machines, etc. Of course, these parts would first be roughed off on the sides by planing or milling. All other operations such as drilling, finish facing, counterboring, counter-sinking and reaming can be accomplished by using the device here illustrated. Other parts such as fly wheels, valve seats, etc., which cannot be securely fastened by their peripheries, can also be drilled, chamfered, reamed, counterbored and even ground and polished by the use of the equalizing levers.



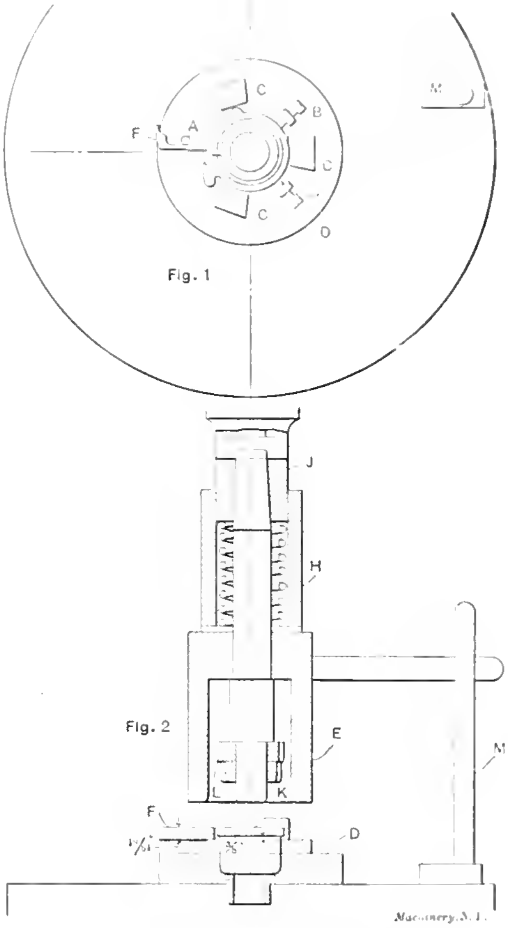
A Device for Automatic Machines, designed to equalize the Pressure, due to the Thrust of the Cut, upon Work which cannot be properly supported

Elizabeth, N. J. PETER ZELINSKI

COMBINATION LOCATING, CLAMPING, DRILLING AND COUNTERBORING TOOL

I have noticed in my travels among the manufacturing plants that many are wasting time by using poor jigs and fixtures. Some will acknowledge that they use poor tools, and the excuse offered is that there is not enough time lost to pay for better ones, but this is rather a poor argument.

The plan view of the drilling fixture shown in Fig. 1 is one that I saw on one of my recent visits to New York City, and this fixture is a fair illustration of the point in mind. The locating of the work was accomplished by the two screws B and the pin A, and the three clamps on pads C held it in place.



A Tool for the Drill Press which locates the Work and then holds it for the Drilling and Boring Operations

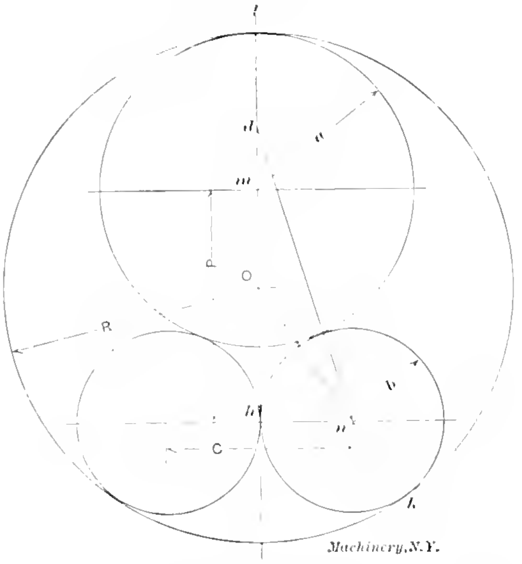
With this fixture the operator machined about 300 finished castings per day. With the improved tool shown in Fig. 2, some 1,000 finished castings constituted a day's work—a gain that well paid for the building of the improved device. This is a combination tool for locating, clamping, drilling and counterboring the work. In constructing this tool the old fixture minus the clamps was retained. This part is located in a central position on the top of the drilling press table, and the three locating points B are used to center the casting with the sleeve E that surrounds the counterbore, which is held in the spindle by its taper shank. This cylindrical bushing E is bored a little smaller in diameter than the outside of the casting F, and the mouth of the bore is flared out in a bell-shape as shown. The lower face of the sleeve is cut away in places in order to clear the projections on the casting to be machined. The top part of the sleeve is bored to a running fit for the shank of the counterbore in order to bring it into alignment with the cutters. A machine steel pin prevents the bush-

ing from revolving out of position. Within the tube *H*, which is a sliding fit on the spindle *J*, there is a steel wire spring which keeps the bushing *E* against the shoulder on the end of the counterbore. This spring also holds the casting down in the jig when the cutters are at work. On the end of the counterbore there is a pilot which enters the bushing which is placed in the center of the fixture *D*, just before drilling takes place, and keeps the counterbore rigid. The casting *F* is drilled and counterbored in one operation by two cutters *K* and *L*. Cutter *K*, which bores the through hole, has a rounded end, while the cutter *L*, which does the counterboring, has a square end. When using this tool, the drill-spindle handwheel is equipped with a long lever, which enables the operator to move the tool rapidly to and from the work. In the face of the drill press table a vertical stud *M* is placed, which acts as a stop and prevents the locating and clamping bushing from moving past its correct position. F. W. HALL.

Berlin, N. J.

DETERMINING THE DIAMETER OF A CIRCUMSCRIBED CIRCLE

On the "How and Why" page of the May number of MACHINERY, the problem given by "J. F. P." of finding the radius *R* (see diagram) when distances *P* and *C* are given, has a different solution from the one that I recently worked out for a similar problem, which is as follows: First find the radius *a* by the method given in the solution referred to; as there stated $a = mn - b$, but $mn = \sqrt{mh^2 + hn^2} = \sqrt{P^2 + (\frac{1}{2}C)^2}$.



The Problem is to determine the Radius R when the Dimensions P and C are given

Next, lay out a distance *ld* equal to the radius *b*. Then *dh* equals $mh + md$ or $P + md$. (md equals the difference between *lm* and *b*.) Tangent angle *hdn* equals $\frac{hn}{dh}$. Angle *hOn* equals 2 × angle *hdn*. *On* equals cosecant angle *hOn* × *hn*. Then *R* equals $On + nk$.

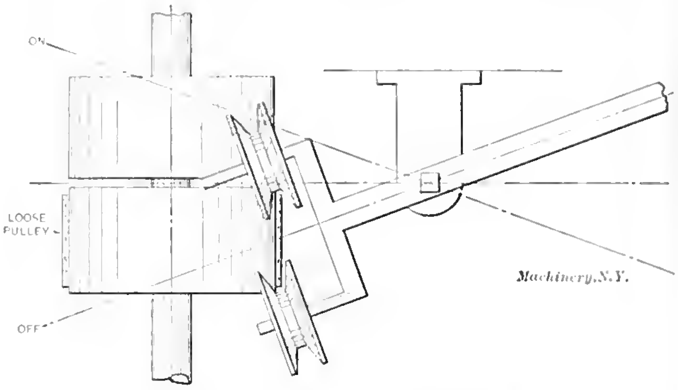
This solution, dealing with trigonometry, may not be as readily understood by some as the one given in the May number, but to one working with angles every day it is much simpler than the one using the algebraic equation.

Ilion, N. Y. A. C. JOHNSON.

IMPROVED FORM OF BELT SHIFTER

A 4-inch crossed belt driving one of our grinders annoyed us by turning over when shifted, and remaining so until, after half a dozen twists were in, it had to be run off the pulleys and straightened. In its twisted condition, the belt was more or less unevenly strained, and when the joint passed through the fork additional chafing was produced that not infrequently pulled out the hooks and disconnected the belt. The grinder was of the type built with the counter-shaft on the base at the rear and served by a shipper-lever that reached forward to a position convenient to the foot. An ordinary iron fork straddled the belt, and, as the machine was started many times an hour by the "approved" method of starting, which was to give the lever a vigorous kick, the time spent in keeping the belt in shape can be surmised.

To "cut out" all this waste time, a new fork was made having turned ends on which were mounted deeply grooved guide rollers between which the belt ran. Thus protected, no amount of kicking at the lever could twist the belt which, being in contact with rolling surfaces only, was not abraded. It will be noticed from the engraving that the rollers never lie in the same plane except when the belt is half on each pulley; they are confined on the forks only by the belt with which they are free to move endways, stop collars not being necessary. These rollers are made of maple, treated to two coats of filler, it being considered better to replace a pair of such inexpensive rollers once a year than to use metal ones which would demand careful lubrication.

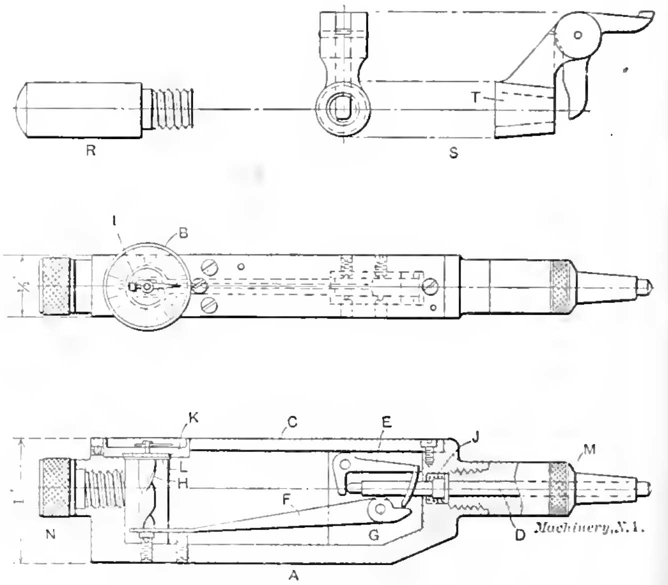


Belt Shifter which will not turn the Belt when operated quickly

Middletown, N. Y. DONALD A. HAMPSON.

COMPACT FORM OF DIAL INDICATOR

A compact form of dial indicator for use on external and internal work is shown in the accompanying engraving. The working principle of this tool, which was also illustrated in the April number of MACHINERY, is as follows: The rod *D*, which is in contact with the work being tested, when forced back strikes the lower arm of lever *E*, while at the same time the upper arm of this lever, in which there is an elongated slot through which rod *D* passes, strikes the fork lever *F*, which causes it to swing on the fulcrum pin *G*. On the long end of this lever there is likewise an elongated slot, that is an exact sliding fit on the flat of the spiral leadscrew *H*. This screw is supported at the upper and lower ends similarly to the pinion shaft of a watch, and rotates on its centers freely without any perceptible jar or friction. As the slotted end of the fork lever *F* is raised it engages with the spiral or thread of the screw *H* and causes it to revolve. At the top of screw *H* is fastened pointer *I* which gives the reading.



Section and Plan showing the Construction of a Dial Indicator

To bring the levers, screw and rod *D* back to their original position, there is a fine wire spring *J* in the head of body *A* that rests against the shoulder on rod *D*, and there is also a watch hair spring *K*, one end of which is fastened to spiral screw *H* and the other end to the dial *B*. Underneath this spring there is a copper washer *L*, which prevents lever *F* from striking the spring. Both of these springs should be so adjusted as to bring back their respective parts to the normal position without any further unnecessary tension, because if these springs are made heavy and a high tension put on them, it will be found that the bearings, etc., of the different levers will soon wear, and therefore the accuracy of the indicator will be lost.

The body *A*, dial *B* and cover *C* may be made of some good grade of cold drawn steel, and all other parts of a high grade tool steel, and hardened. When filing the end of lever *F*, extreme care should be taken in forming it to the proper curve, to compensate for the loss and increased movement at the point where lever *E* bears against it. It is very important that all levers have a free oscillating movement, that all pinion screws are carefully adjusted and that they are a snug fit in their respective tapped holes.

The part *R* is a tail piece or an extra attachment to go with the indicator; this is used to take the place of part *N* when it is found necessary, for instance, to use the indicator in the lathe, in which case it can readily be caught in a boring tool holder. The part *S* is also an extra attachment, and it can be readily attached to the taper end of nose piece *M*. This attachment is used when it is desired to use the indicator to obtain inside measurements. The taper hole *T* should correspond with taper on the nose piece *M*, which is about 1½-inch taper per foot. The lever should work freely without any perceptible vibration, and should be hardened.

Buffalo, N. Y. Lucien Haas.

AIR BLAST ON THE PUNCH PRESS

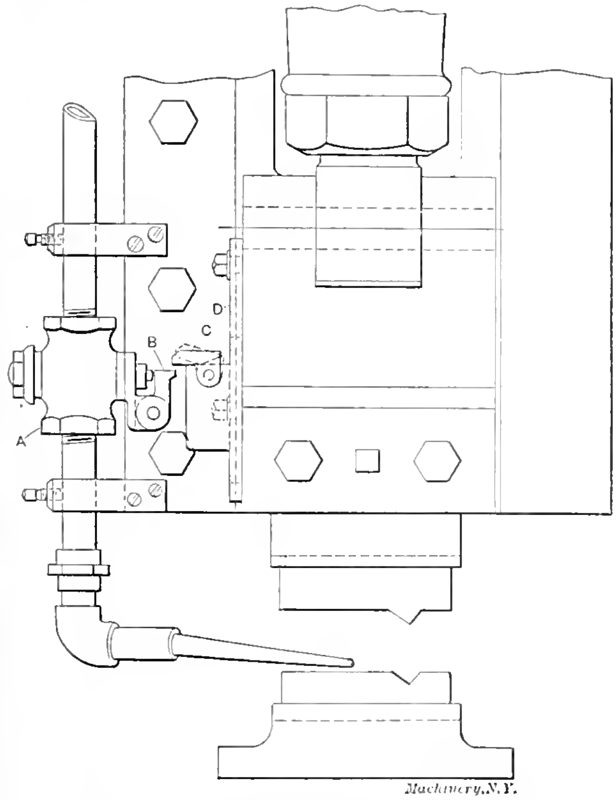


Fig. 1. Pneumatic Punch Press Attachment which automatically removes the Work

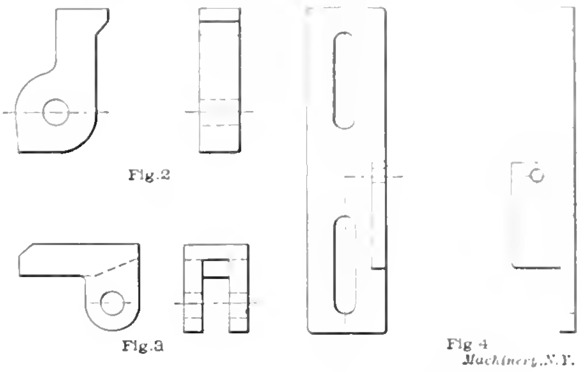
An arrangement for blowing work from a forming die in a punch press, by means of compressed air, is shown in Fig. 1. It is simple and durable, and is used on about forty presses in a large plant, with satisfactory results. The engraving shows a plain forming die in position under the plunger of a press, while at the left of the plunger is the air valve *A* with its attachments. This valve is a Lunkenheimer whistle valve. It is held by the pipes which are screwed into each end, these pipes being held by the brackets which are screwed to the frame of the press. Below the valve there is a union and some other connections, and a bent tube which may be turned so as to apply the jet of air most advantageously. In some cases two unions are used to facilitate the adjustments. The lever of the whistle valve has been removed and in its place the trigger *B*, which is shown in detail in Fig. 2, is mounted. This trigger is so designed that it remains vertical when not in action; it is seen in position against the plunger of the valve. The trigger is operated by the pawl *C*, shown in detail in Fig. 3, which is mounted on the bracket *D* shown in Fig. 4. The bracket is made of angle iron and is provided with two long slots for adjustment when the dies vary in thickness. It is held by two screws which are tapped into the plunger.



Figs. 2 to 4. Some of the Details of the Attachment

As the plunger descends, the end of the pawl *C* rises, as shown by the dotted outline, and passes below the head of the trigger *B*. On the upward stroke the end of the pawl engages the cam on the end of the trigger and thus operates the valve. In this way a jet under full pressure is suddenly directed against the work, blowing it out of the operator's way before the plunger reaches its highest position. When we realize that more time is usually consumed in removing the pieces by hand, than in placing them in position, the saving of time is appreciated.

The same device may be used to advantage for removing dry chips from a vise on a milling machine when doing light work. Often the operator wastes more time in brushing away chips than in doing the actual work. The valve may be clamped to the column of the machine and operated by a slight extra movement of the table. The writer has also adapted the scheme with success to a drill press used to drill wood, on which the table moves.

Camden, N. J. Herbert C. Barnes.

WHAT WOULD JIM HAVE SAID?

The answer given "F. O.," who asked for a general rule for locating a driving and driven pulley on shafts not parallel, in the May number of Machinery, brought before my mind an incident that occurred when Jim and I were employed in a small shop a few years ago. We had a superintendent whose load of wisdom was manifestly all he ought to carry, and no one who knew him would willingly attempt to add to his burden in that line. It was desired to move a machine around at an angle to the main shaft, so the "super" squinted around a little and told Jim to stand the counter on some marks on the floor which he had made. The belt ran off as fast as they tried to put it on, and after that the "super" kept Jim pinching that heavy counter-shaft around the floor for two days trying to find the place where it could be located and have the belt run on the pulleys. Meanwhile the rest of us, who worked by the piece, were waiting for the stock to be put through that machine. Now the "super" (who had brought up one family) had just taken unto himself a new wife and she used to send for him to come home and see her once or twice every day. It was one of these absences that gave us a chance to use the rule given us by an old millwright for belting a machine that was placed at an angle with the line shaft. So when the word went around that the "super" had had a "summons," we went out to see if we could not get that machine to run without his knowing how we did it. Jim's disgust was apparent on his face and more so in his remarks, but he was good for one more try.

and when we said, "Plumb the centers of the delivering faces," Jim understood, and we stayed with him and helped lace the belt so that the "super" would think it just happened to come right.

The answer given "F. O." made me wonder what Jim would have said if someone could have handed him that rule. I imagine he might have read as far as the word tangent and then said, "Tangent to your grandmother," or something more forcible, and then gone on pinching that counter-shaft around to the next trial location. The rule referred to is complete and not very obscure, but I will venture to assert that not one in ten of the better class of men in the shops will understand it without some help. I suppose there are a great many homely rules, which were used before the present generation of mechanics came on the stage, that are just as easily understood as the one given in the foregoing, and if they could be rounded up and written down, would help some one over a hard spot. Who has another? C. A. H.

SOME MILLING MACHINE DETAILS

Times were bad—nothing doing—and our equipment of milling machines was nearly as bad as the times, so we decided to build a couple of millers for our own use. Drawings and patterns were made, and the machines pushed on as rapidly as possible. The drive, as originally designed, was by a three-speed cone, back gears, and a two-speed counter giving twelve speeds to the spindles. After careful consideration and a little figuring, we decided to alter the drive to double back gears. Unfortunately, before we arrived at this decision the body castings had been made so that we had to be content with a two-speed cone in place of the three-speed one, but as this (with the double back gear and two-speed counter) also gave us twelve spindle speeds, we were quite satisfied, though we had to do a moderate amount of extra chipping, facing, etc., to get the new arrangement into the place designed for the old one.

One of my reasons for writing this is to show what a great advantage double back gears have over the ordinary single back gear. Perhaps some readers who are concerned with millers or other cone and single back gear machines will be tempted to alter their drives to the double back gear type—at any rate I should certainly advise them so to do—for in my opinion double back gears are only slightly removed from the constant speed or gear box drives now coming into use and are not by any means so expensive.

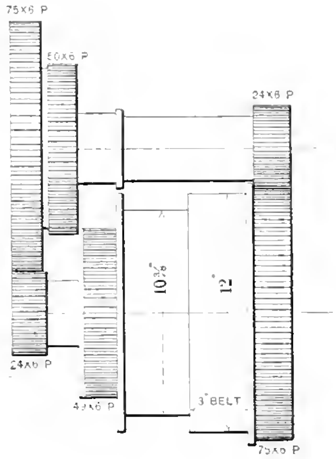


Fig. 1

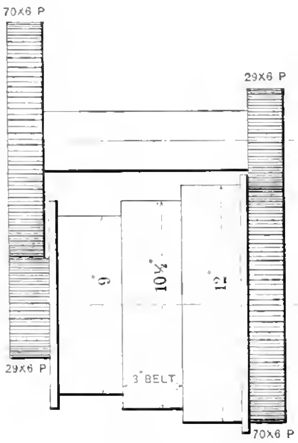
Fig. 1 Double Back Gear



Machinery, N.Y.

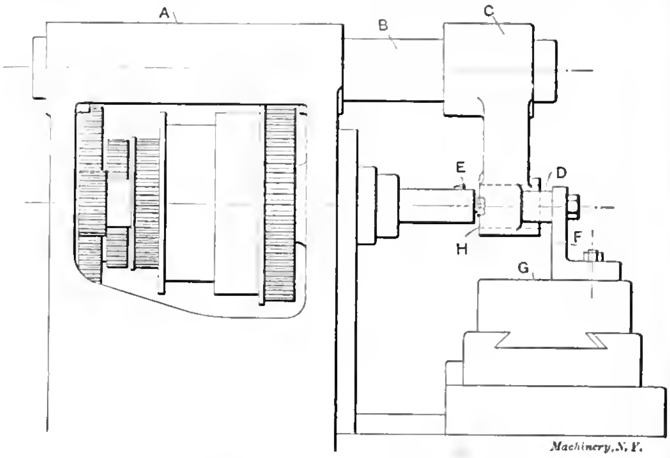
Fig. 2

Fig. 2. Single Back Gear

Fig. 1 shows diagrammatically the two-speed cone and double back gears, and Fig. 2 the three-speed cone and single back gears which were discarded. There are two methods by which we may compare the power of the two arrangements: First by finding the average horse-power transmittable by the cone belt, and second by comparing the average belt and gear purchase. As the first is the shorter method we will apply it here. In any cone drive the horse-power transmitted by the belt varies through more or less wide limits, because as the speeds are varied the belt is working on a larger or smaller step of the counter cone, with the result that the horse-power varies as the diameters of the cone speeds and also (in the case of a two-speed counter) as the counter speeds vary. If, then, we find the horse-power for each belt speed and divide the sums of these quantities by the number of belt speeds, we shall have the average horse-power. The formula for obtaining the horse-power transmitted by a belt is $H. P. = \frac{D \times \pi \times W \times S \times 40}{33,000}$, where D = diameter of pulley in feet, $\pi = 3.1416$, W = width of belt in inches, S = revolutions per minute of pulley, 40 = pull of belt in pounds per inch of width.

It was found that the average power transmitted by the double back gear drive was 30 per cent more than for the single gears. By comparing the two by the second method, that is, by the average belt and gear purchase, the double back gears make a still better showing.

The formula for this method is $D \times R \times W$, where D = diameter of cone step, R = ratio of gears, W = width of belt. Since in this case W is the same for both examples, it may be left out and $D \times R$ used as the formula. If this is worked out for each spindle speed and the average taken as before, we find that the double gear arrangement is more powerful by 40 per cent.



Machinery, N.Y.

Fig. 3. Method of Boring Overhanging Arm

Another valuable feature of double back gears is the comparatively high spindle speeds obtainable through the gearing; this is a very important item in these days of heavy cutting at high speed.

With each machine there is a blue-print table, which gives the spindle speeds, how each speed is obtained, feeds and how obtained, suitable sizes of cutters for each spindle speed at various cutting speeds, and feed per minute for each speed at any one of the fifteen feeds. By this means the operator knows exactly what he is doing; or, what is perhaps even more important, how to get what he wishes to get without any reference to a stop-watch, cut meter or other similar instrument.

I might say in concluding this rather long eulogy of double back gears that we have taken a cut ⅜ inch deep off a piece of cast iron 3½ inches wide at a cutting speed of 50 feet and a feed of 3 inches per minute. The cutter was 8 inches in diameter and was screwed onto the spindle nose, which had eighteen inserted high speed steel cutters.

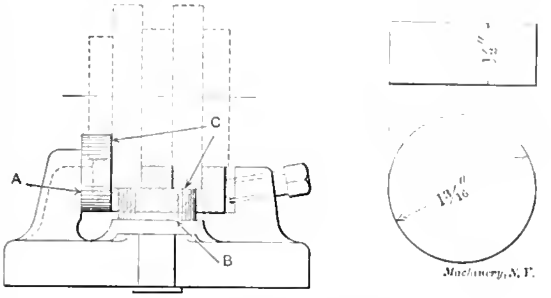
One little detail of construction may prove of interest and that is the method we adopted of boring the arbor bearing in the outer support. This had been previously bored in the lathe, but when we tested it we found that the bearing was considerably out of line with the spindle, so, to insure an accurate job, we rebored it by the method shown in Fig. 3. The outer support C was firmly clamped to the overhanging arm B and the latter was adjusted to its bearing A (by means of the clamp bolts), so that it was a close sliding fit.

The angle plate F was bolted to the table G and also to the brace lug D, care being taken to have the bearing H as nearly in line with the spindle as its inaccuracy would permit. A boring tool E mounted in the taper hole of the spindle completed the outfit, the bearing H being trued up with one roughing and one finishing cut with the regular automatic cross feed for feeding. This made a very good job and one that couldn't

be anything else but accurate. Another method of overcoming error in the bearing of the outer support is to make the bush which fits the hole *H* slightly eccentric so that it may be adjusted to the proper center; but our method is thought to be much better as the bush is then a plain straightforward job easy to replace when worn. RACQUET.

LOCATING TOOLS AND CUTTERS IN PLANING AND MILLING FIXTURES

As one who has had considerable experience with fixtures for planing and milling, I would like to condemn the common practice of providing fixed locating faces, to which tools and cutters should be set directly when machining the pieces held in the fixtures. My experience has shown that sooner or later these locating faces become damaged by contact with the tools, through carelessness or otherwise. A much better practice is to provide locating faces set back from the line of the tool point or face by a certain amount, say ½ inch, so that a standard height block can be inserted between this locating face and the tool. The block is held by hand when setting the tool or fixture until it just touches both the locating face and the tool. By this means a very sensitive adjustment can be made and the locating faces preserved. One of the height blocks, and also its method of application, is shown in the accompanying engraving, in which *A* and *B* represent two locating faces, and *C* the ½-inch blocks locating a milling cutter sideways and for height. HEIGHT BLOCK.



Method of Locating Cutters in Correct Relation to Finished Surfaces on a Fixture

TWO BENDING DEVICES

In the manufacture of gasoline lamps on a small scale, a jobbing shop uses two bending jigs that may be of interest. The upper part of the framework of the lamp is made of rather heavy brass tubing about a quarter of an inch outside diameter, bent as shown in Fig. 1. This tubing is bent with the tool shown at the left in the engraving. When in use it is screwed flat on the bench, near one corner, where the handles may be easily worked. The levers *A* and *B* and the attached roller are slipped off the pivot pin and a piece of tube of the proper length is passed between the roller on lever *C* and the first former, through the hole in the post *D* and against the stop shown. The lever *C* is then pulled around, bending the tube over onto the second former. The levers *A* and *B* are then slipped on and the final bend is finished. The two levers *A* and *B* are used for adjusting purposes. The tubing is heavy enough to bend nicely without filling, the rollers being of course, grooved the size of the tubing.

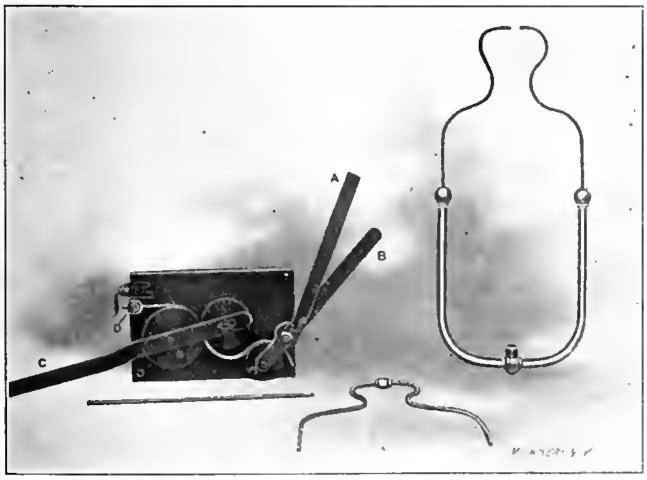


Fig. 1. Tool of Simple Construction for Bending Brass Tubing

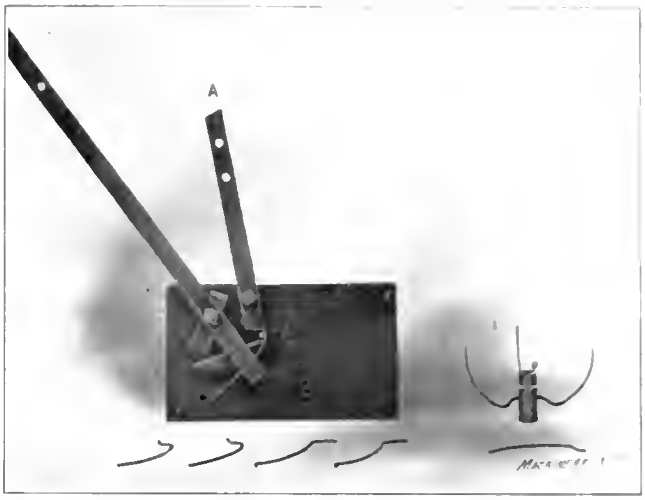

Fig. 2 Device for Bending the Wires shown in the Illustration

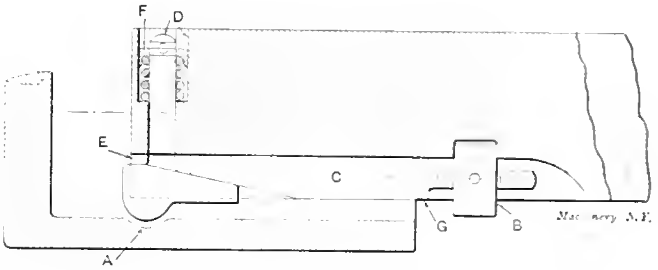
Fig. 2 shows the tool for bending the wires used to hold the glass globes in place. In order to get the little kink in the end of the wire, a hole is drilled in the end of lever *A*, into which the end of the wire is slipped while the end of the other lever is up as far as possible. Lever *A* is then pulled up against the stop-pin and held there while the bend is finished with the other lever. E. V.

ADJUSTABLE BORING TOOL FOR TURRET LATHE

To effectively accomplish all the work of the turret lathe with the general line of tools with which a machine is equipped is impossible; some form of boring-tool which can be adjusted without altering the position of the turret head will often be of value. There are many types of this class of tool, some of which are altogether too flimsy to be used when heavy cuts are necessary. The tool illustrated herewith is stiff and rigid, and, consequently, it can be used on heavy cuts. The illustration shows a part section of a casting, the bore of which was first machined with the bars in the turret. The special adjustable boring-tool is used to form the recess shown at *A*. The tool is adjusted to the proper position in the bore as shown, and then it is fed into the metal by turning the feed-nut *B* which forces the wedge-shaped feed bar *C* under it, thus giving steady feed.



Recessing Tool which may be fed into the Work without Changing the Position of the Turret

When making a bar of this type care should be exercised when fitting the cutting tool, as it should be a close sliding fit in the hole *D*, and, at the same time, have a good bearing on the sides of the slot *E*. The spring shown should be strong enough to keep the tool rigidly on its seat. The cap *F* retains the spring and prevents any dust or borings from getting to the spring and tool-shank. The cutting tool is made of high-speed steel, and the feed bar *C* of mild steel with taper end case-hardened. That part of the tool-shank which passes through feed bar *C* is flattened in order to reduce the width of the slot in *C*. A thread of fine pitch on the end of the feed bar provides a slow feed to the cutting tool. The slot at right angles to the bar which receives the feed-nut *B* should

be circular, so as not to weaken the section of the bar more than is necessary. Obviously, any shape or form of cutter can be used for various classes of work, such as clearing out the cast recess in the combustion chambers of automobile cylinders, etc. Needless to say, the slot and feed bar must be long enough to allow the feed-nut to be outside the bore of the work being operated open, so that the nut can be turned readily. Lines can be scribed on the edge of the feed-bar slot, as at *G*, to indicate the exact position of the cutting tool and when the required depth of cut has been reached.

CONTRIBUTOR.

SHEARING PUNCH AND DIE

We received an order in a tool job shop to make about fifty shearing punches and dies that were required to make about as many different size blanks. Extreme accuracy as to dimensions was not specified or necessary, but nicely cut laminations were insisted upon. The design submitted had been carefully worked out for a tool that would last a long time and produce an immense number of punchings before having to be replaced. The first consideration, that will be apparent to all, in the design of this die is rigidity. The die-holder, it will be noticed, is massive and well laid out to firmly support the steel members and lessen the liability of springing during the action of cutting and causing premature wearing away of the cutting edges. The stock used for the lamination is 1/64 inch sheet iron, of a brittle quality, and covered with scale that is detrimental to a keen-edged tool or sharp corners. For this type of die, in order to obtain the most satisfactory results, extra hard steel is of special importance, while for the piercing punch, hardness should be combined, as far as possible, with toughness, to insure the acute edges standing up.

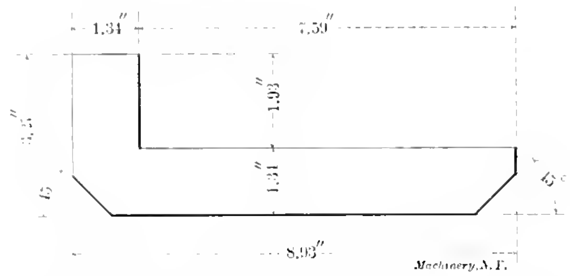


Fig. 1. Blank produced by the Punch and Die shown in Figs. 2 and 3

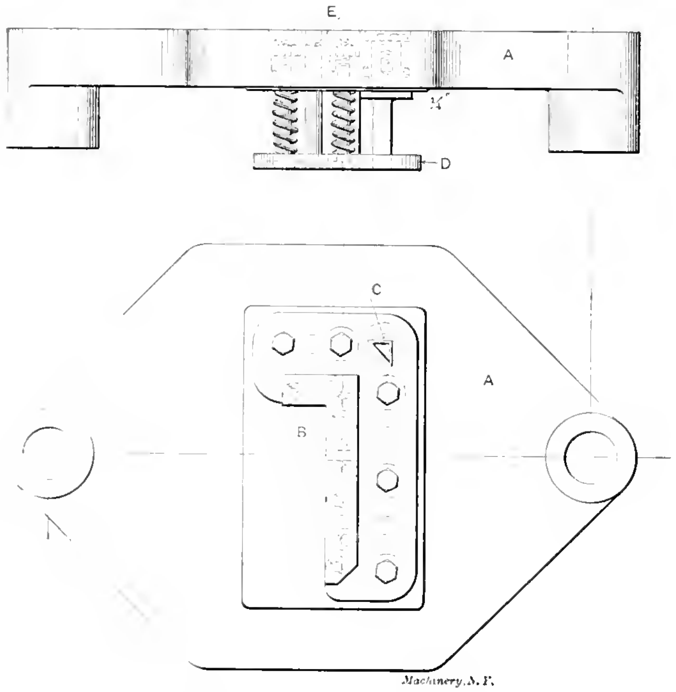

Fig. 2. Punch for the Die shown in Fig. 3

The outline of the blank is shown in Fig. 1, and the punch and die are illustrated in Figs. 2 and 3, respectively. By careful reference to the drawings, the construction will be understood. In Fig. 2, *A* represents the cast-iron punch holder; *B* the shearing punch secured to the holder by screws and pins; and *C* the piercing punch that cuts away the corner of the lamination. The combined stripper and stock-holding plate *D*, made of machine steel, is moved downward by compression springs and maintained in place by screws and nuts as shown. Pins *E* are provided to steady this plate, as it is not very closely fitted to the punch. A clearance of 1/32 inch is given around the piercing punch to avoid springing this member, should the stripper cramp.

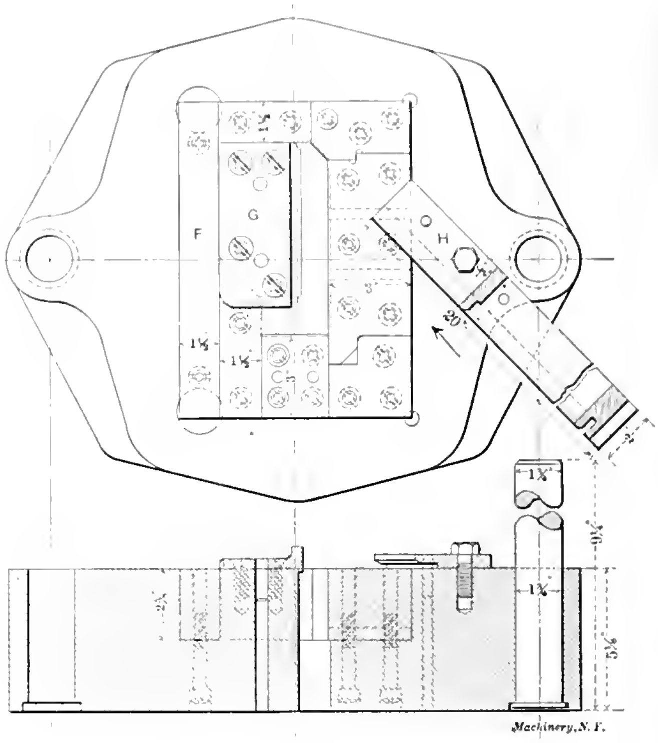

Fig. 3. Section and Plan of a Die for producing the Blank, Fig. 1

In Fig. 3 the manner of arranging the parts is clearly shown. The box-shaped holder is carefully planed to receive the six steel sections that, when assembled as indicated, comprise the working parts that do the piercing of the stock and the shearing away of the blank. The machine steel bar *F* fills in a cavity that is first machined out to allow clearance for the planer tool when working out the inside. The backing plate *G*, as will be seen, is secured to the face of the holder by screws and dowels; this member acts as a stop for the stock and also supports the punch and prevents it from springing away from the cutting edge of the die. A machine steel guide *H* for the stock is fastened to the die, and like the backing plate, has to be removed when sharpening is necessary. The punch and die are sub-pressed with 1¾-inch pins, for without these die-aligning studs the setting of such heavy tools in a press becomes a time-consuming operation, while with them it is only a matter of a few minutes. No clearance is given in the die, except on the three sides of the piercing hole, the blanks being almost free as soon as they are forced down in the die beyond the overhanging edge of the backing plate. The springing of such thin plates eliminates friction at the ends and permits them to drop out of the die.

Under working conditions, preparatory to shearing the blanks, the stock which rests against the back guide *H* is fed from right to left in the direction indicated by the arrow until it butts against the backing plate *G*. On the first stroke of the press, a portion of a blank is cut and a hole pierced; the second stroke either cuts off a perfect punching or a nearly complete one, according to its length. The only waste is that on the end and sides and the small triangular piercing. Owing to the shape there is considerable loss at both ends, hence sheet stock of longest length is provided. Twenty-five thousand is the average run per day, and between sharpenings fifty thousand clean cut plates free from burrs are sheared.

It may be well to call attention to the fact that the accurate size and location of the piercing punch is of utmost importance. Should this be at all out of place, notches on the inside of the laminations or sharp points at the angles will be manifest.

TOOLMAKER.

SHOP KINKS

PRACTICAL IDEAS FOR THE SHOP AND DRAFTING-ROOM

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary

TWO USEFUL BLACK-BOARDS

In connection with the instruction of mechanical drawing, it was necessary to use the black-board frequently, and, as the scale of the drawing was then enlarged, much mental calculation was necessary. The drawing sheets used were 13 × 17 inches, so it was thought a good plan to divide the top edge of the board, which was 48 inches in length, into 17 divisions, and a space along the left-hand edge into 13 equal divisions. These divisions were then, in turn, divided so as to represent half inches. All sketches were then easily drawn to scale, the trouble of figuring the proper black-board dimensions was eliminated, and, incidentally, many questions were not asked which would have been otherwise. There is space still left at the bottom of the board for any explanatory work. Fig. 2 represents a black-board well adapted for the engineer's office. The factory grounds and buildings are permanently drawn on the board with white paint. Any suggestions regarding the changing of or additions to the plant can be conveniently sketched in, and altered without injury to the original plans. C. E. J.

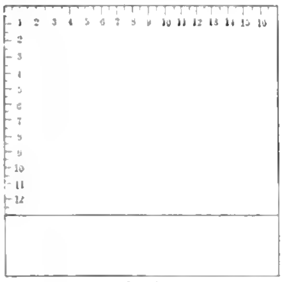

Fig. 1

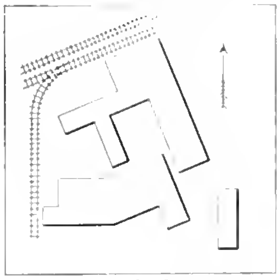

Fig. 2

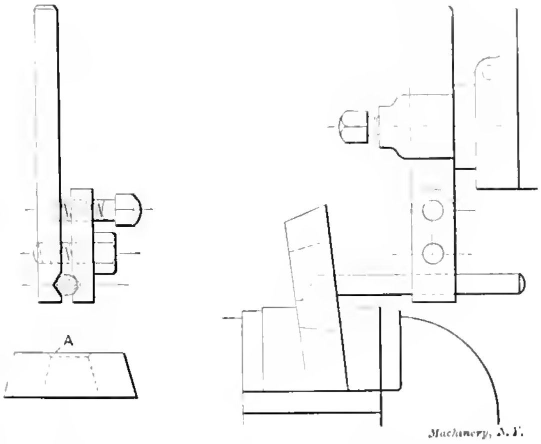
Machinery, N.Y.

ADJUSTABLE SHAPER TOOL

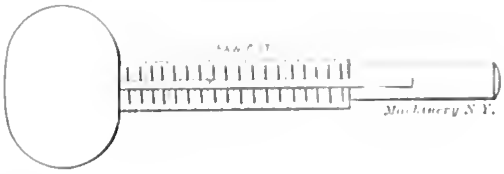
The tool-holder for the shaper described in the February issue of MACHINERY is very similar to one I saw a few years ago, the sketch of which is shown herewith. The tools generally used were a half inch in diameter, although larger or smaller sizes could have been used as well, as will be evident by referring to the engraving. Primarily, this holder was made for planing out blanking dies, the dies being held in the vise in the manner shown. After the core was taken out, the top edge of the blank was beveled as shown at *A*, to prevent the metal from breaking out beyond the finish line.



Stamford, Conn. J. PRICE.

A THUMB-SCREW THAT WON'T JAR LOOSE

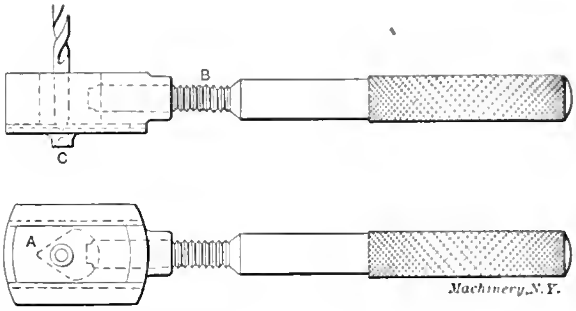
It is sometimes necessary to have a thumb-screw which can be used for adjusting purposes conveniently, that is to say, so it can be used without having to manipulate a lock-nut or other retaining device. The sketch shows a style of thumb-screw which is effective. The saw cut is put in by milling from both sides after the thread is cut, then a die is run over the threads to remove the burrs, after which a narrow thin wedge is driven into the slit which widens the threaded portion at the center. It is obvious that a screw of this kind can be easily put into place as the end is not distorted appreciably, and the compression is gradual. Ordinary malleable iron thumb-screws have enough spring to them to act well. More or less tension can be obtained by making the distortion to suit. H. R. ASH.



Chicago, Ill.

HOLDER FOR SMALL DRILLS

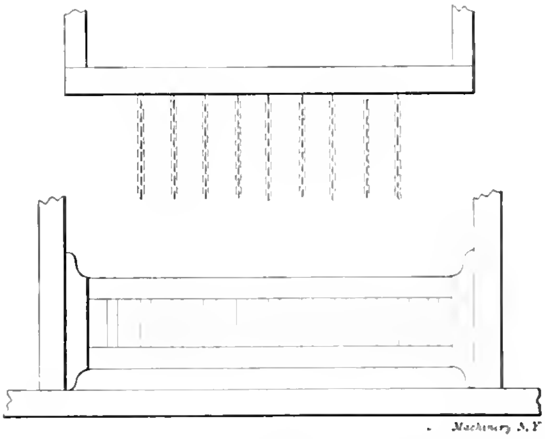
The tool for holding small drills, which is shown in the engraving, is very handy and convenient when small holes are being drilled in the lathe when the tail-center is used to support and guide the drill. The pointed end of the drill is placed in the center in the sliding plate *A* as shown. The screw *B* is then tightened, and the plate follows the drill. As the center *C* is in line with the one on the inside of the plate, the result is practically the same as if there were a center in the drill. W. W. COWLES.



Poughkeepsie, N. Y.

FOREWARNING THE LOWERING OF AN ELEVATOR

Perhaps the cheapest and most convenient device used for forewarning the lowering of an elevator is shown in the engraving. A number of small chains about two feet long are hung from the bottom of the cage. If the elevator is coming down, and an attempt is made by the user to look up from the gate when the elevator is within a short distance from his head, he will have time to avoid a serious, or perhaps fatal, accident because of the warning given by the lowering chain. [Of course it will be understood that the height of the gate is often limited by the distance between the floors.—EDITOR.] This device is in daily use in at least one factory, and doubtless if it were installed in many more, a large number of elevator accidents could be prevented. C. E. J.



HOW AND WHY

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST

Give details and name and address. The latter are for our own convenience and will not be published

ALLOWANCE FOR "SET" OF LOCOMOTIVE PISTON RINGS IN TERMS OF DIAMETER

B. L. H.—What is the proper amount of excess diameter allowance to make in turning locomotive piston rings of the concentric and eccentric types? The chief engineer of our road claims that 1/32 inch allowance per inch diameter is right, but others say that this amount is excessive. The rings are 22 to 23 inches diameter, 11 16 inch wide, and 3/4 inch thick. The cast iron is of medium grade.

A.—The allowance for "set" made in the ordinary snap or Ramsbottom piston rings, varies considerably according to different authorities, the range being from 1 to 3 per cent of the cylinder diameter. Common practice points to about 1½ to 2 per cent in the case of narrow rings of the concentric type. In the case of a 22-inch cylinder, this would mean that the rings would be turned about 5/16 to 1/2 inch larger than the bore of the cylinder. Eccentric rings should be made with practically the same allowance but more can be given if they are sprung together after the excess is cut out and the outside turned to the cylinder diameter while held in a suitable chuck. In general there is no gain in making the allowance greater than one-half the ring depth, that is the radial dimension, for the ring will be practically worn out before the wear has equalized the "set" to the cylinder diameter.

CARRIAGE-BOLT HEADS, SHANKS AND SCREW THREADS

C. H. T.—For some time I have been searching for data on the dimensions of heads and shanks of carriage bolts, but have been unable to find any information, although I have looked over a great many standard mechanical hand-books and textbooks. Kindly publish in an early issue a table giving these dimensions; also data on carriage bolt screw threads.

A.—The accompanying table giving the dimensions of heads and shanks and number of threads per inch of carriage bolts from 3/16 to 3/4 inch diameter inclusive, was supplied by the Michigan Bolt & Nut Works, Detroit, Mich., and gives the standards of this company. There is no recognized standard of carriage bolt thread. The tendency is for users to demand the United States standard thread and pitches. The typical carriage bolt thread is a sort of compromise between the Whitworth and a screw thread, but up to a few years ago hardly any two makers of carriage bolts used the same shape thread or number of threads per inch. When a manufacturer wanted new taps or dies it was necessary for him to send samples to the tap and die makers to insure perfect duplication. Some years ago the J. M. Carpenter Tap & Die Co., Pawtucket, R. I., reduced the conflicting shapes to a standard governed by the pitches of the thread, which they were able to duplicate whenever necessary without the trouble of referring to samples. This standard has been adopted by several large manufacturers of carriage bolts, but as previously stated, the tendency of users is to use the established and readily duplicated United States standard thread and pitches. The second table gives the shape and dimensions of the Philadelphia carriage bolt screw thread, which is typical of carriage bolt screw threads in general.

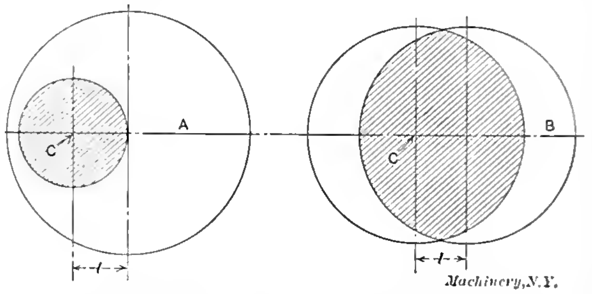
ECCENTRICS AND CRANKS

R. A. B.—What is an eccentric, and when does an eccentric become a crank?

A.—An eccentric is defined as an enlarged crank-pin that encircles the shaft. There are intermediate conditions, however, that make the distinction between an eccentric and crank not always easy. In the illustration, *A* clearly is an eccentric, and *B* may be named either an eccentric or a crank without exciting violent protest. The following points may be considered in analyzing the matter as distinguishing an eccentric from a crank: 1. Relative diameter of crank-pin and shaft. 2. Ratio of throw to diameter of shaft. 3. Whether the function is that of converting rotary action into rectilinear motion, or *vice versa*. The defining line between an eccentric and crank-pin might be assumed to be where the periphery osculates the shaft, all forms being considered eccentrics which completely encircle the shaft and all whose peripheries at any point lie between the shaft surface and its center, as being cranks. In the last, our notion would be to always limit the diameter of the crank-pin to a size not larger than the shaft and to limit *l* (one-half the throw) to not less than one-half the shaft diameter. Then, if the diameter is larger than the shaft, and *l* equals or is less than one-half its diameter, we would call it an eccentric; if the size of crank-pin is less than one-half the shaft diameter, and the throw equals or is greater than one-half the shaft diameter, we would name it a crank. According to this rule both examples shown in the illustration are eccentrics. If the function is that of converting rotary to rectilinear motion, cranks close to the limiting conditions set forth in the foregoing might be preferably named eccentrics, or, conversely, eccentrics may be called cranks. The throw of an eccentric or crank is the stroke, and is 2*l*.



SHOP RECEIPTS AND FORMULAS.

A DEPARTMENT FOR USEFUL MIXTURES.

This page is intended to be used only for the publication of such shop receipts as the contributors know from experience to be practicable. Receipts are solicited on the condition that the contributors personally know that they are reliable. The fact that a receipt is old and supposedly well-known does not bar it, provided it has not already appeared here.

INK FOR WRITING ON CELLULOID

Ink for writing on celluloid triangles, etc., can be prepared by dissolving a tar dye stuff of the desired color in anhydrous acetic acid. JOHN B. SPERRY.

Aurora, Ill.

POLISHING WOOD

A very nice polish on wood is obtained by using the following mixture: ½ pint of alcohol, ¼ ounce of shellac, and ¼ ounce of resin. Dissolve the shellac and resin in the alcohol; then add ½ pint of linseed oil, and shake the whole mixture. Apply with a sponge, brush or flannel. Rub the wood thoroughly after the application. E. W. NORTON.

RECOLORING BRONZE

Bronze may be renovated and recolored by mixing one part muriatic acid and two parts water, and applying the diluted acid to the bronze articles with a cloth. Before applying the acid the articles should be cleaned thoroughly from all grease. After having applied the acid let the article dry, and then polish with sweet oil. E. W. NORTON.

SOLDERING PASTE FOR COPPER WIRES

Soldering paste has come into extensive use in electrical work as a flux for soldering, and the following recipe will be found useful in soldering copper wires when the use of an acid would be objectionable. This paste will not spatter or corrode, and the proportions are as follows: Saturate solution chloride of zinc, one dram; vaseline, 1½ ounce.

Philadelphia, Pa. WILLIAM DAVIS.

TO COVER IRON PULLEYS WITH RUBBER

Thoroughly clean the surface of the pulley; if the pulley has just been turned in the lathe, so much the better. Give it a thorough wash in muriatic acid and let stand over night. In the morning give the iron and rubber a good coat of heavy yellow shellac varnish and apply the rubber and clamp. Let stand until thoroughly set. E. B. GAFKEY.

Lakewood, Ohio.

SOLDERING ALUMINUM AND COPPER

It is often stated that aluminum cannot be readily and successfully soldered to other metals. I have, on numerous occasions, successfully and easily soldered aluminum to both copper and brass by the following method: First tin the aluminum and the copper, or brass, using stearine as a flux; wipe off clean, then use zinc chloride as flux, with solder composed of: tin 67 per cent, lead 33 per cent. T. ILES.

Manchester, England.

CEMENT FOR FIXING LEATHER OR PAPER TO PULLEYS

Soak six pounds of carriage glue over night; then heat until thoroughly dissolved and add six pounds of white lead ground in oil. Reduce the mixture with oil until it is of a free working consistency. Now add one ounce of nitric acid and stir until thoroughly mixed. The pulley surface should be made thoroughly clean and should be warmed to about 125 degrees F. Then apply the cement and clamp on the leather and let stand twelve hours before using. If the job is done right, the leather will have to be turned off in a lathe in order to remove it. E. B. GAFKEY.

Lakewood, Ohio.

SPOTS ON BLUE-PRINTS

We were bothered for some time with peculiar blue spots on our tracings, which were next to impossible to remove, and which caused spotted blue-prints. The office receiving these prints finally requested us to remove the ink blots from our tracings. The trouble was finally located in connection with the blue-printing. The one doing this work had a habit of making one print, washing it at once to prove the color, and then printing the entire lot. Now after washing the first print, he did not thoroughly dry his hands, and on placing the next print, the paper was moistened and the exposure "fixed" some of the blue clear through the tracing cloth.

HOWARD D. YODER

BATH FOR HARDENING HIGH SPEED STEEL.

An excellent bath for hardening high speed steel consists of a mixture of table salt and paraffine oil, in the proportion of one pound of table salt to each gallon of pure oil. The steel is heated to a lemon color, and plunged into the bath, being kept in motion until it has thoroughly cooled. The steel should come out of this bath gray in color, and nearly free from black spots. The bath referred to can be used for almost all brands of high speed steel, with good results. It has been used to great advantage for the Midvale steel, and also on a large number of tools made of Novo, Simeteora, Rex, Jessop high-speed, and Blue Chip steel. On all these, good results have been obtained, but it may be added that this bath seems to give the best results with the Midvale steel.

H. S. STEEL.

FOR HOLDING LEATHER ON IRON PULLEYS FOR BAND SAWS

First soak twelve ounces of good glue in cold water. Put four ounces of boiled oil and four ounces of turpentine into the glue pot, and in this dissolve three ounces of resin. When the resin is dissolved, add the glue. The resin and glue should be well stirred while dissolving.

Before applying the leather cover to a pulley have it warm and dry, and scrape off all matter that may have accumulated on its face. Then, with a swab, apply muriatic acid (full strength) to all parts of the face of the pulley. When dry, wipe gently with waste. Cut leather lengthwise of hide, and a little wider than the face of the pulley. Have the cement melted in the glue pot, apply it across the face of the pulley, with a brush, for about six or eight inches, lay on the end of leather and rub it down hard with the corner of a piece of wood. Fold back the leather and continue to apply cement until the pulley is covered. Two thicknesses of leather are used. Make the first thickness a butt joint, and the last a scarf or lap joint of about three or four inches long. Make the laps on the driven pulleys the way they run, and on the drivers the opposite way. Pulleys should be cleaned by holding a piece of coarse sand paper against them. R. F. WILLIAMS.

Montreal, Canada.

HOW TO SAVE UNDERPRINTED OR OVERPRINTED CONTACT COPIES

Blue-prints are never so over-printed that they cannot be reduced to a suitable depth by a slightly alkaline bath of borax, bicarbonate of soda, washing soda, or ammonia. Black-line, or "ink" process paper, is usually lost if slightly over-printed; if under-printed it develops too gray all over its surface to be of use for tracing or for reproduction photographically. In the winter-time, when prints from thick paper drawings are apt to be under-exposed, I treated a number of such apparently useless prints with a lotion for throat troubles—the first "tonic" available—with excellent results, the invisible lines developing out a strong black on a gray ground. The mixture was tannin-and-glycerine solution to about 20 parts of water. When using this solution it is safer to under-print rather than to over-print, with the resulting weak or broken lines.

Sepia prints, when much over-printed, can be saved by washing in a very weak solution of hyposulphite of soda, which bleaches away the image before it can become fixed by the usual preliminary wash in plain water. The hyposulphite solution is so energetic that it will bleach down the darkest of sepia prints if not previously put in water. Purple tones are obtained, after washing, by treating with any gold-toning bath. CHARLES R. KING.

Staple Hill Park, Bristol, England.

NEW MACHINERY AND TOOLS

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP

THE LODGE & SHIPLEY "MARVEL" LATHE

A new type of lathe has recently been brought out by the Lodge & Shipley Machine Tool Co., of Cincinnati, O., which in many respects differs from the ordinary types, and which possesses many valuable features which are entirely original. The prime object in the design of the lathe has been to produce a machine suitable for the rapid production of duplicate parts made from bar stock cut to the required length. One tool in conjunction with a number of automatic stops will turn any number of diameters on any number of pieces to the same dimensions, providing the number of diameters does not exceed the number of stops furnished. The distances between the shoulders on the turned pieces can also be made exactly the same on any number of pieces by using the automatic longitudinal stops provided. As these features are original with the Lodge & Shipley Company, patents have been applied for, covering all of the new devices embodied in this type of lathe.

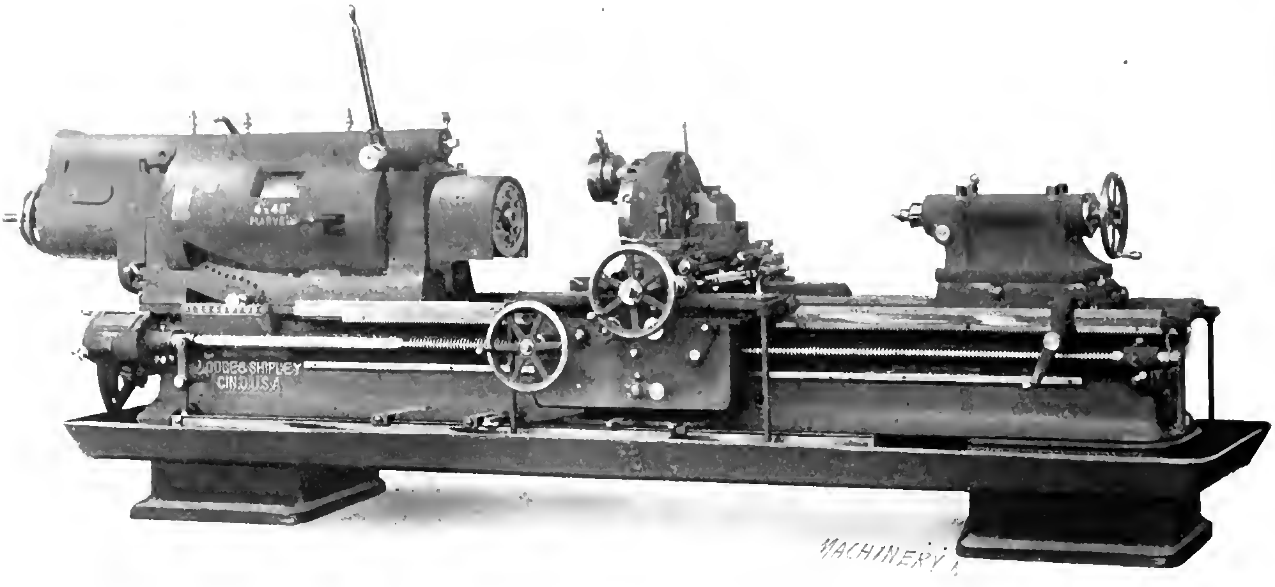


Fig. 1. The Lodge & Shipley 4 by 48-inch Marvel Lathe

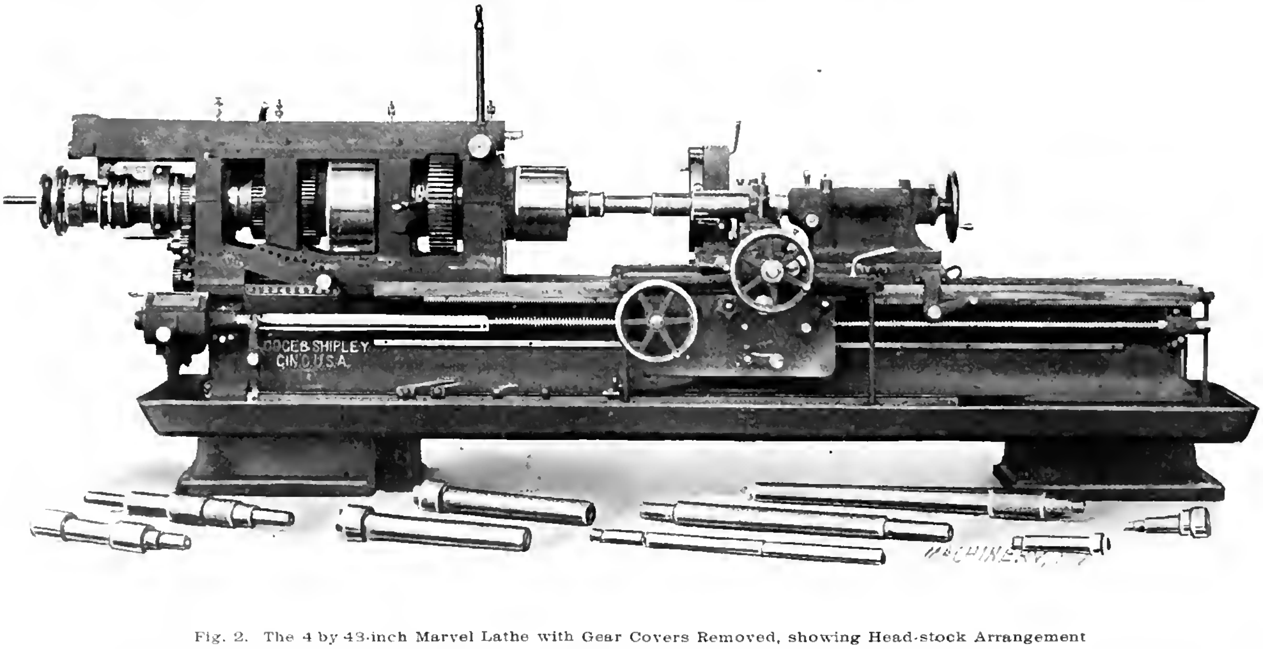

Fig. 2. The 4 by 43-inch Marvel Lathe with Gear Covers Removed, showing Head-stock Arrangement

The machine is built in three sizes, known, respectively, as the 2 by 24, the $2\frac{1}{2}$ by 36, and the 4 by 48-inch, these dimensions referring to the maximum diameters of the stock and the maximum length which can be turned. In Fig. 1 is shown the 4 by 48-inch machine complete, and in Fig. 2 the same machine with the gear guards in the front of the head-stock removed. In Fig. 3 is shown the $2\frac{1}{2}$ by 36-inch size with all parts in place, and in Fig. 4 the same machine with the gear guards at the end of the head-stock removed. In Figs. 2 and 4 the machines are shown in operation, and samples of work are also shown in the same engravings. Figs. 5 to 8 show various details of the machine. Before dealing directly with the operation of the lathe, it will be necessary to give a general description of the design of its various parts.

The Head-stock and Chuck Mechanism

A side view of the head-stock is shown in Fig. 5; the front end is shown in larger scale in Fig. 6, and a view from the front end in Fig. 7. The head-stock is of the same design as that used in the regular Lodge & Shipley patent-head lathe with double back-gears and single pulley drive, the pulley being carried in bearings independent of the main spindle, thus relieving the spindle and its bearings of all belt pull. The main spindle, which is exceptionally large, is bored out to receive a hollow tube, called the draw tube, the bore of which

determines the diameter of the bar stock coming within the capacity of the lathe. The end of this draw tube at the front end of the spindle is threaded, and an adjustable collet fitted to it, the thread furnishing the means for adjusting the collet to any diameter of bar that any one set of jaws will take. The rear end of the spindle projects beyond the end of its bearing, and carries a stepped collar which slides on the spindle. Between the stepped collar and the rear main spindle bearing is another collar backed up by a nut threaded on the spindle. (See Fig. 5.) In this collar are pivoted two steel levers, the outer ends of which are provided with two hardened steel rollers which rest on the inclined faces of the stepped collar. The inner ends of the levers engage a collar fastened to the rear end of the draw tube, the levers passing through a slot in the spindle. On the extreme rear end of the spindle a threaded collar is placed as a stop for the sliding stepped collar. This threaded collar also serves as an abutment for a compression spring acting against the rear end of the draw tube.

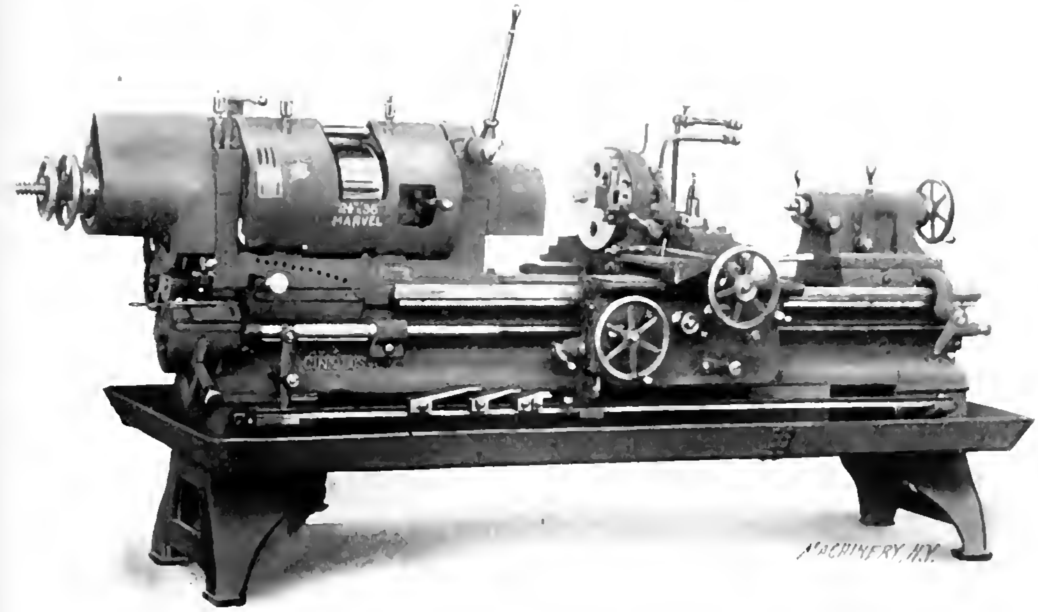

Fig. 3. The Lodge & Shipley 2¼ by 36-inch Marvel Lathe

Directly above the main spindle a guide shaft is placed on which slides a yoke engaging the stepped collar. To this yoke is attached a bar which extends immediately over the guide shaft (and over the main spindle gears and pulley) to the front end of the headstock. On the front end of this bar a rack is cut on the under side. This rack engages with a pinion fastened on a shaft at right angles to the main spindle, the end of which projects out on the front side of the machine. On the extreme outer end of this shaft a clutch is placed, the teeth of which engage another clutch which is loose on the shaft and to which is attached a hand-lever, as shown at the right in Fig. 5. The loose clutch is kept in engagement with the one fastened to the shaft by means of a light spring, which can easily be compressed by hand so as to throw the clutches out of mesh.

The chuck on the front end of the spindle consists of an outer shell or hood threaded on the nose of the spindle. In this hood is secured a hardened conical steel ring. The collet body is carried in a taper bushing in the end of the spindle, the inner end being threaded to receive the draw tube as before mentioned. In the collet body are cut radial T slots into which are fitted hardened and ground steel jaws which bear against the conical steel ring in the shell. Springs are inserted in each jaw to keep them in contact with the conical ring.

When operating the chuck, the hand lever before mentioned (shown to the right in Fig. 5) is pulled forward thereby drawing the stepped collar forward and forcing the lever arms at the rear end of the spindle outward. As the inner ends of the levers bear against the collar at the rear end of the draw tube this latter is forced backwards together with the collet body, and the radial jaws are caused to slide on the conical ring in the shell, thus gripping the stock. When relieving the grip, the hand lever is reversed, thereby withdrawing the stepped collar from between the lever arms and allowing the spring which acts against the rear end of the draw tube to force it and the collet body forward. The springs in the radial jaws force these out against the conical ring in the shell, thus releasing the stock.

A coarse pitch screw acting as a stock stop passes through the center of the draw tube and is supported at the front end by a collar which is a sliding fit in the bore of the draw tube, and on the rear end by a nut secured to the extreme rear end of the main spindle. Mounted on the screw immediately behind the nut are two hand-wheels, the inner one of which is keyed onto the screw by a key movable longitudinally in a spline, and the outer one threaded and operating as a lock-nut. When the inner hand-wheel is revolved, the screw revolves with it, and is caused to travel through the nut secured to the main spindle, thus giving end adjustment. The screw can be locked in any desired position by the outer hand-wheel. The front end of the screw is arranged to receive either a small center or straight stop bar.

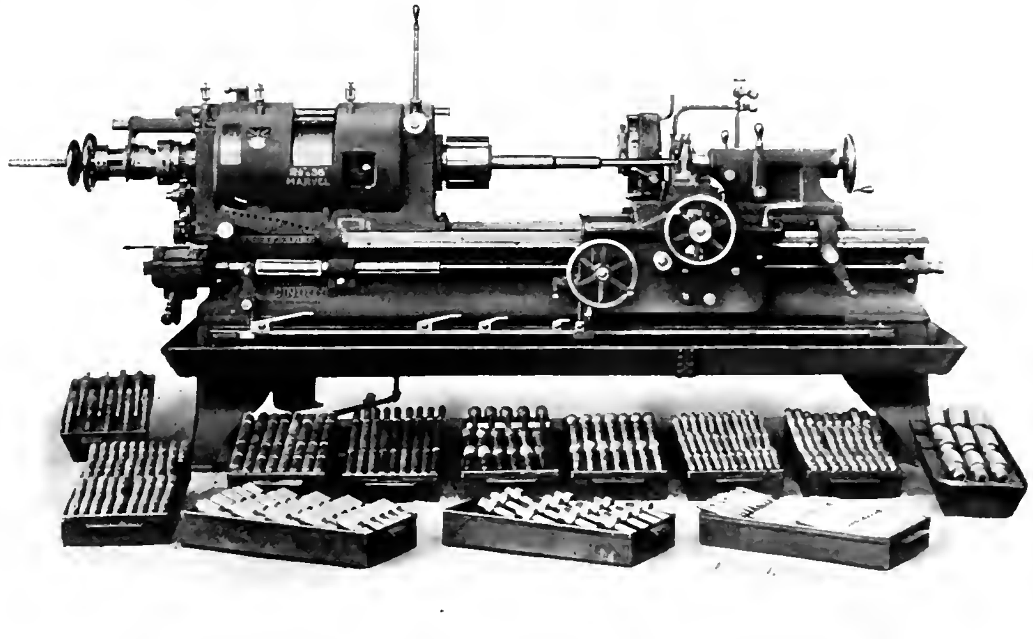

Fig. 4. The 2¼ by 36-inch Mervel Lathe with Covers Removed showing Chuck-operating Mechanism

Carriage and Tool-posts

The arms of the carriage bear on two outer V's of the bed. The bridge also has a bearing on the top and inside

of the flat track of the front shear. The bridge of the carriage is exceptionally wide and, as will be seen from Figs. 7 and 8, is extended beyond the back of the carriage. Two independent transverse dove-tails are planed on the bridge, the one on the right-hand side (looking at the machine from the front) being raised considerably above the other and extended the entire length of the bridge and its rear extension. The other dove-tail extends from the rear of the bridge extension a little past the lathe center. The right-hand dove-tail is fitted with a slide which carries the front and back tool-blocks. The front tool-block consists of a slide fitted in a dove-tail parallel with the main spindle, for the purpose of providing a longitudinal screw adjustment for the front tool; when adjusted, this tool-block is locked in position by a clamp screw. A large longitudinal T-slot at the top receives the usual form of tool-post and step washer. The rear tool-block has transverse hand adjustment and is clamped by two T-bolts in a T-slot planed in the main slide. This block also has a large transverse T-slot for receiving either the usual form of tool-post or a tool-holder of the European type, shown in place in Figs. 6, 7 and 8. Due to the separate adjustment, the tools in the front and rear tool-blocks can be set in any required relation to each other and can be rapidly, independently and accurately adjusted.

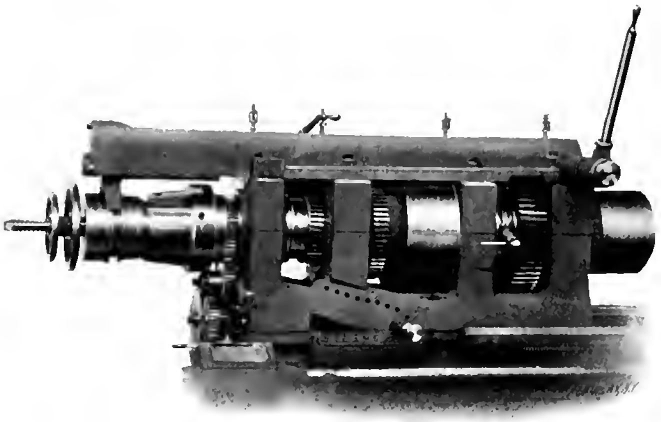

Fig. 5. The Head-stock of the 4 by 48-inch Marvel Lathe with Covers Removed showing Details of Head Construction

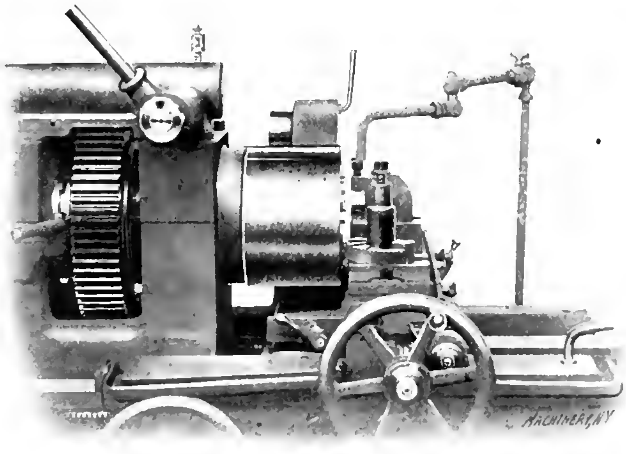

Fig. 6. Front End of Head-stock of 4 by 48-inch Marvel Lathe, showing Chuck, and Lever for operating Chuck Mechanism

In the left-hand dove-tail of the carriage is fitted a slide which carries a rotating tool-holder, a kind of vertical turret. In the face of this tool-holder which is turned toward the head-stock are reamed four holes to fit various tool shanks. (See Fig. 8.) The holes are so placed that when the tool-holder slide is locked to the carriage by means of a spring plunger provided for the purpose, each one of the tools in the face of the revolving tool-holder can be brought into a position so that its center coincides with the axis of the main spindle. The revolving tool-holder is locked to its slide in each position by a spring plunger. Tools of various types, such as centering tools, die holders, etc., may be placed in the holes in the revolving tool-holder, and necking tools, cutting-off tools, and turning tools may be carried in holders bolted to the face of the revolving tool-holder, so that their cutting edges project beyond the edge of the tool-holder itself. These tools, then, can be used for turning operations. An adjustable stop is provided in the carriage for use in connection with turning and necking tools, so that they may repeatedly be brought into exactly the same position relative to the main spindle center, thus insuring exact duplication of work without measuring each piece. A single lever operates this stop and also the spring plunger, which locks the revolving tool-holder slide to the carriage. A similar lever also operates the plunger which locks the revolving tool-holder to its slide. Both these levers are shown in Fig. 8, one at the end of the slide, and the other on the side of the projecting housing. The right-hand slide carrying the front and back turning tool and the slide carrying the revolving tool-holder are traversed back and forth by the same hand-wheel at the front of the carriage; but, at the same time, the movement of each of these slides is entirely independent. This is accomplished by means of a friction or slip member inserted in this hand-wheel.

Automatic Stops

One of the most important and noteworthy features in the design of the carriage is the automatic stop used in connection with the front and rear tools carried on the right-hand slide, by which a number of different diameters can be rapidly and accurately turned on a number of duplicate parts. The construction of this stop is as follows: Along the side of the bridge of the carriage next to the tail-stock, and journaled in two hubs cast on the front and rear arms of the carriage, as shown in Fig. 7, is a heavy bar with T-slots milled lengthwise through that part of the bar which is between the arms of the carriage. The bar is reduced at one end for a certain distance to a diameter just below the bottom of the T-slots, so as not to interfere with the insertion of the T-bolts into the slots. The bolts secure small steel stops in any desired position on the slotted bar, as clearly shown in Fig. 7. On the front end of the bar means are provided for taking up end wear, so that a snug running fit may always be maintained. On the outside of the rear bearing is secured a steel clutch, the teeth of which correspond to the T-slots in the bar. Engaging with this is another clutch keyed to the rear end of the slotted bar, and kept in engagement with the stationary clutch by means of a spring. On the outside of the clutch on the bar are cut spiral grooves corresponding in number to the number of slots in the slotted bar. On the edge of the tool-block slide next to the tail-stock are two hubs, the front one being cast solid with the slide, while the rear one is adjustable longitudinally by means of a T-slot and T-bolt. In each of these hubs a shaft is journaled parallel with the slotted bar; to the inner ends of the shafts steel fingers are secured. In the ends of these fingers and also parallel with the slotted bar, two screws are threaded and provided with means for locking them in

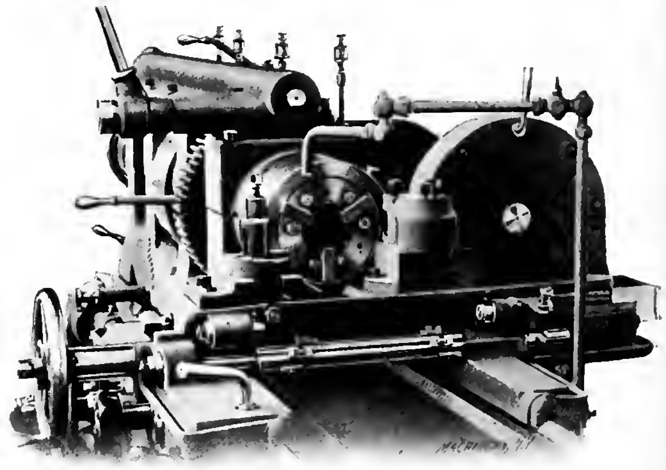

Fig. 7. Front View of Head-stock and Side View of Carriage of 4 by 48-inch Marvel Lathe showing Automatically-revolving Stop Bar

position when adjusted. The fingers each have two positions, one for engaging the stops on the slotted bar and the other for allowing the fingers to pass over the stops. These positions are both maintained by means of a spring latch.

The slotted bar has two sets of stops as shown. One set engages the screw in the steel finger on the front end of the slide and is used in connection with the front tool. The other engages with the steel finger carried by the adjustable block on the rear end of the slide and is used in connection with the rear tool. In the rear hub there is also a spring pin, the end of which engages with the spiral grooves cut on the outside of the clutch keyed on the end of the slotted bar. These grooves are so formed that the forward movement of the slide will cause the end of the spring pin engaging the spiral groove to compress the spring which keeps the clutches in engagement. This action continues until the clutch teeth are disengaged, at which time the slotted bar will revolve by the continued movement of the slide, the end of the spring pin traveling in one of the spiral grooves. The length of the spiral grooves is so determined that when the slotted bar has revolved sufficiently to bring the next set of stops into position, the end of the spring pin passes out of the groove and at this time the clutch teeth come into engagement, the clutch being actuated by the spring previously compressed. The movement of the slide is then continued until a stop is reached. On the return movement of the slide the end of the spring pin will again enter the same groove, but instead of any movement being imparted to the clutch, the groove is so formed that the spring pin will ride over the top of the spiral and drop into position in the next groove in the clutch. It is obvious that by means of this automatic stop arrangement a number of various diameters, not, however, exceeding the number of stops on the slotted stop bar, can be rapidly turned on a number of similar parts.

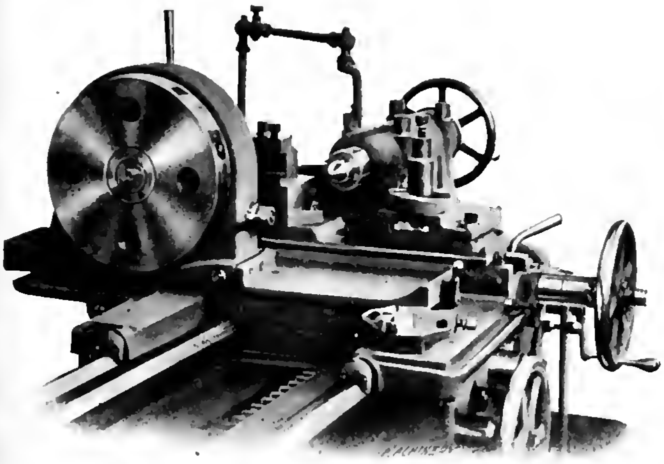

Fig. 8. Side View of Carriage of 4- by 48-inch Marvel Lathe, looking toward Tail-stock, showing the Rotating Tool-holder

The longitudinal stops provided on this lathe are of the same type as those described in connection with the Lodge & Shipley crank-shaft lathe in the June, 1909, issue of MACHINERY and will be but briefly referred to here. Along the front of the bed just below the apron is placed a rectangular bar, which slides in brackets bolted to the bed. The top of the bar is planed in the shape of a dove-tail, and telescoping stops adjustable the entire length of the bar are screwed to it by means of clamp bolts. The head end bracket, holding the bar, carries a spring and solid abutment which limits the sliding movement of the stop bar. The lead-screw is divided at the front of the head-end box, thus making two separate parts; on the right-hand end of the short piece in the box is formed a clutch, which engages with a sliding clutch keyed to the end of the lead-screw. This clutch is connected to the stop bar along the front of the bed by means of a lever pivoted to a stud as shown in Figs. 1 to 4. When actuated the bar has just sufficient movement to disengage the clutch.

At the bottom of the apron, as shown in Figs. 1 to 4, is bolted a bracket with a pivoted arm which engages the stops on the sliding bar. When engagement takes place, the bar slides with the carriage until the clutch on the lead-screw is drawn out of mesh, thus stopping the feed. At the same time the bar comes against its solid abutment at the head end of the bracket. The pivoted arm may be raised out of engagement with the stop, at which time the spring previously compressed by the movement of the bar will force the bar back to its former position and re-engage the clutch thereby again starting the feed.

The previous description of the main features of the machine will make a concise description of the operations performed on the machine possible.

Operation of the Marvel Lathe

The stock to be operated on is delivered to the operator of the machine cut in pieces to the required length. The advantages of this procedure over that of using the stock in a bar passed through the spindle are marked. A considerable amount of floor space is saved, and no stock projects beyond the back end of the machine. The stock is more easily handled, and when the machine is in operation there is no vibration and no noise from a long bar, seldom quite straight, revolving in loose supports. The vibration caused by parts revolving in this manner also greatly impairs the accuracy of the work and the smoothness of the finish.

In the Marvel lathe the piece to be operated upon is inserted in the front end of the chuck and is gripped so that sufficient stock is left for the operation to be performed. The gage screw inside the draw tube is brought against the stock and is then locked. Now the revolving tool-holder carrying a centering tool is brought into position and the projecting end of the piece is centered. The revolving tool-holder is then returned to its rear position, and the tail center is inserted into the center just made in the work and is then clamped in place. The first cut is now started with the tool in the front tool-post and the first stop on the diameter stop bar at the rear of the carriage is clamped in position to give the diameter required. The cut is then allowed to travel the required distance, and the shoulder stops in the front of the machine are set in position. The tool is then withdrawn and the back tool is used for squaring the shoulder, its stop being properly set. The forward movement of the slide for the next cut revolves the diameter stop bar and brings the second stop into position, and the second diameter and shoulder are then turned in the same manner as the first. When the turning of the piece is completed, it is removed from the chuck, but if the piece is of such a nature as to require an operation on the end gripped by the chuck, the finished end is inserted into the chuck and the rough end permitted to project sufficiently to complete the work to be done. When the piece is gripped in the chuck, the projecting end is centered in the same manner as before and the tail-stock center inserted, the following operations being the same as already described.

It is evident that in this manner any number of pieces can be turned rapidly and accurately to the same dimensions. On one of these machines in the Lodge & Shipley shops, any twenty-five pieces taken from a lot have been found not to vary over 0.002 inch either in diameter or length between shoulders. The method of holding the work insures the greatest possible accuracy, in addition to which some operations impossible on the ordinary turret lathes and screw machines are easily performed.

BESLY DOUBLE SPIRAL DISK GRINDER

The accompanying half-tone illustrates a new grinder brought out by Charles H. Besly & Co., 15-21 So. Clinton St., Chicago, Ill., and manufactured at the company's works at Beloit, Wis. The machine is known as the No. 26 Besly double spiral disk grinder and embodies the same general features as to construction, power, rigidity and accuracy, which have previously been referred to in these columns in descriptions of the Besly grinders.

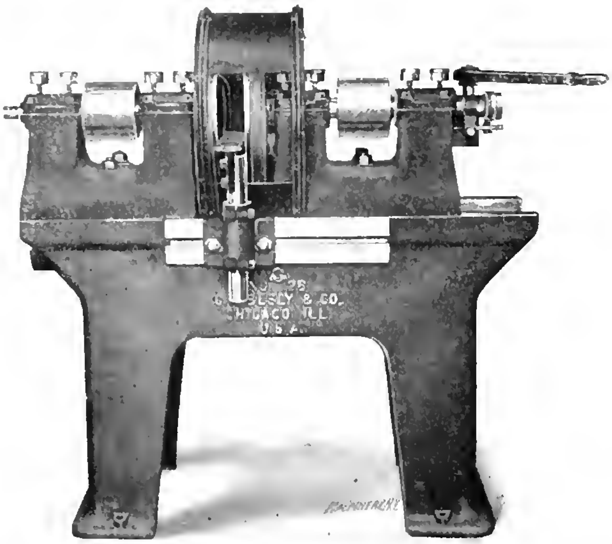
The bed and legs of the machine are cast in one piece, and the bed is provided with a T-slot pad in the front, as shown. The work-rest carriage is attached to the machine by means of two bolts fitting into the T-slot. Seven work-rests are fur-

nished with [illegible] each one varying in width from 7/16 inch up to and including 2 7/16 inches. The heads of the machine are carefully fitted to the top of the bed casting, and are bored and reamed to receive bearing bushings. These bushings are made in halves with the exception of the long rack or lever bearing at the right-hand end of the machine, which is 10½ inches long and made in one piece. The end thrust is taken up by hardened and ground steel collars of large area, and ample provision is made for taking up all wear. Over the bushings are fitted removable caps into which the oil cups are screwed; particular attention has been given to the lubrication of all the parts of the machine.

A dust hood of special construction encloses the disk wheels. This dust hood is built on the telescoping plan, so that the opening between the edges of the dust hood are never greater than the width of the pieces being ground. The top of the hood is hinged and can be thrown back instantly to give free access to the wheels. An opening is provided below the wheels for attaching a 5-inch exhaust pipe.

An interesting feature in the design of this machine, to which attention should be called, is the provision made for a third wheel and rocker shaft, which can be attached to the left-hand end of the machine at any time. On this shaft can be mounted either the geared lever feed table or the swinging or tilted tables made by the company.

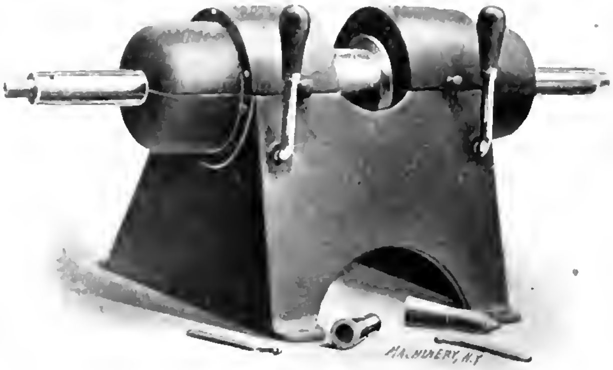
The operating floor space required for the machine is 5 by 10 feet, the floor space of the machine itself being 20 by 44 inches. The height from the floor to the center of the spindle is 42 inches. The disk wheels used are 18 inches in diameter and 5/8 inch thick and run at a speed of 1,650 revolutions per minute. The maximum opening between the disks is 10½ inches. The spindle pulley is 6 inches diameter with 5¼-inch face. The counter-shaft should run at 618 revolutions per minute in order to drive the disks at 1,650 revolutions. The driving pulley and drum pulley are 16 inches in diameter for 5-inch belt, and the tight and loose pulleys 10 inches in diameter for an 8-inch belt. The weight of the machine complete with counter-shaft, not crated, is 2,100 pounds.



No. 26 Besly Double Spiral Disk Grinder

DUPLEX INDEPENDENT END BUFFING LATHE

One of the inconveniences of the ordinary double end buffing lathe used by jewelers, silversmiths and others for polishing, is that it is necessary to stop work on both wheels when one wheel is changed, due to the fact that both polishing wheels are fastened to the main shaft. As the wheels have to be changed frequently, and as it requires some time to change a wheel, the loss of time is considerable. To overcome this difficulty, single end lathes are sometimes used, but the comparative unsteadiness with which they run makes it impossible for an operator to perform good work, and the extra amount of space required for an equal number of operators is considerable. For this reason, A. B. Nutting & Co., Amesbury, Mass., have brought out a new double polishing lathe where the polishing wheels can be independently thrown into or out of engagement with each other by means of simple friction clutches, operated by the hand levers in the front of the machine shown in the accompanying illustration. A slight movement instantly throws one wheel into or out of action without shifting the belt or interfering with the running of the other wheel.

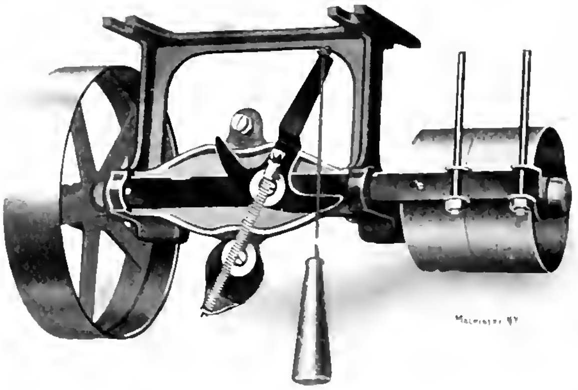


Nutting Duplex Independent End Buffing Lathe

The frame of the machine which occupies a bench space of 12 by 17 inches is made in box form and is provided with dust-proof casings covering the bearings and working parts completely. The bearings are cast to the frame so that they are always in alignment and the journals are constantly flooded with oil. The spindles and the main shaft have a special adjustment to compensate for the end thrust wear. The ends of the spindles are detachable and any length or form can be substituted, making it possible to use the machine for all classes of work. The drive is by means of a 3 by 3-inch pulley running between the bearings as shown and belted from above or below. All the running parts are balanced and can be run at a rate of 3,500 revolutions per minute without causing difficulties.

PULLET BELT SHIFTER AND COUNTER-SHAFT

A decided improvement on the old wood shipper for shifting the belts on counter-shafts is shown in the accompanying half-tone, illustrating the Pullet belt shifter and counter-shaft brought out by the L. & D. Co., 88 Broad St., Boston, Mass. The construction of this shifting device is as follows: An oscillating lever to which a pull cord is attached is mounted on a sliding shifter bar and is kept in position by a compression spring which also locks the shifter bar at each stroke. The pivoted spring support always keeps in line with the direction of the push of the spring. When the handle attached to the cord is pulled, one wing of the oscillating lever engages a pin fixed in the base-plate. This pin then acts as a fulcrum so that the shipper bar is forced to the left (assuming the parts to be in the position shown in the illustration). The initial pull on the pull cord forces down the shipper bar so that the notch in it no longer engages the frame casting, thereby permitting the bar to move.



The Pullet Belt Shifter and Counter-shaft

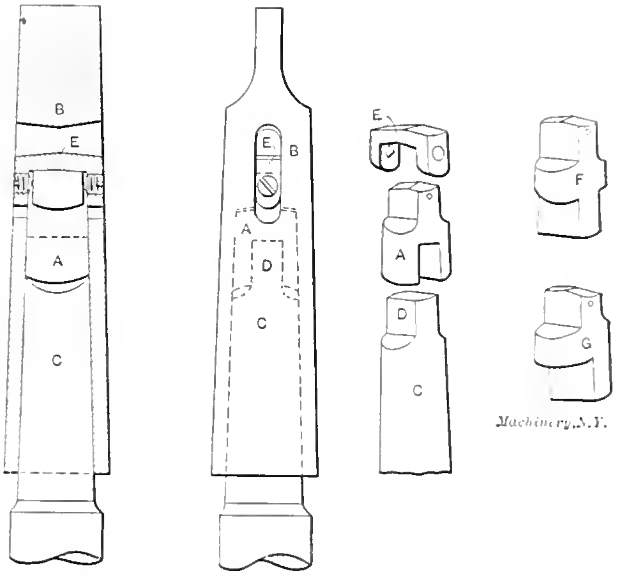
At the end of a stroke, however, the notch at the other end engages a stop on the base-plate, and as the center of rotation of the oscillating lever is now on the opposite side of the vertical center line, the spring throws it into a position the reverse of that shown in the illustration, from which it is ready to be shifted back by a new pull on the cord. Thus a pull on the cord will shift the belt in either direction.

One advantage of this shifter is that the handle can be located directly over the work. By clamping the base-plate upside down and running the cord over pulleys, the machine can be stopped and started from any point. The shifter can be applied to any ordinary counter-shaft by clamping it to a pipe screwed into a flange in the ceiling, thus making it adjustable vertically. In the illustration, however, the special Pullet counter-shaft is shown, provided with a frame to which the shifting device is directly attached. While the hanger and shifter support are complete in one casting, the shifting device can be quickly inverted, so that a pull cord can be run over pulleys as already mentioned.

There are three sizes of the Pullet shifters, each size being adjustable for two lengths of throw (two widths of belt). For instance, a shifter for 1½ and 2-inch belt, respectively, can be used for the one or the other, simply by turning over the shifter bar so that the respective notches are brought into use. The shifters have the further advantage that they cannot easily get out of order. They make the shop look neater and more pleasant than when full of wooden shippers, and the simplicity of construction brings the cost to a very reasonable figure.

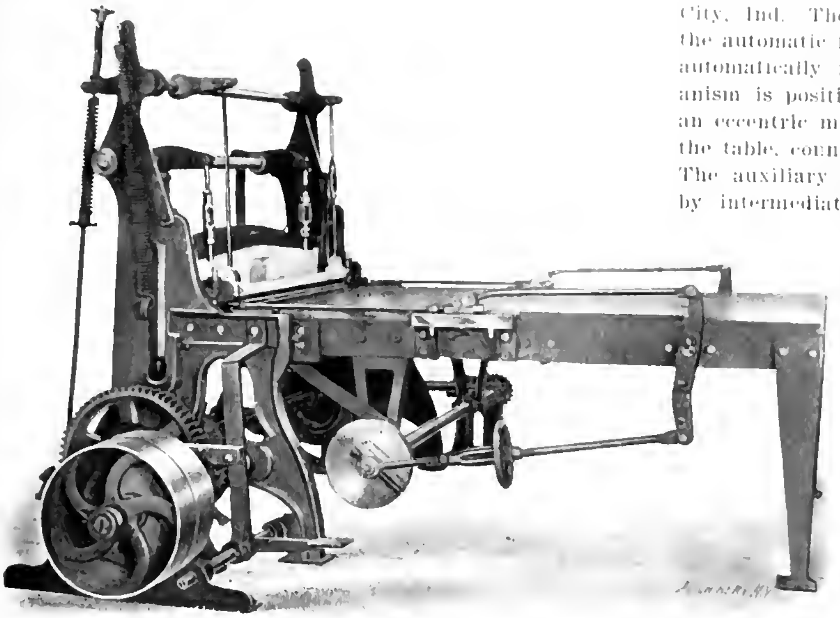
GROSS & GROSS INTERMEDIATE DRILL SHANK TANG

The device shown in the accompanying line engraving is an improved method of driving twist drills and other tools provided with an end tang for driving, and is the invention of Messrs. Gross & Gross, 1616 No. 4th St., Harrisburg, Pa. In order to overcome the common occurrence of the tangs of twist drills becoming distorted or broken off on account of being subjected to too great a stress, an intermediate driving block *A* has been provided which may be placed in the socket *B*, and it is only necessary to form a new tang on the drill shank *C*, after the original tang has been broken off. Any torsional stress on the drill shank and tang will be transmitted to this intermediate tang, which will break before the new tang *D* on the drill shank *C*. If the intermediate tang *A* breaks, a new one can readily be substituted for the broken one at a cost which is comparatively slight as compared with the cost of a new drill. In operations where a frequent change of drills is not required, the intermediate tang *A* is used without the part *E*, but in operations where it is required to change the drill often, the intermediate tang is used in connection with a holder *E* to prevent the falling out of the intermediate tang from the socket at the time of removal of the drill; this holder may also be conveniently manipulated to disengage the drill in the socket. The intermediate tang *A* may be used for any make of socket. At *F* and *G* are shown modified forms of the intermediate tang.



A New Device for making possible the Use of Broken-off and Re-tanged Twist Drill Shanks in Regular Drill Sockets

BERTSCH AUTOMATIC FEED SHEAR



Automatic Feed Shear built by Bertsch & Co.

In the accompanying illustration is shown a new shear recently designed and built by Bertsch & Co., of Cambridge City, Ind. The most prominent feature of this machine is the automatic feed mechanism whereby the sheet to be cut is automatically fed in between the blades. This feed mechanism is positive and works very accurately. It consists of an eccentric mounted on an auxiliary shaft suspended under the table, connecting rods and levers, and a clamping device. The auxiliary shaft is driven from the main driving shaft by intermediate gearing. The clamping device consists of two plates or jaws which at the proper time grip the sheet and automatically move it towards the blades. At the moment when the feeding mechanism has placed the sheet in the required position to be sheared, the regular "hold-down" descends ahead of the top knife and holds the sheet in place during the shearing operation. While the shearing is being done, the plates or jaws of the feeding mechanism release the grip, and move away from the blades into a position where they are ready to grip and feed the sheet for the next cut. The jaws gripping the sheet are opened and closed by means of an eccentric on the main driving shaft, which actuates the connecting arms and rods shown in the illustration above the clamping device. The feeding mechanism can be so adjusted that it will automatically shear the sheet into uniform strips of any width from 1/16 inch to 12 inches. Either a single sheet of any desired width up to the capacity of the machine, or several narrower sheets placed side by side can be automatically fed in this manner. Owing to the fact that the feed mechanism is designed as an independent device attached to the machine, it can be applied to any standard shears built by the makers.

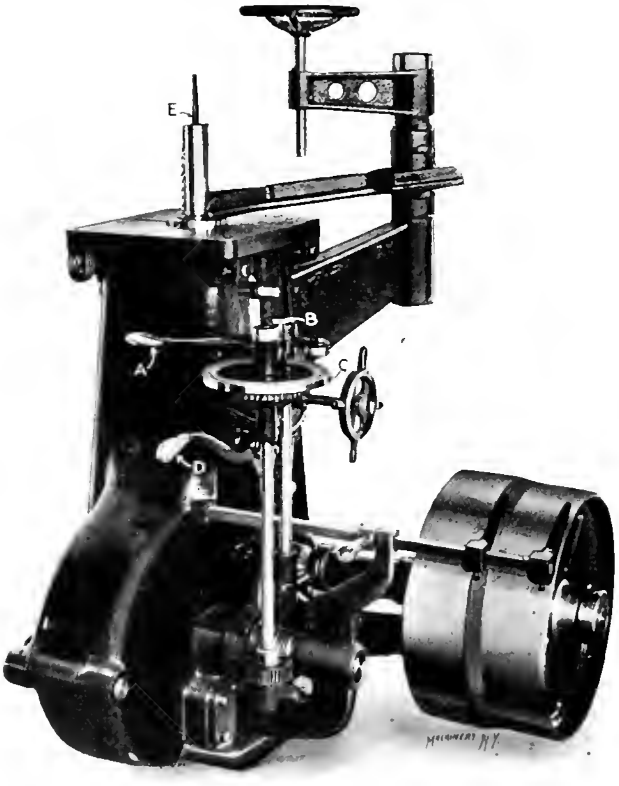
An automatic feed arrangement of the type shown adds considerable to the usefulness of the shear, and makes possible a marked increase in the output, at the same time as accuracy of the product is much more easily obtained.

LEES-BRADNER AUTOMATIC GEAR-CUTTING MACHINE

The accompanying illustration shows a general view of a machine designed by Mr. E. J. Lees of the Lees-Bradner Co., 923 Schofield Building, Cleveland, O., and intended for hobbing spur, spiral and worm gears and also for threading worms. The machine has a capacity of cutting spur and spiral gears of up to 14 inches in diameter and four diametral pitch; worm gears of the same diameter up to one inch circular pitch; and worms of one inch pitch and any lead, up to 8 inches long and 8 inches in diameter. The machine works on the generating principle, using hobs for cutting gears. For worms, however, a single cutter is used, the machine working in a manner similar to a thread milling machine.

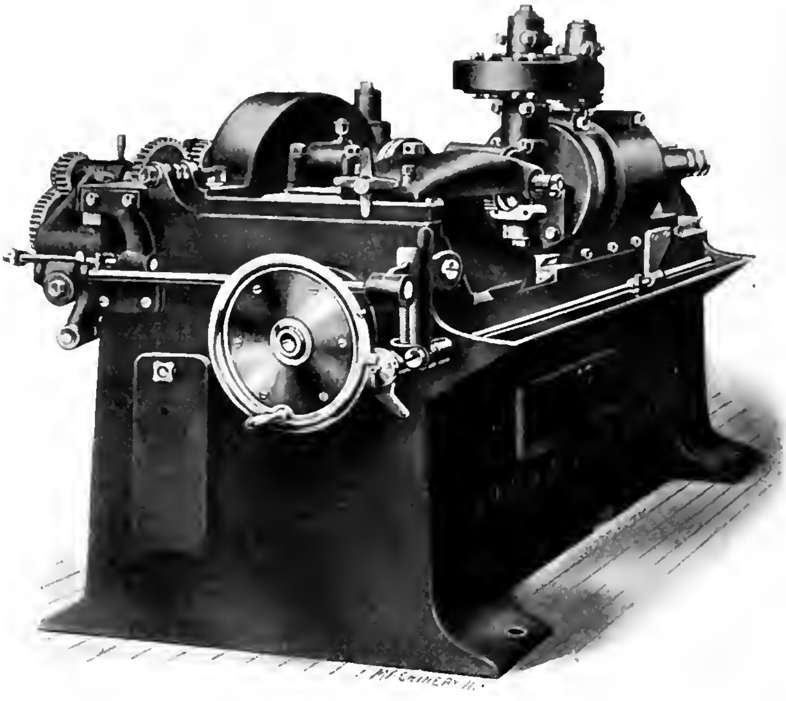
The drive of the machine is by belt on a three-step cone, and the machine is back-geared in the ratio of 8 to 1. The swiveling head can be moved 180 degrees and has no over-hang. The swiveling mechanism consists of one pair of bevel gears inside of a large cylindrical head, which in turn fits into another cylindrical bearing on a slide. The mechanism is rigidly locked to the slide by bolts on either end. All movements are in one direction in all operations, so that back-lash is entirely eliminated. The screws used for feed and head slides operate with a draw pull and not with a pushing action.

The work-spindle and arbor are horizontal, and the arbor is rigidly supported at both ends, which is highly important, especially when cutting the teeth in spiral gears. Provision has been made in the design so that the larger the diameter of the gear to be cut, the closer the cutter is brought to the original point where the power to the cutter spindle is delivered. As the work-spindle has a three-inch bore, gears made in one piece with, or placed on, a shaft can be either held in the spindle with a draw-in collet or can be held between centers.



Lapointe Vertical Key-seating Machine with Automatic Feed, Release of Cutter and Stop

A micrometer is provided for gaging the depth of the cut with graduations on a disk 6 inches in diameter, which is locked at zero with a thumb-screw when starting to take the reading. This provides for an easily adjusted and quickly operated micrometer for duplicate work. When operating the machine the necessary depth is obtained by adjusting the head at the same time the micrometer is set, after which the work is fed across the cutter head. At the completion of a cut the main drive is automatically thrown out and all mechanisms stopped simultaneously. This is a necessary requirement in cutting spiral gears and relieves the operator of constantly watching the machine in order to stop it at the right moment. When setting for the depth of cut, a stop rod collar is adjusted, and an original feature introduced permits the slide to be backed away to any distance and yet returned to its original setting to a positive stop without attention to graduations; although, if the operator wishes to set the cutter in or out a few thousandths inch, the original reading is visible on the disk and can be worked from.



Lees-Bradner Machine for Cutting Spur, Spiral and Worm Gears and for Threading Worms

A feature of interest in the machine is that it can cut worms advantageously. When cutting or threading worms a single cutter is used running from 75 to 117 revolutions per minute. The cutter head is very rigid in order to eliminate any possibility of lack of uniformity in the worm thread. The worm can be mounted on an arbor held either between centers or in a draw-in collet, the other end of the arbor being supported either on a center or in a bushing.

All the mechanism is in one horizontal plane, and, therefore, all parts can be readily reached. Adjustments are provided where required for taking up back lash. The chips are disposed of without coming in contact with any of the moving parts and are removed by taking out a pan located directly back of the door in the frame of the machine. The chip pan and the receptacle for oil are the only parts inside of the frame. The oil pump is located on the outside and below the oil supply, which obviates the necessity of priming the pump.

LAPOINTE VERTICAL KEY-SEATING MACHINE

The machine illustrated in the accompanying half-tone engraving is designed and built by the Lapointe Machine Tool Co., Hudson, Mass. It is intended for general key-seating, and is provided with automatic feed, automatic release for the cutter, and automatic stop for any depth of keyway desired. The work to be operated upon in the machine is first put onto a bushing fitting the hole in the work, and is fastened by means of a clamping arm, one end of which rests on the work and the opposite end on a post adjustable to the height of the work; the clamping arm is held down by

means of a screw provided with a hand-wheel. The machine is then started by means of the operating handle *A* and the depth of cut required is determined by means of the depth regulator *B*, which can be set in any of the holes in the index plate *C*. When the machine is in operation, the index plate revolves, and in due time the depth regulator or finger comes in contact with a cam on the operating lever, thereby stopping the machine. The index plate is provided with forty holes, the distance between each hole being equivalent to a depth of 0.010 inch in the keyway.

The cutter consists of a broaching bar provided with ten teeth, each cutting its proportionate part at each stroke of the bar. The fact that the bar is provided with a series of teeth reduces the number of strokes necessary for cutting keyways as compared with the time required when using a bar with a single cutter. The feeding of the cutter is accomplished by means of a wedge *E* sliding on the back of the bar, automatically advancing at every stroke, and automatically released on every return stroke by allowing the wedge to drop back half the distance of its advance, so that the cutter is prevented from rubbing against the work on the return stroke. The machine is provided with quick return for the cutter bar.

The machine has a tilted table used when cutting tapered keyways, and is also arranged for hand operation when required, the feed being disconnected by the feed-key releasing handle *D*. The drive is by means of a tight and loose pulley, so that it can be belted directly to the main shaft, thereby making a countershaft unnecessary. The loose pulley is provided with a self-oiling arrangement and will run for at least a year without attention.

THE CHICAGO DUPLEX HAND MILLING MACHINE

A number of improvements have been introduced in the new design of the Chicago hand millers, manufactured by the Chicago Machine Tool Co., of Chicago, Ill., the most important ones of which are illustrated in the accompanying half-tone engravings. The machine is of the "Duplex" type, the name being derived from the fact that a vertical attachment is furnished with each machine. The combination of both vertical and horizontal spindles on the same machine together with an exceptionally large range for a hand miller, adapts it to a large variety of work. The machine illustrated is known as the No. 3 Duplex miller, and is shown in Fig. 1 with the vertical attachment in place. This attachment is one of the most important features of the machine, as it makes it particularly adapted to tool-room work and also makes it valuable in the manufacture of small parts for locks, typewriters, guns, sewing machines, etc. In Fig. 5 is shown a front view of the machine with the vertical attachment in place. It will be noted from these two illustrations that the machine is of a particularly rigid design. The table has a very wide bearing on the saddle in order to insure rigidity, which is an essential feature in any type of milling machine. A taper gib is provided for taking up the wear; this gib is easily adjusted when required.

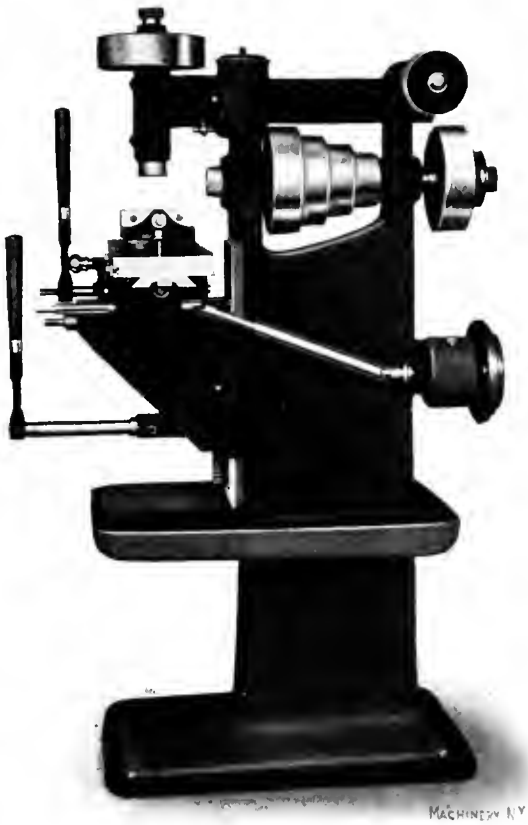


Fig. 1. Chicago Machine Tool Co.'s No. 3 Duplex Hand Milling Machine with Vertical Attachment

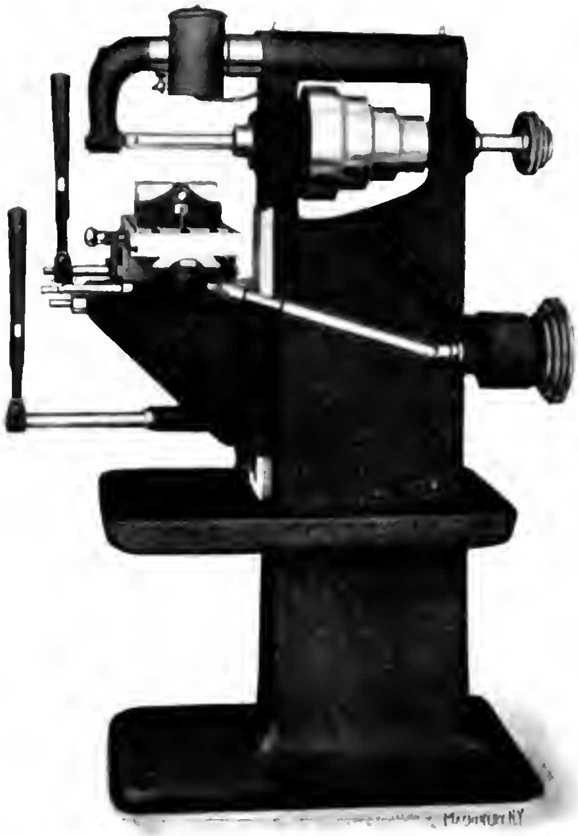

Fig. 2. The Chicago Duplex Miller with Overhanging Arm, ready for Horizontal Milling

Fig. 3. Parts of Vertical Milling Attachment

The saddle is so proportioned that the overhang of the table is minimized even when feeding the work to the limit of the capacity of the machine. The design permits the application of automatic feed at any time, if required. The knee is of box construction, and having no opening at the top, there is no tendency to spring it when the saddle is clamped. It will be noted in Fig. 1 that the knee has a long bearing on the column in order to give the required stiffness. The machine has a crank feed for the table as well as a hand lever

feed or hand feed. The hand lever can be used to good advantage for quick return of the table after a cut has been taken. A hand lever feed for the vertical movement of the knee is also provided, as shown in Fig. 5. This hand lever is fastened to a shaft carrying on its other end a pinion meshing with a rack, secured to the column. A bracket which carries the nut for the transverse feed-screw is fastened to the saddle and extends into a slot cast in the side of the knee. This arrangement protects the feed-screw and prevents chips or dirt from falling inside the knee.

Fig. 4. Part of Column for Hand Miller, showing Oil Reservoirs

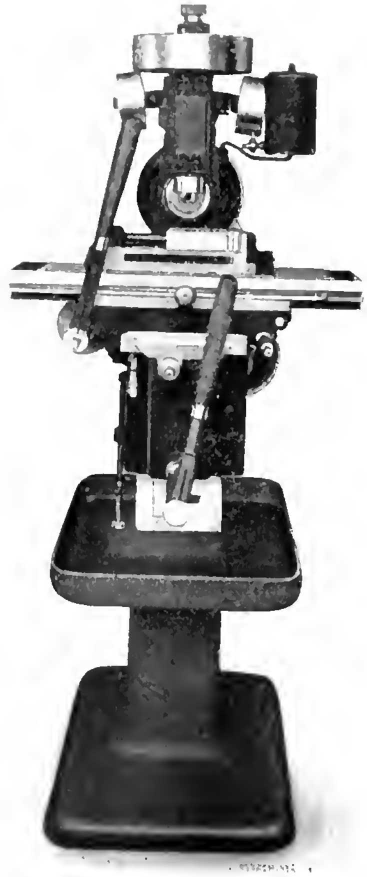

Fig. 5. Front View of Chicago Hand Miller with Vertical Attachment

The Vertical Attachment

One of the main features of the vertical attachment is that there are no gears in connection with its drive, it being driven by a belt from a pulley on the rear end of the horizontal spindle, as shown in Fig. 1. The belt runs over idler pulleys shown at the top of the machine. In Fig. 3 are shown the main parts of the vertical attachment. The spindle *A* is bored to receive a No. 9 Brown & Sharpe taper. This spindle runs in the split bronze bearing *B*, a slot in which runs the entire length of the bearing and in which is laid a wick for lubrication. The casing *C* which contains the spindle bearing, spindle and other parts, is also split and provided with screws for taking up any wear that may occur in the bearing. In this casing an oil reservoir *D* is provided, this being cored out in the casting. The ends of the wick previously mentioned are dipped into this reservoir which contains enough oil for the running of the machine for a full year. The arrangement insures perfect lubrication of the bearings, eliminates wear, and makes smooth running possible. The same illustration also shows the draw bar *E*, the sleeve *F* and the collet *G*. End mills are held in place in the vertical attachment by the draw-in collet, this latter being interchangeable on the vertical and horizontal spindles.

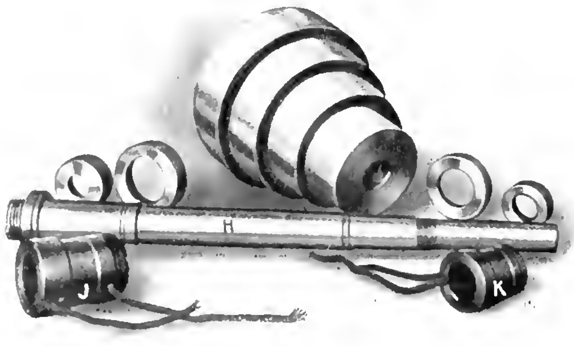

Fig. 6. Horizontal Spindle and Bearing Bushings

The Machine Used as a Horizontal Miller

In Fig. 2 the machine is shown with the vertical attachment removed and the overhanging arm in place supporting the outer end of the arbor. It takes but a few minutes to change over the machine from vertical to horizontal. The horizontal spindle of the machine is bored to receive a No. 9 Brown & Sharpe taper shank.

The respective parts of the horizontal spindle are shown in Fig. 6, in which illustration *H* is the spindle proper, and *J* and *K* bronze bearings fitted to tapered bores in the column. Adjusting collars are provided for taking up the wear occurring in the bearings. The wicks provided for the lubrication are also shown and a good idea of the novel arrangement provided for the oiling of the bearings may be obtained from Fig. 4. Two reservoirs *L* and *M*, cored out in the casting, are provided in the column under each bearing; these are filled with cotton and oil and furnish sufficient lubrication for a full year by means of the wicks in the bronze bearings laid in a groove cut for the purpose. The machine may thus be run at high speeds without danger of heating the bearings.

The Power Feed

The power feed of the machine is taken from a cone pulley at the rear end of the spindle to a three-step cone pulley on the rear of the gear box, as shown in Fig. 1. From the gear box the drive is through the universal joint shaft to a pair of 45-degree spiral gears in the saddle. As shown in Fig. 7, a worm is fastened on the same shaft as one of these spiral gears and the whole mechanism is held in a rocker which throws the work in and out of mesh with a rack in the table. The worm has at all times five teeth in working contact with the rack.

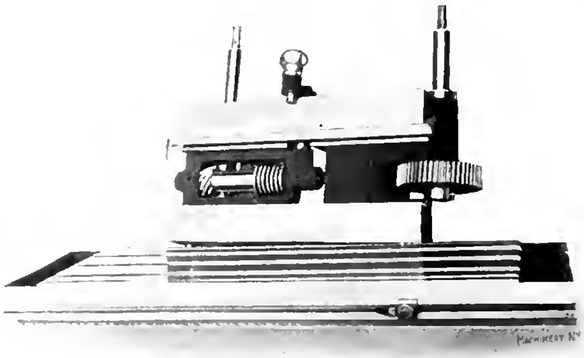

Fig. 7. Table and Saddle of Chicago Hand Miller

The design of the gear box is shown in Fig. 8. The feed gear mechanism consists essentially of a set of planetary gears contained in a compact case. Through this set of planetary gears the desired reduction of the spindle speed is obtained to give the proper feed for the table. The feed mechanism is

extremely simple and yet very effective. The cone pulleys which transmit the power from the spindle to the feed gear box are interchangeable, so that six changes of feed are obtainable.

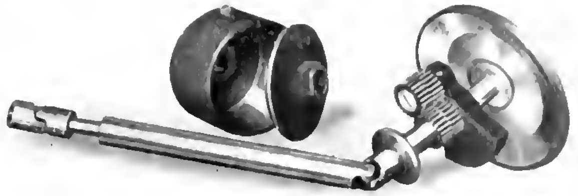

Fig. 8. The Simple Gear-box Parts of the Chicago Hand Miller

The counter-shaft furnished with the machine has self-oiling shaft bearings and it is not necessary to refill the oil chambers more than once a year. This feature alone is of great importance as it eliminates the usual counter-shaft troubles.

Messrs. Hill, Clarke & Co., of Chicago, Ill., are the selling agents of this machine and it may be seen in operation in the demonstration shops of this concern.

ATTACHMENT FOR CUTTING HELICAL STEEL GEARS

In the April, 1909, issue of MACHINERY an article was published entitled "Cutting Helical Gears on the Brown & Sharpe Automatic Screw Machine." This described the tools and methods employed in the unusual operation of cutting helical gear-teeth in the screw machine. As will be remembered, this was done by running a revolving gear, having teeth of such shape as to mesh properly with the finished work, over the revolving blank; the face of the gear was ground, and set in the same plane with the axis of the work, thus providing a cutting edge which formed the teeth in the blank. The tool illustrated herewith, made by the Brown & Sharpe Mfg. Co., Providence, R. I., works on the same principle, as will be understood from the following description. Certain very interesting changes have been made in its construction, however, to fit it for heavy cutting in steel, the former tool being better adapted to work on brass and similar materials.

In the original attachment, the cutter was driven from the work by a three-cornered center, which was forced by spring pressure into the bore of the blank. For cutting steel it was found unsafe to trust this, so another, and very ingenious, expedient was resorted to. On the rear cross-slide in Fig. 1 is shown mounted a milling attachment. Just previous to the tooth-cutting operation, the work spindle is stopped, and the revolving cutter of this attachment [illegible] up [illegible] the outer end of the unfinished blank, milling a keyway [illegible] not quite to the center, as shown in Fig. 2. The milling attachment is then withdrawn, the work spindle is started up and the tooth cutting tool is brought into action. The point of the driving spindle A, Fig. 4, enters the bore of the work. To A is pinned the clutch B having a single tooth, which engages the cut or recess in the work, and thus drives the spindle A and the connected train of gears. After the cutting of the teeth, the hub of the work is faced off as shown to the right, Fig. 2, thereby removing the milled recess. This method gives a drive strong enough for the heaviest duty, up to the point of breakage.

The principle of operation is the same as in the case of the original tool. As the attachment is fed onto the work, the spindle A (Fig. 4) is driven by the means just described, clutch B being held in engagement by the pressure of a long spring in the shank of the tool. A long worm D, keyed to the spindle A, and moving longitudinally with it, engages a worm wheel E, which is keyed to an arbor carrying driving gear F (Fig. 3) at the outer end. This latter, through idler G, drives gear H, which is keyed to the cutter spindle. The cutter J is thus driven in synchronism with the rotation of the work.

As described in the previous article, provision is made for keeping the cutter and work in step with each other during the longitudinal feeding of the turret slide. As the attachment is pushed over the work, spindle A, clutch B (in engagement with it), and worm D are pushed back against the pressure of the spring in the shank of the tool. This backward movement, through the axial movement of D, rotates worm-wheel E in just the right ratio to keep the cutter in step with the work. The cutter J and the work are thus always in step with each other, whatever the rate of rotation of the work, or the feeding movement of the attachment. The slow forward feeding of the latter over the work thus causes the hardened and ground face of the cutter J to form teeth of the desired shape in the work.

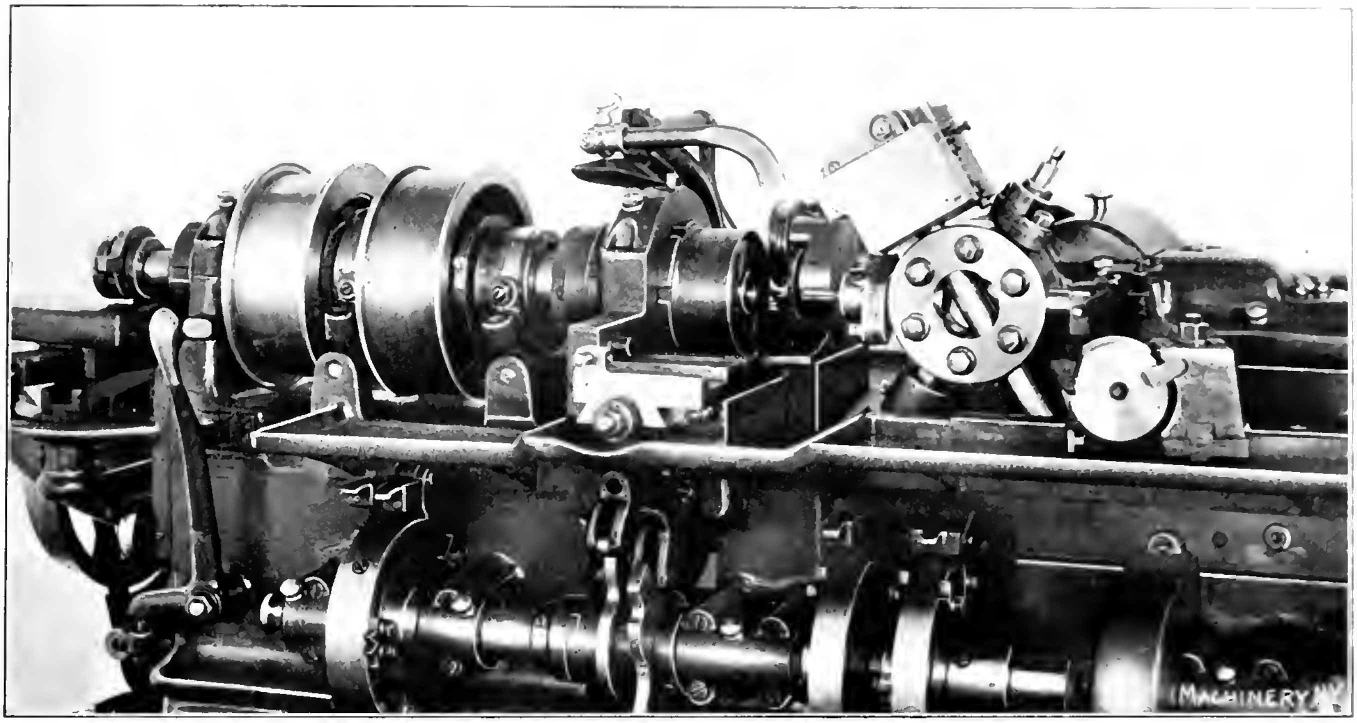

Fig. 1. Automatic Screw Machine with Attachment for Cutting Helical Steel Gears

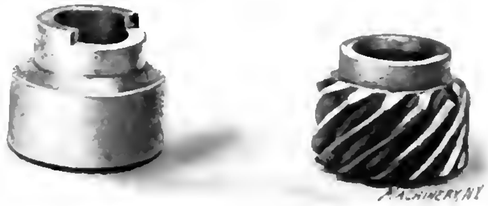

Fig 2. Blank with Recess for driving while Teeth are cut, and Finished Gear

A number of adjustments are provided in this improved attachment, which tend toward increased convenience and accuracy. The spindle of worm-wheel *E* and gear *F* is mounted in an eccentric sleeve, which may be rocked by suitable adjusting screws to take up all back lash between *D* and *E*, and still leave a running fit. Sector *K* is pivoted to a hub on this eccentric sleeve, so that *G* is always in proper mesh with *F*, and so that it may be adjusted to properly mesh with *H*. A screw locks this adjustment.

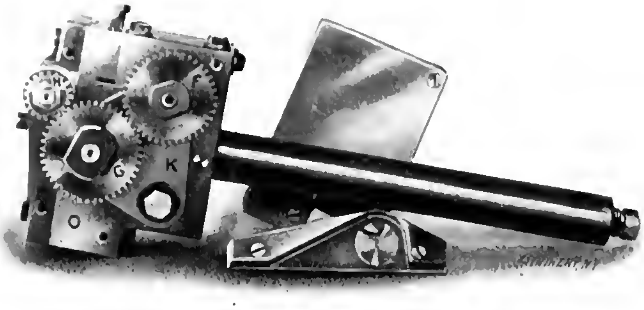

Fig 3. Front Side of Spiral Gear-cutting Attachment for Steel Gears, showing Gearing

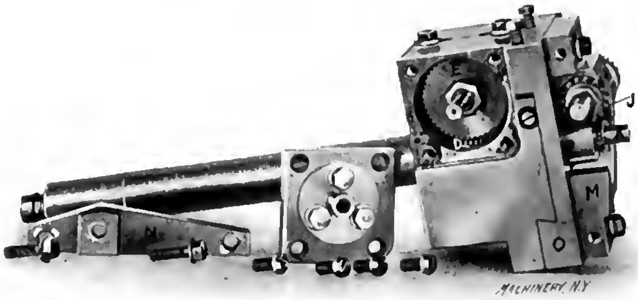

Fig 4. Rear View of Attachment showing Driving Clutch, Worm-gear and Tooth-cutting Tool

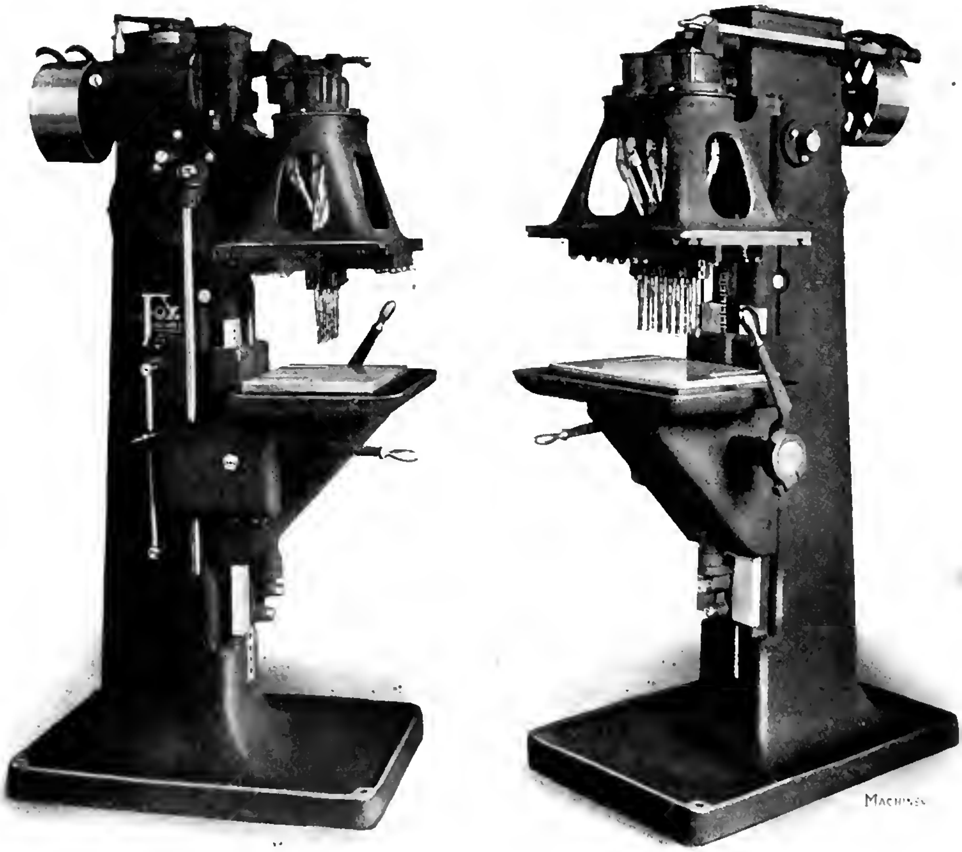
The cutter spindle is mounted in a slide *M*, which is adjusted vertically to give the desired pitch diameter for the finished gear teeth. The overhanging end of the spindle is supported by the outboard bearing *N*. Slide *M* is supported, in turn, on cross-slide *O*, which may be adjusted horizontally to bring the face of the cutter in the same plane with the axis of the work. Both the vertical adjustment for diameter and the horizontal adjustment for centering the cutter are effected by fine pitch adjusting screws; when made, the adjustments are firmly held by clamp bolts.

FOX ADJUSTABLE MULTIPLE SPINDLE DRILL

The accompanying illustrations show two views of the No. 2 Fox universally adjustable multiple drill, a description of the various features of which is given below. This machine is built and placed on the market by the Fox Machine Co., 815-825 N. Front St., Grand Rapids, Mich.



Figs. 1 and 2. Fox Universally Adjustable Multiple Spindle Drill

The machine is intended for drilling any number of holes up to sixteen, simultaneously. Each drill is driven through a universal joint, the drill spindles proper having an independent vertical adjustment of two inches, so that even though the drills may be of different lengths, they may be all set so as to start at the same time. The spindles are driven entirely through gears, four speed changes being obtainable. The main drive consists of a loose and tight pulley having a 4-inch belt. The pulleys are 14 inches in diameter and are so placed on the machine that a convenient arrangement for motor drive can easily be made.

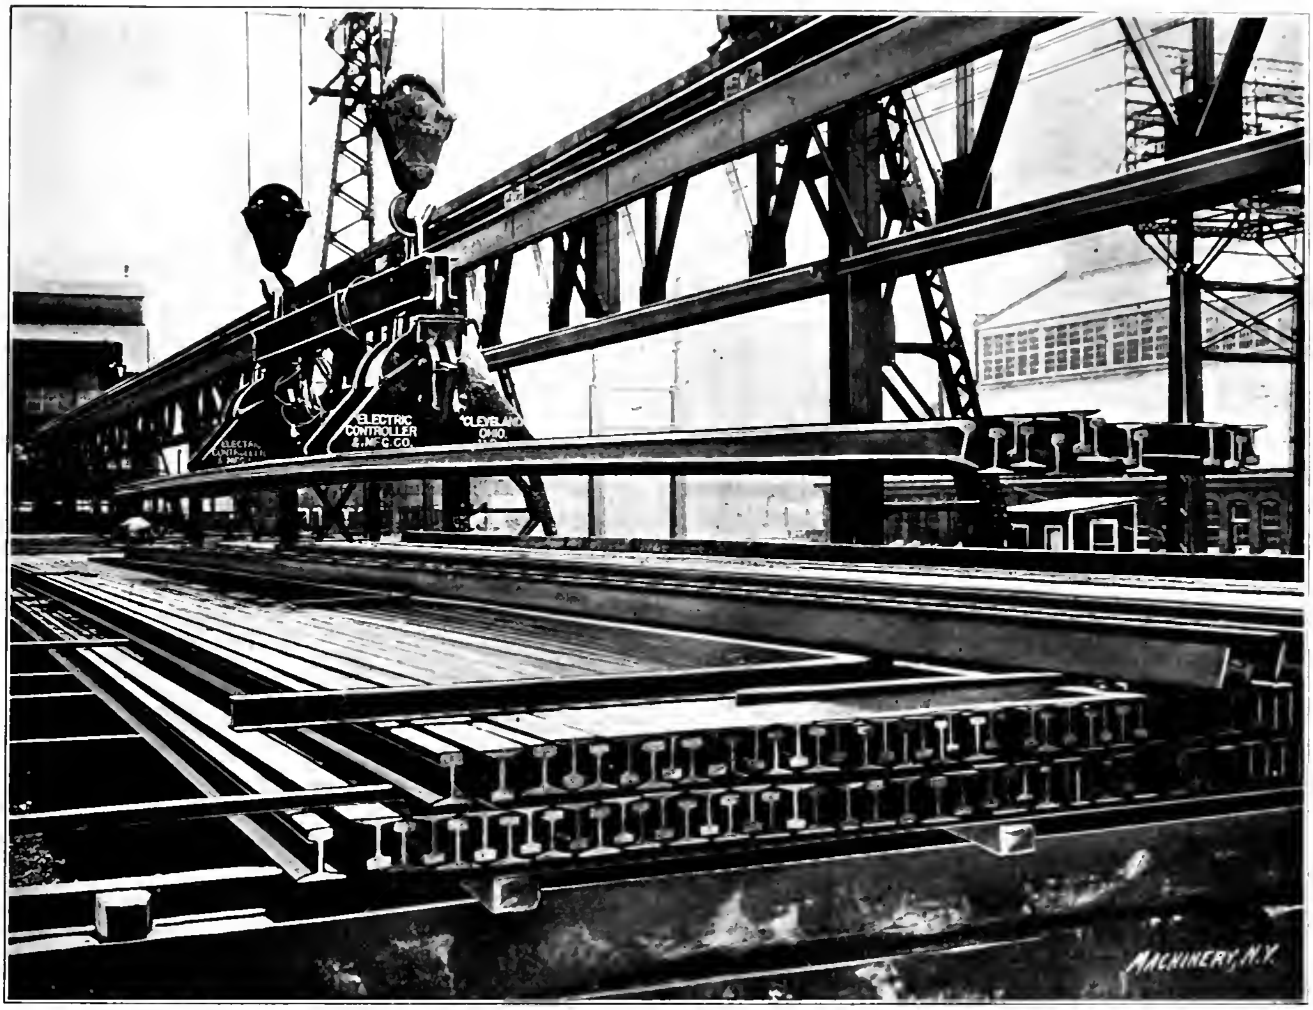
The drill head is bolted solidly to the column and the feed is accomplished by raising the knee of the machine while the drills remain stationary in the longitudinal direction, capable only of the vertical adjustment, already referred to. The standard drill head is adapted for drilling holes within a rectangle 8 inches wide by 14 inches long, but the head may be varied somewhat to meet special conditions. The main driving shaft runs at a constant speed and the feed mechanism is operated directly from this shaft. Five changes of feed are obtainable, and as the whole feed mechanism is operated by means of gearing, it is entirely positive in its action. An automatic trip is provided so that at the proper time the feed is thrown out, and then the table returns automatically to its lowest position. An adjustable buffer is provided so as to eliminate the shock when the table descends to the required position on the machine. The knee may be operated either by hand or power feed through a steel pinion meshing with a wide steel rack bolted to the face of the column. This latter is of a cored-out box section and is provided with a very substantial base having an oil pan along the edges; the table is also provided with very liberal oil channels along its outer edges. The knee is made of a full box section to insure sufficient strength and eliminate vibration. The entire machine is constructed on the unit system, each of the various units being attached to the main frame.

Spindles, shafts, etc., are all finished in the grinding machine. All sliding bearing surfaces are carefully scraped, and the drill spindles are made of high grade steel running in bronze bearings. The gears are all made of steel or bronze, and the principal steel gears are case-hardened.

The machine, as regularly furnished, will drive from 1/16 to 3/8-inch drills. The latter size drills require somewhat heavier spindles and universal joints than the former. The machine may, however, be furnished for special requirements to drive sixteen 3/8-inch drills, twelve 1/2-inch drills, ten 5/8-inch drills, and eight 3/4-inch drills.

RAIL-LIFTING MAGNETS

An improved design of rail lifting magnets brought out by the Electric Controller & Mfg. Co., of Cleveland, O., was illustrated and described in detail in the December, 1908, issue of MACHINERY. The same company has lately completed some very large lifting magnets for the handling of the entire output of the rail mill of the United States Steel Corporation's plant at Gary, Ind. This rail mill is of the most modern design in every respect and electric power has been used throughout for driving purposes. It was therefore a logical development to handle the finished rail by lifting magnets, provided a successful magnet could be designed. The difficulty met with in the design of the magnet was that, while it was desirable from the standpoint of rail mill and railroads alike to ship rails in locked sections, this arrangement of the rails made it particularly difficult to handle them with a magnet, the difficulty arising from the fact that the top layer of the rails practically short circuited the magnet field, and the magnets had to be very powerful and carefully designed in order to have sufficient strength to lift the bottom layer. Successful magnets were, however, furnished by the Electric Controller & Mfg. Co., and in the accompanying illustration one of these magnets is shown in operation. The magnets are capable of lifting locked sections of both 33- and 60-foot rails having an aggregate weight of 15 tons.



Electric Controller & Mfg. Co.'s Rail-lifting Magnets in Use lifting 60-foot Rails

The advantages of using lifting magnets for work of this kind may be summed up as follows: Sufficient labor can be dispensed with to make the application commercially profitable as regards cost; a large saving in time of handling is effected, and as there is no possibility of bending the rail when loading by magnets, loss on this score is eliminated.

MACHINE FOR HOBBING TAPS

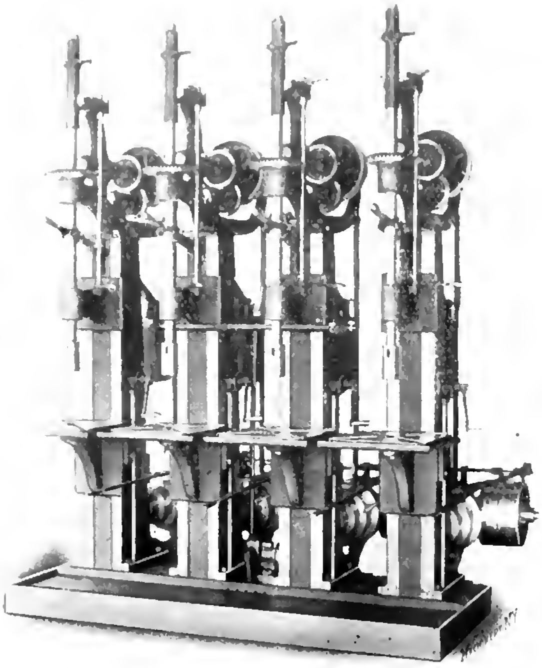
A new type of drill press, specially designed for use in the manufacture of taps, is shown in the accompanying illustration. The machine is built by the Hoefer Mfg. Co., Freeport, Ill., and embodies several interesting features which, together with the simplicity of action of the machine, ought to make it valuable for the purpose for which it is intended.

The machine resembles in many respects an ordinary drill press, but it differs notably in that the automatic feed is obtained by means of a lead-screw on the upper end of the spindle, which for this purpose is extended through the crown gear. The upper end of the spindle is turned down to a smaller diameter, and the lead-screw, consisting of a threaded sleeve, is fastened on the spindle by means of a lock nut. The lead-screw is removable, so that in each case it has the same lead as the tap to be threaded.

The tap blank is inserted in the vertical spindle in the same way as the tap itself would be inserted in a drill press used for tapping, whereupon the blank is driven through a die bolted to the table below. The tap blank passes through two dies, one for roughing and one for finishing. When the threaded portion of the tap blank has passed through the die, the special fixture or chuck holding the tap blank releases its hold on the shank, and the tap drops through a hole in the table. At the same time an adjustable dog clamped on and revolving with the threaded sleeve or lead-screw throws out of mesh the nut which engages the sleeve, whereupon the spindle returns to its original position, automatically, actuated by a counter-balance weight. The machine is then ready for another blank. The nut engaging with the sleeve is again thrown in mesh by means of a hand lever on the side of the lower spindle bearing.

The lower end of the spindle is provided with a Morse

upper end which is fitted a special fixture for holding the shank end of the tap blanks. An interesting feature in connection with the spindle end is the special method employed for cutting the slot required for removing the Morse taper shanks. Most manufacturers make slots for drift pins by drilling three holes through the spindle and then working out the remainder of the metal by means of a chisel. In the present case, however, the slots in the spindle head are milled out on a machine made for that purpose with two milling cutters working one from each side simultaneously. This results in a central and smoothly finished slot.



Hoefer Mfg. Co.'s Machine for Threading Taps

The machine as shown in the accompanying illustration is provided with four spindles and thus provides for two sets of dies. One man can easily operate a machine of this type. Each of the spindles is attached to an independent column, and is equipped with its own independent driving mechanism, although all four columns are bolted to the same baseplate. As will be seen from the illustration, the columns supporting the spindle heads and driving mechanism are of the box type, in order to provide strength. The upper head is fitted with an additional brace supporting the outer end of the cone pulley shaft. One oil pump supplies oil to all the four spindles, and drainage is provided from the tables to the oil pan base so that the oil can be used over and over.

Due to the fact that the threading of tap blanks does not require high speed, the back-gears are designed to be left permanently in mesh and changes of speed are made only by shifting the belt on the cone pulleys. Each lower cone pulley is driven at right angles from a shaft having a loose and tight pulley, so that each spindle can be stopped independently by means of the belt shifting levers projecting through under the tables. Each table can also be raised and lowered independently of the others by means of a screw passing through a nut attached to the table and provided at its upper end with a bevel gear drive and crank.

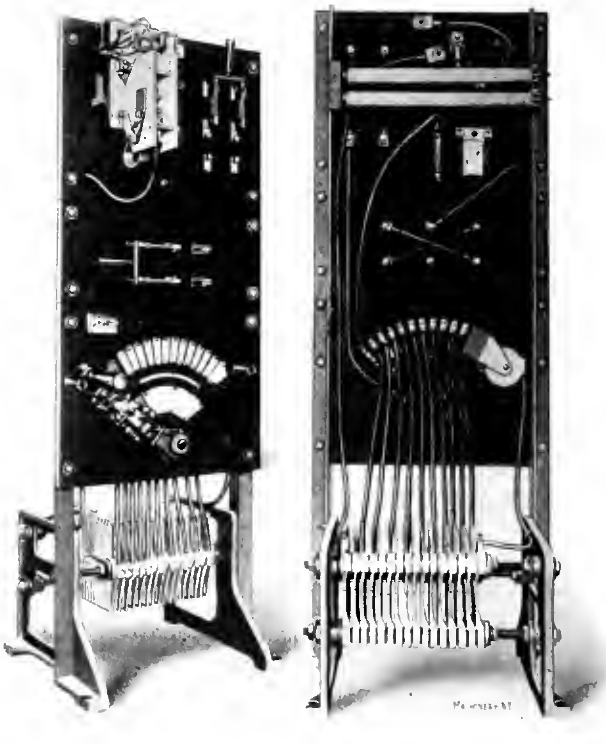
A NEW LINE OF MOTOR STARTERS

A new line of motor starters has been brought out by the Electric Controller & Mfg. Co., of Cleveland, O., one example of the new type being shown in the accompanying half-tone, where both a front and rear view are illustrated. The new design has been brought out on account of the demand for a motor starter of rugged construction. The improvement on previous types is embodied in the following features. The magnetic switch can be closed only by bringing the arm to the "off" position, thus preventing injuries and overloads to the motor upon the return of voltage after voltage failure. The magnetic switch can be held closed to the arm on any accelerating step only by holding in a push button; this prevents any of the starting resistance being permanently left in the circuit and thereby burning out the resistance. Finally, the magnetic switch will maintain itself closed only when the arm is at the "full-on" position.

The new line of starters is essentially of the mill type design. They are made in panels having supporting feet, as shown, and are completely self-contained; the dimensions of the different types vary only in height. Nothing projects beyond the slates, so that adjacent starters may be placed side by side, forming a continuous control board.

Experience has shown that the no-voltage protection secured by a spring return arm is open to the objections that the spring is likely to be either broken or weakened, so that upon voltage failure the arm does not return to the "off" position; in the second place, the contacts may become so roughened that the spring is not powerful enough to move the arm. Besides, an ignorant operator may block the arm in the "off" position, so that it is impossible for the spring to properly perform its function. If the arm is not returned to the "off" position upon voltage failure, the motor will be subjected to a damaging overload upon the return of the voltage. In this line of motor starters, therefore, the spring is eliminated, and the no-voltage protection is secured by a magnetic switch which opens upon voltage failure. The same magnetic switch in connection with an overload coil is used for securing overload protection. The feature for securing overload protection thus possesses the same arc breaking ability as a circuit breaker.

The resistance fingers, contacts, etc., used in these motor starters are of the same design and material as used in the builders' controllers for heavy service. The starters are furnished in several forms, beginning with a very simple type, and elaborated on to embrace such features as no-voltage release, overload protection, and separate and different overload protection for accelerating, the last-named feature allowing more current to flow through the motor during starting than during running. Since starting is relatively infrequent, the motor will not be injured by employing a starting current in excess of the running current. This feature is of particular value when the motor is connected to loads having great inertia, such as a hot saw or press with a heavy fly-wheel, where the mere acceleration of the load demands a considerable expenditure of work. By allowing more current to flow through the motor during starting, the starting time will be materially reduced, which in many instances is of particularly great importance.

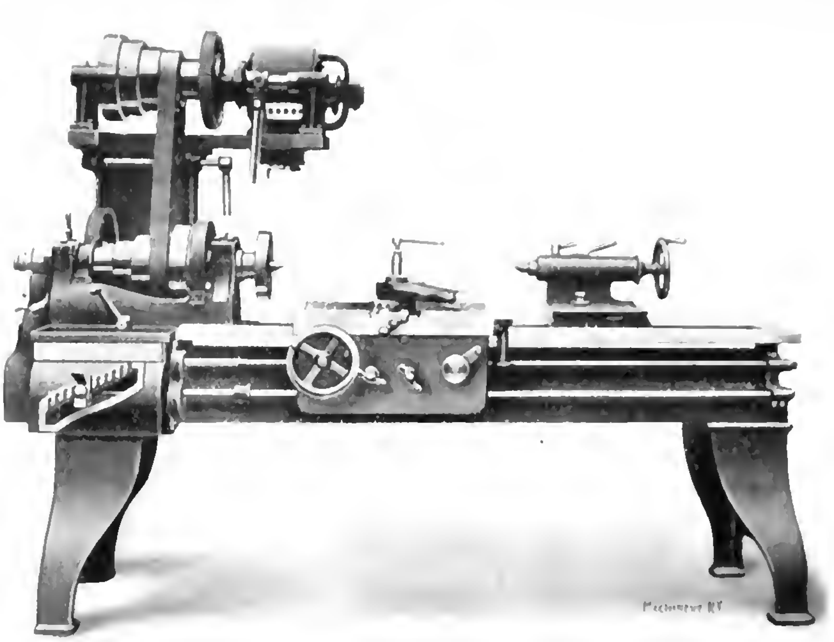


Front and Rear Views of the Electric Controller & Mfg. Co.'s Mill Type Motor Starters

DAVIS 16-INCH ENGINE LATHE WITH MOTOR ATTACHMENT

In the July issue of MACHINERY, reference was made to a 14-inch lathe built by the W. P. Davis Machine Co., Rochester, N. Y. The accompanying illustration shows a 16-inch by 8-foot engine lathe, built by the same company, provided with a motor attachment. This latter can be attached to any size or type of lathe and is of a very simple design. A small lever is placed directly under the table on which the motor and counter-shaft are mounted; by means of this lever the belt can be tightened from time to time and no lacing is required. A friction clutch is provided in the counter-shaft, attached directly to the inside of the large spur gear. By means of this friction clutch the counter-shaft can be stopped and started as required without stopping the motor.

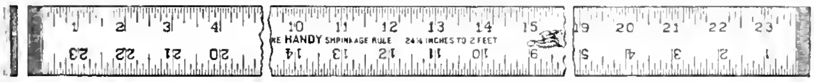
A quick change feed device is provided on the lathe by means of which any thread ranging from 3 to 40 threads per inch can be cut, and any feed required for turning obtained. A feature of considerable convenience and importance in this lathe is introduced in form of a small dial attached to the right-hand side of the carriage, by which, when cutting threads, a nut can be opened and closed on the lead-screw, so as to "catch" the thread at the proper moment.



Davis 16-inch by 8-feet Motor-driven Engine Lathe

HANDY SHRINKAGE RULE

A handy shrinkage rule, as shown in the accompanying illustration, has been brought out by the Keuffel & Esser Co., Adams and Third Sts., Hoboken, N. J. It is intended to fill the demand for an accurate, well finished shrinkage rule at a moderate price. The particularly desirable feature of this shrinkage rule is that each of the four edges is graduated in 16ths, instead of in 8ths, 10ths, 12ths and 16ths, on respective edges, as is the case with the old style shrinkage rule. All the edges are numbered from left to right, so that the rule is always in proper position for use. The rule is two feet long, nominal size, the graduations being made in four different scales for 12.1, 12 1/8, 12 3/16 and 12 1/4 inches shrinkage measure, respectively, to the foot.



Keuffel & Esser Shrinkage Rule

* * *

A German company has, according to the *Scientific American*, placed on the market a special electric generating equipment adapted to be operated by wind power. The installation comprises a dynamo and a storage battery, the latter serving to store the excess power until such time as it is required. The apparatus is entirely automatic, and requires absolutely no attention except in time of storm, when it is necessary to reduce the sail area of the wind wheel. A special regulator used with this apparatus automatically keeps a constant pressure on the lighting circuit, this being entirely independent of the number of revolutions of the dynamo or the condition of the storage battery.

* * *

A large power station is being built in Japan to furnish current for Tokyo, Yokohama, and adjacent cities and towns, which will have a capacity of 60,000 horse-power. The power will be derived from a 600-foot head of water. Six generators of the 3-phase, 25-cycle type, directly coupled to turbines, will be installed. Each turbine will develop 13,500 horse-power.

NEW MACHINERY AND TOOLS NOTES

SET OF COLD AND CAPE CHISELS: Lynn Tool & Forge Co., Lynn, Mass. Set contains twelve tools consisting of hand forged cold and cape chisels, including center punch. The tools are hand forged from 7/16-inch octagon steel, [illegible] inches long, and placed in a cloth case with a place for each tool.

COMBINED MILLING AND BORING MACHINE: Cincinnati Punch & Shear Co., Cincinnati, O. This tool resembles a slab milling machine of the planer type, except that the spindle is provided with the longitudinal feed necessary for boring. This makes a combination tool which has been found very useful on a wide range of work.

TEST INDICATOR: J. L. Wolfe, Bridgeport, Conn. This indicator is readily applied to work in the lathe, milling machine, and shaper, or on the bench. It has a dial graduated to thousandths of an inch, and the scale covers 1/16 inch in either direction. It is simple and compact and for this reason suitable for work in the machine shop.

FRICTION DRIVEN DRILL PRESS: Barry & Zecker Co., Lancaster, Pa. In this machine the driving friction disk rests directly on the driving pulley, and the friction is secured by means of the weight of the disk. The position of the disk in relation to the driving pulley is controlled by the foot, as is also the position of the driving belt. The friction disk can easily be raised out of contact with the wheel, so that a single pulley drive can be used. The machine will drill up to 9/16-inch holes.

FLAT TAPER SHANK DRILL: Cleveland Twist Drill Co., Cleveland, O. This tool, known as the Paragon drill, is twisted from flat stock and provided with a flat shank, not twisted, but forged and ground to size. The shank is of uniform taper on the flat sides as well as on the rounded edges. A socket to take these flat drills is also provided, the outside of which fits the regular drill socket tapers. The strain on the flat shank is distributed over its total length, thereby eliminating danger of breakage.

DOUBLE BACK-GEARED ENGINE LATHE: New Haven Mfg. Co., New Haven, Conn. This lathe is built in two styles, either with quick change gear device or with a feed box having three feeds. Threads or feeds from 2 to 28 per inch can be obtained by the former, while with the latter, threads ranging from 1 to 28 per inch can be obtained with only nine change gears. The lathe has nine spindle speeds for each counter-shaft speed, which with a two-speed counter gives from 7½ to 333 revolutions per minute.

OIL BURNING FURNACE FOR HEAT TREATMENT OF STEEL: Tate, Jones & Co., Pittsburg, Pa. This furnace has been designed on account of the ease with which the temperature can be regulated in oil burning furnaces, and is of iron construction with fire-brick lining. The oil is carried in a tank at the side of the furnace and is forced into the burner from the tank by means of air pressure from the regular shop blast, or from a small blower placed at the side of the machine. The flame is so diverted that a uniform temperature is maintained in all sections of the furnace.

PLAIN GRINDING MACHINE: Modern Tool Co., Erie, Pa. This machine, known as the No. 12 grinder, is heavily designed and the head-stock and foot-stock are secured to the vertical rail

by special clamping devices. The automatic cross-feed gives a range from 0.00025 to 0.004 inch for each reversal of the table. The machine will grind straight or taper work up to 5 inches in diameter and 31 inches long, with any taper up to 1¾ inch per foot. The wheel is 12 inches diameter by ¾ inch face and the floor space 41 x 110 inches.

Oval Socket Breast Drill: Lancaster Machine & Knife Works, Lancaster, N. Y. The distinguishing feature of this breast drill is the fact that its socket is provided with an oval taper hole for driving drills with oval taper shanks. This system of driving was described in the department of New Machinery and Tools in the September, 1908, issue of Machinery. The drills with the oval tapers are made by the Whitman & Barnes Mfg. Co., of Akron, O., who offer them as a regular article of trade independent of the breast drills here mentioned.

Combined Surface and Tool Grinder: XX Century Tool Co., 1289 Marquette Road, Cleveland, O. The most prominent feature of this machine is the height of the spindle and table, the former being 51 inches from the floor, thereby bringing the work so high that the operator does not have to stoop to watch it. The machine is designed especially for grinding screw machine and other tools with parallel surfaces, and can also be used as a surface grinder for small work. The traverse of the table is 6 inches, the cross-feed 3 inches, and the vertical adjustment 4 inches.

Rapid Blue-Printing Machine: Williams, Brown & Earle, 918 Chestnut St., Philadelphia, Pa. A special feature of this blue-printing machine is the rapidity with which the prints can be produced. When used in pairs, the light from one set of lamps will be sufficient for two machines, and the maximum capacity of blue-prints is then 16 feet per minute for the two machines, at the cost of one set of lamps. Each machine in a pair is independent of the other, and one can be run at its maximum speed for fast blue-printing while the other is run slowly for sepia or negative work.

Electric Recording Pyrometer: Edward Brown & Son, 311 Walnut St., Philadelphia, Pa. This instrument is constructed for use in conjunction with a thermo-couple, but the type of recording gage used can also be employed for very accurately recording pressures of steam and air, voltage, etc. When used as a pyrometer, the instrument can be supplied for any desired range in temperature, and the record charts can be made to revolve once in twenty-four hours, or once in seven days, as preferred. The instrument is very simple in its construction, which is of great advantage when used under regular industrial conditions.

Grinding and Polishing Machines: Adamite Surface Machine Co., 217 High St., Newark, N. J. These machines are both of the vertical and horizontal type, equipped with cloth belts charged with abrasive. The vertical type of machine has two belts, one for roughing and one for finishing the metal being ground. The belt containing the abrasive runs over an endless leather belt, both belts being supported back of the work, which rests on a table in front. The horizontal type is better adapted to work which is more easily handled by holding it down onto the belt. A special machine is built for polishing tubing, shafting and similar work.

Heavy Power Press: George A. Ohl & Co., 157 Oraton St., Newark, N. J. This machine is of powerful design capable of cold bending up to ½-inch soft steel to a right angle, and is designed for forming the thick sheet metal work which enters into the construction of steel passenger cars, metal furniture, etc. The openings in the housings through which the work passes are 30 inches wide by 15 inches high. The stroke is 4 inches with a position adjustment of 4 inches to suit different heights of dies. The height of the machine is 16 feet over all. It occupies a floor space of 16 by 8 feet and measures 12½ feet between the housings. The machine weighs 108,000 pounds and requires 35 H. P. for driving.

Portable Electric Breast Drill: Willey Machine Co., Jeffersonville, Ind. This is the smallest size in the line of breast drills built by the makers; the largest size with gear drive was shown in the November, 1908, issue of Machinery. The main feature of this line of drills is the simplicity of construction, which is a most important matter in devices of this kind, which are often subjected to rough usage when in service. The present size is suitable for drilling holes up to ¼ inch in diameter. The entire machine can be easily taken apart by simply removing two nuts, leaving the whole mechanism open for inspection. The drill chuck is attached directly to the armature shaft, and a snap switch located on the side of the frame makes the starting and stopping of the drill very convenient.

* * *

A New York concern—Wyckoff, Church & Partridge—has taken the agency for the Herring-Curtiss aeroplane, and advertises machines for sale, subject to delivery within forty days from date of order. This announcement indicates that the flying machine proposition has reached the commercial stage so far as supplying the wants of amateurs is concerned, at least.

STANDARDS FOR RECIPROCATING STEAM ENGINES FOR ELECTRICAL PURPOSES

The Engineering Standards Committee of Great Britain has just issued a report on reciprocating steam engines for electrical purposes, which contains some propositions for standardization which may well be considered in this country as well. The steady increase in steam pressures that has marked the development of the steam engine during the last few decades has led to a certain specific, yet somewhat loose, classification of types, which at times is rather confusing. The committee has, therefore, defined the meaning to be attached to such phrases as low pressure, high pressure, extra high pressure, medium vacuum and good vacuum, etc. In respect to steam pressures the following standards for pressures measured at the throttle valve are suggested:

	Pounds per Square Inch Gage Pressure
Low pressure	100
Intermediate pressure	150
High pressure	200
Extra-high pressure	300

With respect to vacuum measured by mercury column at the exhaust flange of the engine, the following values are suggested as definitions of "medium" and "good":

	Pounds per Square Inch, Absolute.
Medium vacuum	2.5
Good vacuum	1.5

With respect to speeds of engines the following table is given to indicate the limits of the terms "slow," "medium," and "high" speed in reference to revolutions per minute and rated output:

Rated Output in Kilowatts	Revolutions per Minute at Rated Output		
	Slow	Medium	High
30	...	...	625
40	...	...	600
50	...	...	575
60	...	...	575
80	...	...	525
100	107	250	500
150	107	250	428
200	107	250	375
250	107	250	375
300	94	214	375
400	94	214	375
500	94	214	300
750	83	188	250
1000	83	188	250

Regarding the size of engines to be used for different sizes of generators the committee lays down the general rule that the engine shall be capable of driving the generator continuously at all loads up to the rated output and for at least two hours at twenty per cent above the rated output of the generator without undue heating of the bearings, or other mechanical trouble. It is also suggested by the committee that the size of engine cylinders should be such that the mean pressure in pounds per square inch referred to the low pressure cylinder at full load should not exceed that indicated by the table below:

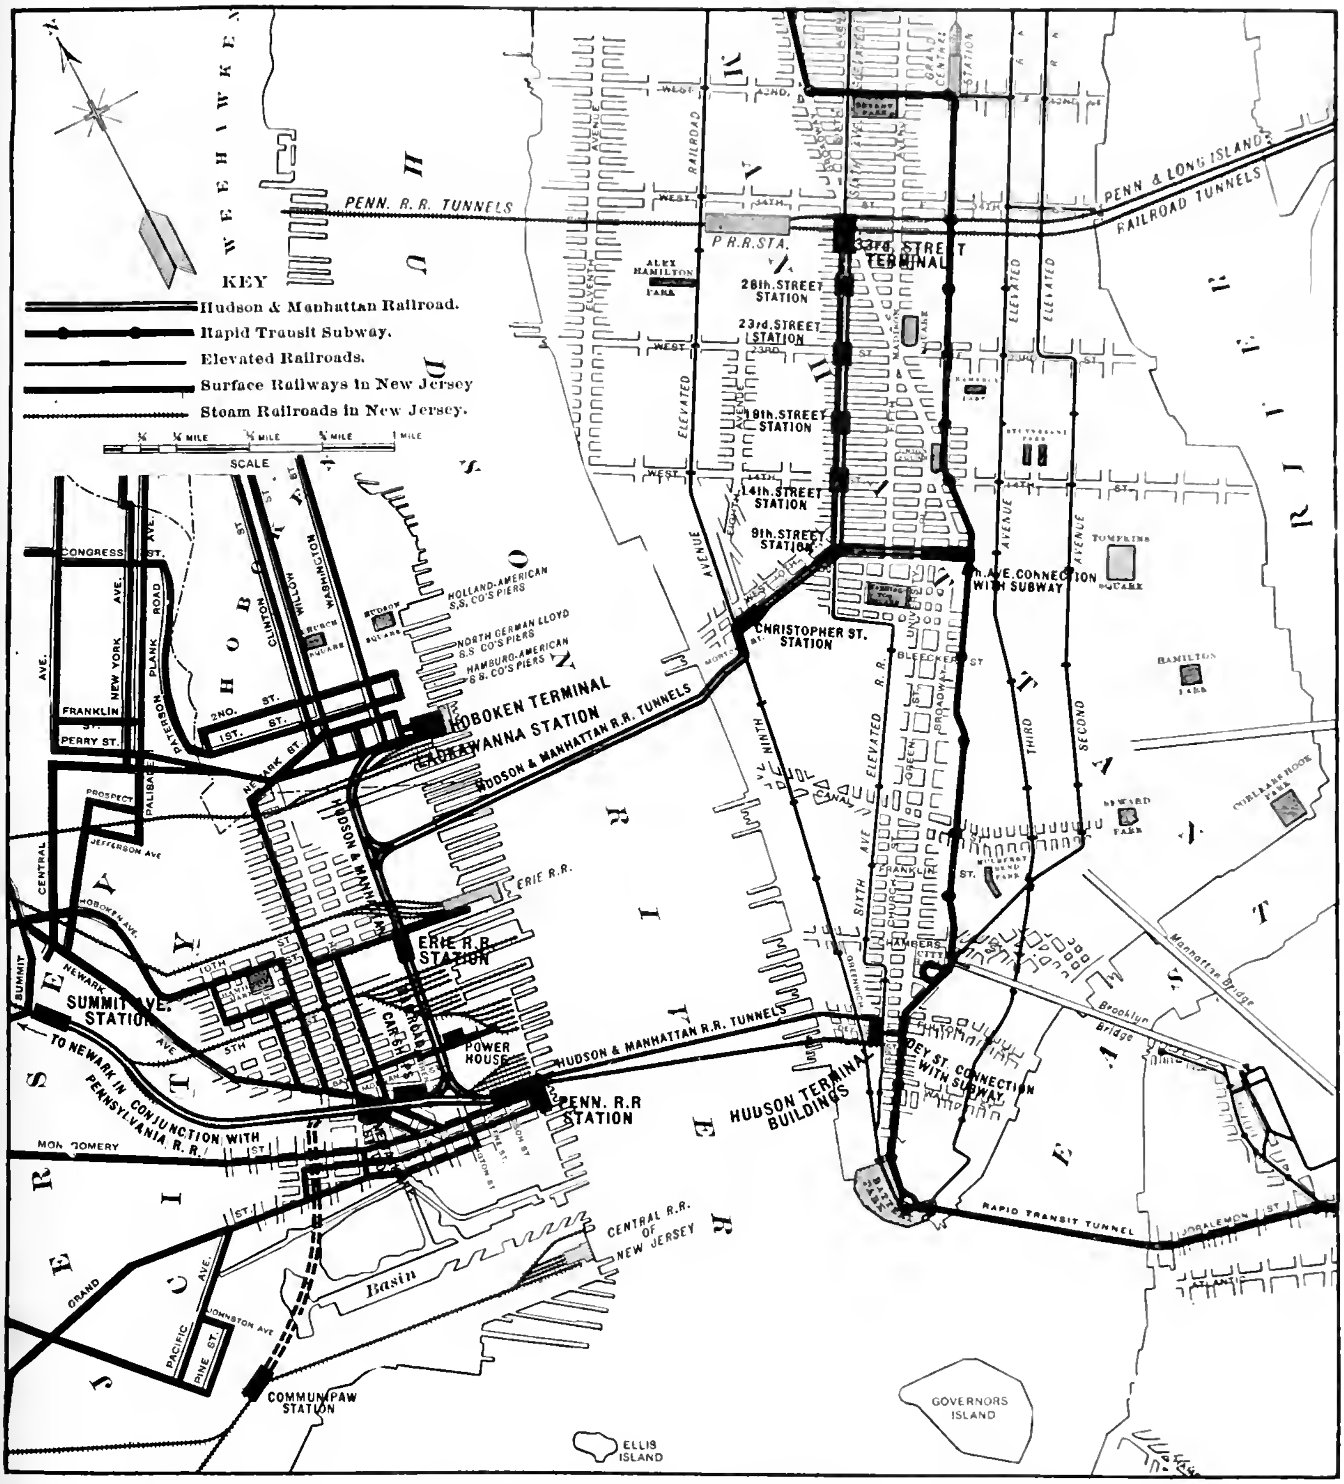
Steam Pressure, Pounds per Square Inch	100		150		200		300	
Class of Engine	Compound	Triple	Compound	Triple	Compound	Triple	Compound	Triple
Non-condensing	35	..	44	42	51	48	59	56
Condensing, medium vacuum	32	29	40	36	45	40	50	45
Condensing, good vacuum.	30	27	37	34	41	37	46	41

Regarding the speed variation it is stated that the maximum temporary variation in speed due to the load being varied gradually, or by steps not exceeding twenty per cent of the rated load, should not exceed five per cent of the standard full load speed.

OPENING OF SECOND HUDSON TUNNEL

The downtown tunnel of the Hudson & Manhattan Railway Co., connecting the Hudson Terminal in New York and the Pennsylvania Railroad terminal in Jersey City, was opened to public traffic July 19. The completion of this tunnel adds another link to the great transportation system that will eventually connect all the railroad terminals in New York City, Jersey City and Hoboken, with the exception perhaps of the West Shore R. R. The tunnel opened February 25, 1908, connects the Hoboken terminal of the Delaware, Lackawanna & Western R. R. with Christopher Street station and the stations on Sixth Avenue including 23rd Street. This line will soon be completed to the new Pennsylvania R. R. station at 33rd Street, and a franchise was recently granted for extending it to the Grand Central station on 42nd Street, the terminal of the New York Central and the New York, New Haven & Hartford railroads.

Early in August the link connecting the Pennsylvania R. R. station with the Lackawanna will be completed, which also connects with the Erie R. R. When the system is completed it will be possible for a traveler to reach any of the railroad terminals of New York by the tunnel route with the exception noted above, on payment of a five-cent fare. The tunnel system will connect with the New York Subway at Broadway and 9th Street, and a foot path tunnel will connect the Hudson Terminal with the Subway at Broadway and Dey Street. The two great tunnel systems will thus be connected so as to make emerging to the street unnecessary in a trip from Brooklyn or the Bronx to New Jersey.



Map of the Hudson & Manhattan Railroad Co.'s Tunnel System, showing also Subway, Surface and Elevated Railway Lines

The Hudson Terminal consists of two great twin buildings on Church Street covering a large portion of the two blocks between Fulton and Cortlandt Streets. In the common basement of the buildings is a great concourse extending under Dey Street, and in the sub-basement are the tracks and passenger platforms. The machinery trade is interested in the Fulton building particularly because of the Machinery Club on the 21st and 22nd floors which has a large membership in the machine tool and other lines of machinery trade. It is possible for a member to enter an elevator at the club floor and emerge on

the concourse floor and take a train to Jersey without going onto the street. See MACHINERY, March and June, 1908.

It is estimated that the tunnel system will handle 100,000,000 passengers annually from the start, much of which will be new business, judging from the history of other New York transit improvements. The present ferry traffic across the Hudson is estimated at 128,000,000 annually, but it is not likely that there will be serious diminution of the ferry traffic until the railways have made the tunnel system a more closely connected part of their terminal systems. When that time comes, the total estimated capacity of the tunnels may be required, that is 220,000,000 passengers annually with eight-car trains operated at an interval of 1⅛ minute in rush hours.

The cost of the tunnel system will be about $70,000,000 when completed. It was begun in 1874 by D. C. Haskins, a civil engineer who conceived the idea of constructing a brick tunnel from Hoboken to New York. About 1,200 feet of the tunnel was built when the company failed and in 1880 the work was temporarily abandoned. In 1890 another company was organized with English capital and added about 1,800 feet to the part already built, when it also failed and once more the enterprise was held up. In 1901 William G. McAdoo, a young Southern lawyer, became interested in the project of rapid transit to the Jersey shore, and organized the present company. The old method of construction using a brick lining was abandoned. The present tunnel is lined with cast iron rings made in sections and bolted together. The chief engineer is Charles H. Jacobs, to whom much credit is due for the rapid progress of the work and the remarkable freedom from serious accidents to life and limb that has characterized this gigantic and dangerous undertaking.

SHOP DOOR CLOSING DEVICE

The heating of machine shops, factories, round-houses, and other buildings having large doors is seriously retarded by the leakage of volumes of cold air in over the doors at the top. The ordinary large sliding or swinging door almost invariably bulges at the top making a crack of considerable width through which the cold air blows in greater or less volume according to the exposure, and velocity of the gale. During the past few years the heating of large shops and round-houses has received a great deal of attention, and no modern structure is considered complete without adequate means of heating. The old idea that the men should keep warm by hustling has been generally discarded and now every up-to-date factory manager realizes the importance of providing as nearly as possible a uniform, comfortable temperature in all work-rooms. The cost of heating large buildings in northern latitudes is a heavy item, and practical means that will shut out the cold air where it should not enter merit attention.

Realizing the serious loss that results from bulging doors in railway shops, as well as in other works having large doors, through the lack of close fit at the top, Mr. J. C. Hassett, technical instructor of apprentices of the Erie Railroad, Meadville, Pa., has devised the shop door closing device illustrated in Figs. 1 and 2 in which the action of the device and the details of the component parts are illustrated. As will be seen, the arrangement provides means by which the door is clamped and forced solidly against the jamb at the top by means of the curved piece *A* which is worked by a connection and lever conveniently located on the door. The connecting rod may be of any length required to suit the door height,

THE RESULT OF ONE YEAR OF THE FITCHBURG IDEA

Last September a co-operative high school and industrial training course was inaugurated in Fitchburg, Mass., as described in the October number of MACHINERY. It was an adaptation of Prof. Herman Schneider's idea worked out in the University of Cincinnati and known as the co-operative industrial course, but modified to suit the local conditions of Fitchburg and its high school. The course was conducted under the direction of Prof. William B. Hunter, and the result of the work has fully justified the enthusiasm of Prof. Hunter and others responsible for the initiation of the work and its successful conduct.

The course of study was patterned after that in the University of Cincinnati, it being a form of apprenticeship system whereby the boys receive instruction in the shop one week and instruction at the school the next week. The course is of four years duration and the first year is spent wholly in the school, thus leaving three years for the alternate weekly work in school and shop. The shop work consists of instruction in the operation of lathes, planers, milling machines, punch and shear work and other mechanical work within the ability of apprentices. The boys are paid for their work in the shop. For the first year the rate of payment is 10 cents per hour, for the second year 11 cents and the third year 12½ cents per hour, making $5.50 per week or $165 for the first year, $6.05 per week or $181.50 for the second year and $6.87 per week or $206.25 for the third year. Thus the boy in this course may earn a total of $552.75 in three years while obtaining a practical and theoretical education.

The principal, instructors, students and manufacturers of Fitchburg speak highly of the results of the initiatory year. The *Fitchburg Daily News* for June 17 gives an extended account of the close of the school year with a list of eight questions propounded to twenty-two boys and the answers received from fourteen, which will be found of interest by those closely concerned with industrial education.

AEROPLANE CROSSES ENGLISH CHANNEL

Louis Bleriot, a Frenchman, crossed the English Channel Sunday morning, July 25, on his aeroplane. The distance across the channel is twenty-one miles, and the trip was made in thirty-seven minutes, the rate of travel, therefore, being thirty-four miles per hour. The trip was without accident except at the landing when the machine was whirled around two or three times and the propeller broken by striking the ground. Bleriot wins the *Daily Mail* prize of $5,000 offered to the first man who performed the exploit. The Bleriot machine is a monoplane, there being only one supporting surface, as compared with the biplanes used by the Wright brothers, Curtiss, Farman, and others which have two superimposed planes.

* * *

PERSONAL

Perley E. Harey, master mechanic of the Chapman Valve Mfg. Co., Springfield, Mass., has resigned his position.

A Munch, manager of the railway department of the Northwestern Metal Mfg. Co., Minneapolis, Minn., has been elected a director and the secretary of the company.

H. C. Patterson has taken the position of electrical and mechanical engineer with the Illinois Traction System, vacated by the resignation of Mr. H. C. Hoagland.

Arthur Williams, chief inspector of the New York Edison Co., has been elected one of the Board of Trustees of the Museum of Safety and Sanitation, New York.

Fred E. King, Springfield, Mass., has resigned his position with the King Automobile Co., to become foreman of the tool room of the Dickinson Mfg. Co., of that city.

J. A. Bell has been appointed master mechanic of the Dubuque division of the Illinois Central R. R., with headquarters at Waterloo, Ia., succeeding R. J. Turnbull.

P. V. See, who until recently was in the employ of the Twin City Traction Co., of St. Paul and Minneapolis, has been appointed general foreman of the Illinois Traction Co.'s shops at Decatur, Ill.

The volume of studies of American life and labor, "Social Engineering," by Dr. William H. Tolman, director of the Museum of Safety and Sanitation, New York, has been translated into French.

E. M. Haas, formerly connected with the Southern Illinois McKinley Interests, has been transferred to Decatur, Ill., to fill the position of superintendent of the bridge and building department of the Illinois Traction System.

Coker F. Clarkson was elected assistant general manager of the Association of Licensed Automobile Manufacturers in June to fill out the term of Mr. C. E. Chalfant, who recently resigned as general manager.

A. P. Warner, vice-president of the Warner Instrument Co., Beloit, Wis., has purchased a Herring Curtiss areoplane. Probably it will be fitted with a special anemometer connected with a Warner autometer to indicate the velocity of flight!

Leon J. Canova, Havana, Cuba, has been appointed, by President Gomez, director of the Bureau of Information, established at the beginning of the present fiscal year. Manufacturers interested in Cuban trade are invited to communicate with him.

Otto Shilling, formerly superintendent of the Peoria division of the Illinois Central R. R., will re-enter railroad work after being some time engaged in other business; he has taken the position of train-master for the Texas & Pacific Railway at Texarkana, Texas.

Dr William H. Tolman, director of the Museum of Safety New York, read a paper at the twenty-second convention of the National Association of Accident Underwriters, Hotel Clifton, July 13-16, Niagara Falls, New York, entitled "Perils of Peace, or a Safer America."

The jurisdiction of Frank Lane, chief electrician of the Wabash Railroad, Moberly, Mo., has been extended over the entire Wabash system, his headquarters being at Decatur, Ill. Mr. Lane's successor at Moberly is William Erwin, who has been night stationary engineer at the Decatur shops.

Benjamin Whittaker resigned as treasurer of J. H. Williams & Co., manufacturer of drop forgings, Brooklyn, New York, July 1, and will now give his entire time to the exporting business for the same company and others, with headquarters at 17 State St., New York.

Herbert V. Purman, formerly assistant superintendent of the National Manufacturing Co., Worcester, Mass., and more recently labor superintendent of the Corbin Motor Vehicle Corporation, New Britain, Conn., has returned to Worcester to act as general foreman of the Heald Machine Co.

William Threlfall has resigned his position of general manager of the Chapman Valve Mfg. Co., Springfield, Mass. A number of the foremen gave Mr. Threlfall a banquet at the Worthy Hotel, June 8, at which he was presented with a handsome hunting case gold watch with suitable inscription.

August Kittleberger, who for the past fifteen years was associated with the Clayton Air Compressor Works, has been engaged by the American Air Compressor Works as superintendent of its Brooklyn plant. Mr. Kittleberger's long experience in the construction of air compressors and vacuum pumps has well fitted him for his new position.

Hugh M. Wilson, formerly editor and publisher of the *Railway Age*, became associated with the Barney & Smith Car Co., Dayton, Ohio, August 1, as director and vice-president. Mr. Wilson disposed of his publication business something more than a year ago, having recently returned to the United States after spending nearly a year in foreign travel.

Joseph H. Williamson, for eighteen years business manager of the Manufacturers' Advertising Agency, New York, and for seven years business manager of the Viennot Advertising Agency, Philadelphia, Pa., resigned from the Viennot Agency October, 1907, and up to April, 1909, had charge of the company's New York business on a salary basis. Mr. Williamson has now opened an office at 719 Temple Court, New York, where he will act as a representative of trade journals. He is well known to the publishers of trade journals in the United States, and any business entrusted to him will receive careful attention.

* * *

OBITUARIES

Gust. A. Dalin died at the Rockford Hospital, Rockford, Ill., July 10, aged forty-seven years. He was in partnership with his brother in the firm of Dalin Bros., machinists. He was the inventor of a friction drill, and was engaged in the manufacture of small milling machines. The business will be conducted by the brothers, A. G. Dalin and S. Dalin. Mr. Dalin is survived by a mother, four sisters and three brothers.

A. Bradshaw Holmes, secretary and treasurer of the Independent Pneumatic Tool Co., and the Aurora Automatic Machinery Co., Chicago, Ill., died June 30, 1909, from injuries received by accidentally falling from the piazza of his hotel. Mr. Holmes was well known in the pneumatic tool business, having been connected with the Standard Pneumatic Tool Co., and the Rand Tool Co. for a number of years prior to his connection with the Independent Pneumatic Tool Co., of which concern he was secretary and treasurer since its organization. He was thirty-one years old and unmarried

Brown & Sharpe Mfg. Company

Providence, Rhode Island, U. S. A.

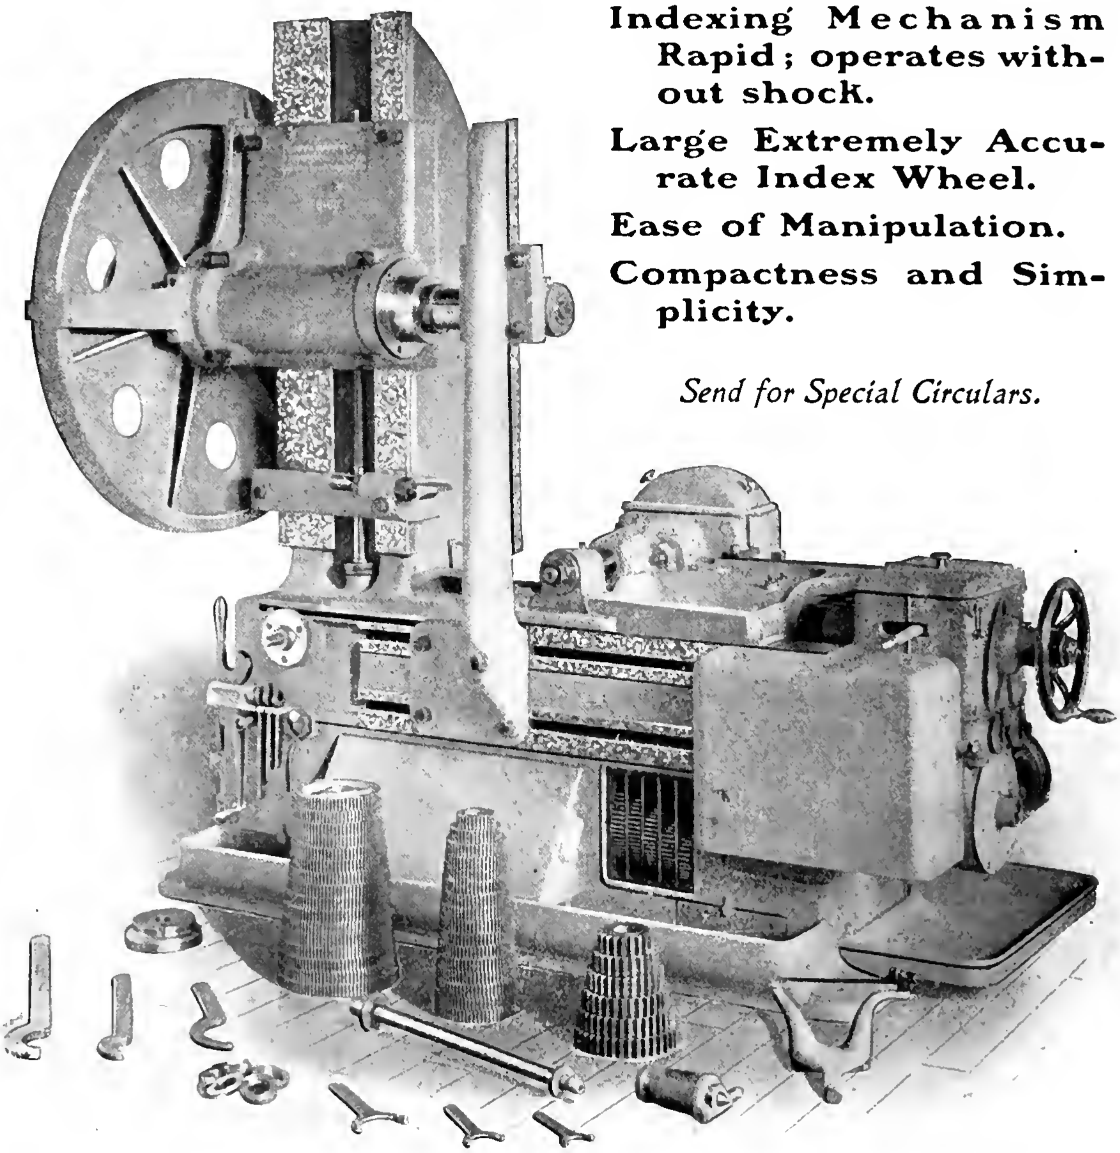
B. & S. Automatic Gear Cutting Machines

Designed and Built for the Rapid Production of Gears of Great Accuracy.

IMPORTANT FEATURES

- Correctly Designed, Accurate Bearing Surfaces.
- Cutter Spindle Powerfully and Smoothly Driven.
- Exceptionally Large Diameter Work Spindle.
- Indexing Mechanism Rapid; operates without shock.
- Large Extremely Accurate Index Wheel.
- Ease of Manipulation.
- Compactness and Simplicity.

Send for Special Circulars.



No. 6 Automatic Gear Cutting Machine.

Brown & Sharpe Mfg. Company

Providence, Rhode Island, U. S. A.

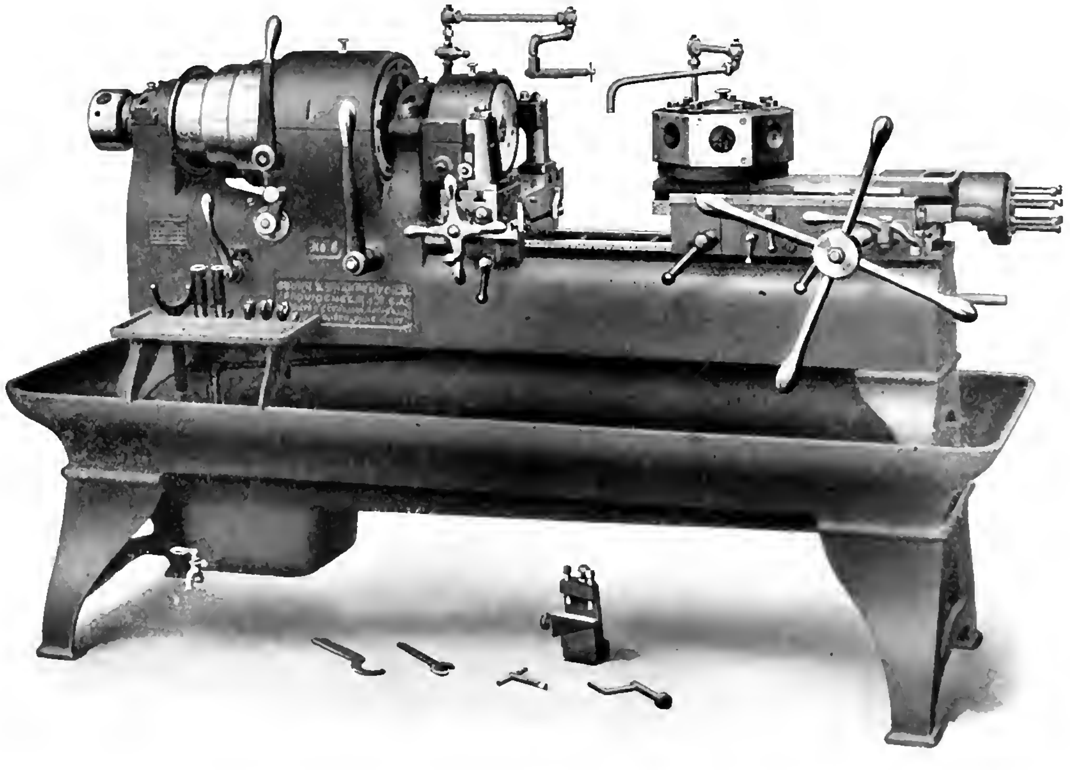
B. & S. Wire Feed and Plain Screw Machines

Correctly Designed and Carefully Constructed Machines of Great Accuracy and Remarkable Durability.

IMPORTANT FEATURES

Rigid Construction of All Parts.
Economical Consumption of Power.
Independent Stop for each Hole in Turret.
Vertical and Transverse Adjustment for Turret Slide.
Graduated Scale on side of Turret Slide.
Adjustable Stop on Cross Slide.
Gearing Fully Enclosed.

Send for Special Circulars.



No. 6 Wire Feed Screw Machine.

COMING EVENTS

August 9-14. Seventeenth National Irrigation Congress, Spokane, Wash., for the consideration of an action on irrigation, drainage, forestry, good roads, deep waterways, and home building. Arthur Hooper, secretary, Board of Control, Spokane, Wash.

September 25-October 9. Hudson-Fulton celebration of the three hundredth anniversary of the discovery of the Hudson River by Hendrick Hudson in 1609, and the one hundredth anniversary of the successful application of steam to the navigation of the Hudson River in 1807. The headquarters of the commission are in the *Tribune* building, New York City, General Stewart L. Woodford, president, and Mr. Henry W. Sackett secretary. The commission solicits the loan of collections of machinery, models, books, etc., having a bearing on the history of early steam navigation in the United States.

September 27-October 1. Autumn meeting of the Iron and Steel Institute, London. G. C. Lloyd, secretary, 28 Victoria St., London, S. W.

October 4-8. Annual conventions of the American Street and Interurban Railway Association, American Street and Interurban Railway Accountants' Association, American Street and Interurban Railway Engineering Association, American Street and Interurban Railway Claim Agents' Association, American Street and Interurban Railway Transportation and Traffic Association, American Street and Interurban Railway Manufacturers' Association, at Denver, Col. Bernard V. Swenson, secretary and treasurer, 29 West 39th St., New York.

October 12-13.—Convention of National Machine Tool Builders' Association, New York. P. E. Montanus, secretary, Springfield, Ohio.

October 11.—MACHINERY's seventh annual outing.

April 1-June 30, 1910. American Exposition in Berlin to stimulate trade relations with Germany and American export business generally. The exposition will be held in the Exposition Palace, having 110,000 square feet floor space. Max Viewger, American manager, 50 Church St., New York.

SOCIETIES AND COLLEGES

SOCIETY FOR THE PROMOTION OF ENGINEERING EDUCATION held its seventeenth annual meeting at Columbia University, New York, and Pratt Institute, Brooklyn, June 24-26. The program included papers on technical education, features of engineering practice, etc., among which were: "Present Tendencies in Technical Education," President Frederick E. Turneaure, dean of the University of Wisconsin; "Highway Engineering," L. W. Page, director of the Office of Public Roads, United States Department of Agriculture; "The Relation of Engineering Education to Industries," Charles B. Going, editor *Engineering Magazine*; "Efficiency in Education," Prof. George F. Swain, Massachusetts Institute of Technology; "The Extension Work of the University of Wisconsin," Prof. Louis E. Reber, University of Wisconsin; "The Requisite Qualifications of an Engineering College Instructor," Oliver B. Zimmerman, Charles City, Iowa; "Employer's Requisites of Technical Graduates," Prof. Hugo Diemer, The Pennsylvania State College.

MASSACHUSETTS INSTITUTE OF TECHNOLOGY, Boston, Mass., has appointed Dr. Harold Pender to the professorship of Theoretical and Applied Electricity which is connected with the Department of Electrical Engineering. Dr. Pender is a graduate of Johns Hopkins University and took the degree of Ph.D. at that university in 1901 under the direction of Prof. Rowland. He thereafter taught for a year and a half, during which period he completed the classical experiments of Prof. Rowland which demonstrated the magnetic effect of a moving charge of electricity. Poincaré, the eminent professor of the Sorbonne in Paris and a member of the French Academy, having suggested the desirability of these experiments being performed in Paris for the benefit of French scientists, the Carnegie Institution of Washington arranged with Dr. Pender to go to France for the purpose. Upon returning from France, where his experimental demonstration had been received with acclamation, Dr. Pender went into the employ of the Westinghouse Electric Co., and he has since been in regular engineering employ. He is recognized as notable in his work in mathematical and experimental physics. His teaching at the Institute of Technology will consist of a course for third-year undergraduate students and courses for graduate students in the more advanced theories of electric current flow and the electric transmission of power, in addition to the direction of experimental research by advanced students.

NEW BOOKS AND PAMPHLETS

STEEL SQUARE POCKET BOOK. By Dwight L. Stoddard. 159 pages, 3¼ x 5 inches, 150 diagrams. Published by the Industrial Publication Co., New York. Price, 50 cents.

This book on the use of the carpenter's steel square has passed into the second edition and has been partly rewritten and rearranged. New matter has been added, including about forty new diagrams. It treats of the uses of the steel square, showing how to cut rafters, lay out angles, and apply this indispensable tool generally to the many purposes required of it by the expert carpenter.

LESSONS IN TELEGRAPHY. By Charles H. Sewall. 88 pages, 5 x 7 inches. Published by D. Van Nostrand Co., New York. Price, $1.00.

This work is designed for use as a text-book in schools and colleges and for individual study, its aim being to furnish the student with not only the ordinary instructions in telegraphy necessary to learn the art, but to teach him what bad telegraphic habits to avoid. It contains sending and receiving exercises for commercial and railway business, press news, market reports, etc. The work contains much that the ordinary amateur never learns until he enters a commercial office, and for this reason should be highly useful to a class of learners who cannot readily acquire such advantages.

TABLES AND DIAGRAMS OF THE THERMAL PROPERTIES OF SATURATED AND SUPERHEATED STEAM. By Lionel S. Marks and Harvey N. Davis. 106 pages, 6½ x 8¾ inches. Published by Longmans, Green & Co., New York. Price, $1.00.

The older tables giving the properties of saturated steam were based on the investigations of Regnault carried out more than sixty years ago. It has been apparent for some time that the total heat of dry and saturated steam as determined by Regnault's researches are below the correct values, and new determinations have been made. The new tables are based on the investigations of Dieterici, Smith Griffiths, Henning, Joly, Grindley, Griessmann, Peake, Knoblauch and Thomas. The book comprises tables of superheated steam temperatures, saturated steam temperatures, saturated and superheated steam, superheated steam at high temperatures, boiling points for thermometer calibrations, thermal properties of water, conversion tables, logarithms to the base of 10, logarithms to the base of *e*. Part III of the book is given up to discussion of sources of the data as follows: Absolute temperature, the specific heat of water, the mechanical equivalent of heat, the pressure-temperature relation, the specific heat of superheated steam, the specific volume of superheated steam, the total heat of saturated steam, the specific volume of saturated steam at high temperatures and the computation of the tables.

GEAR CUTTING MACHINERY. By Ralph E. Flanders. 319 pages, 5¼ x 8 inches. 219 illustrations. Published by John Wiley & Sons, New York. Price, $3.00.

The work gives a complete review of American and European gear cutting machines, and explains the theory of action. It is largely made up of the series of articles on gear cutting machines published in the engineering edition of MACHINERY, 1908, which treated the subject in the thorough manner that its importance deserves. Chapter I describes the methods of forming teeth of gears, and classifies gear cutting machinery accordingly. There are five recognized principles of action and four methods of operation. The formed tool, templet, odontographic, describing-generating and molding-generating principles are illustrated diagrammatically and simply described, and the impression, shaping or planing, milling and grinding methods are similarly treated, thus introducing the reader to the general subject with a full comprehension of the principles and action. The second and third chapters treat of machinery for cutting spur gears, the third chapter taking up in detail a subject that is attracting much attention at the present time, *i.e.*, the hobbing process. Chapter IV describes machinery for cutting the teeth of internal gears and racks. Machines for cutting the teeth of worms and helical gears are described in Chapter V, and worm-wheel cutting machines in Chapter VI. Machines for forming teeth of bevel gears are treated in Chapters VII and VIII. The work is the only complete treatment of gear cutting machinery published; it comprised every known commercial machine at the date of publication. It will be found of much interest and value to those concerned in the art of producing cut gearing.

CATALOGUES AND CIRCULARS

HOGGSON & PETTIS MFG. CO., New Haven, Conn. Catalogue of hand cut steel stamps for all purposes, also seal presses and cutting dies.

EMERSON ELECTRIC MFG. CO., St. Louis, Mo. Bulletin No. 3216 of bi-polar ventilated motors, ½ H.P. direct current.

E. J. BROOKS & CO., 227-229 Fulton St., New York. Circular of nailed box strap and seal and strap pulling device for sealing cases.

HESS-BRIGHT MFG. CO., Philadelphia, Pa. Sheet illustrating crane hook thrust ball bearing mounting equipped with Hess-Bright ball bearings.

WALTHAM MACHINE WORKS, Waltham, Mass. Circular on sub-press die work, illustrating samples of the work done and giving a brief treatise on sub-press dies.

MESTA MACHINE CO., Pittsburg, Pa. Circular of rubber mill machinery illustrating a three-roll calender and a 20 x 22 inch x 72 inch rubber grinder and mixer.

HOGGSON & PETTIS MFG. CO., New Haven, Conn. Pamphlet advertising engraved rolls, molds, cutting dies, rollers, gages, etc., for the manufacture of rubber goods.

ELECTRIC CONTROLLER & MFG. CO., Cleveland, Ohio. Folder illustrating uses of lifting magnets in handling structural material, car axles, scrap, track bolts in kegs, railway rails, cylinder castings, etc.

HESS-BRIGHT MFG. CO., Philadelphia, Pa. Sheet illustrating drill press spindle with Hess-Bright thrust ball bearing mounting, showing two forms recommended.

WICKES BROS., Saginaw, Mich. Catalogue of plate working tools, comprising vertical and horizontal bending tools, punches, shears, riveting machines, flanging presses, annealing ovens, etc.

GOLDSCHMIDT THERMIT CO., 90 West St., New York. Pamphlets entitled "Metals and Alloys Free from Carbon Produced by the Thermit Process" and "Butt Welded Wrought Iron and Steel Pipe by the Thermit Process."

ARTHUR C. FRASER & USINA, 170 Broadway, New York. Bulletin of patent and trade-mark law, comprising the new copyright law, the trade-mark situation, an important patent decision and the revocation of patents in Great Britain.

LINK-BELT CO., Philadelphia, Pa. Bulletin No. 84 of "Maximum Silent Chain," illustrating its application to line shafting, machine tools, centrifugal pumps, blowers, air compressors, cylinder boring machines, mine fans, etc.

NATIONAL METAL TRADES ASSOCIATION, Robert Wuest, commissioner, 1005 Fourth National Bank Building, Cincinnati, Ohio. Synopsis of proceedings of the eleventh annual convention held April 14 and 15, 1909, Hotel Astor, New York.

SCHUCHARDT & SCHUTTE, 90 West St., New York. Catalogue of tachometers and tachographs. These instruments indicate on a dial or record on a chart the revolutions and rate of engine and motor shafts, the speed of fly-wheel peripheries, rate of travel of motor cars, etc.

PEERLESS AUTOMATIC MACHINE CO., Cleveland, Ohio. Leaflet illustrating the Peerless automatic multi-spindle screw machine having a capacity of 1 inch round, 15/16 inch octagon, 7/8 inch hexagon, and 11/16 square stock; length of work 5 inches. See July issue of MACHINERY for description.

BURROUGHS ADDING MACHINE CO., Detroit, Mich. Booklet entitled "A Better Day's Work," being a disquisition on accounting from the Stone Age down to the present, with particular reference to the value and use of mechanical adding machines for accurate and rapid work.

AMERICAN ENGINE CO., Bound Brook, N. J. Pamphlet treating of the balancing of reciprocating forces in steam engines, and illustrating the American-Ball angle compound engine, in which the high-pressure cylinder is horizontal and the low-pressure cylinder is vertical.

INTERNATIONAL-ACHESON GRAPHITE CO., Niagara Falls, N. Y. Circular on Acheson graphite, which is said to be the purest graphite made, being entirely a manufactured product. The circular lists electrodes, battery fillers, paint pigment, lead pencils, oil lubricants, ball bearing lubricants, etc.

INTERNATIONAL EXHIBITION OF RAILWAYS AND LAND TRANSPORTATION, Argentine Republic, Buenos Ayres. Circular No. 14, giving the aim and scope of the exhibition, statistics of the products of the Argentine Republic, railway mileage, organization of the exhibition, and names of the executive committee.

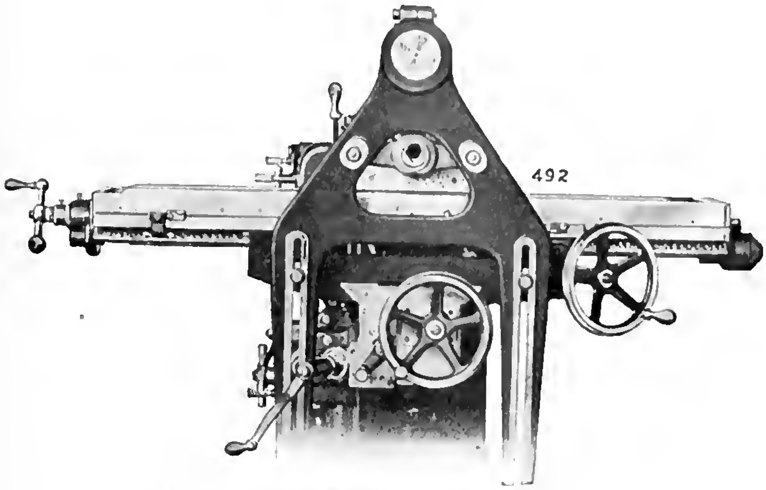
JOYCE-CRIDLAND CO., Dayton, Ohio. Bulletin No. 35 on automatic lever jacks. The construction of the automatic jack is described and illustrated, showing the various operations. It is claimed that these jacks have the power, simple action and closely graduated action obtained with hydraulic jacks without the complication and liability of failure.

MORSE CHAIN CO., Ithaca, N. Y. Bulletin No. 8, illustrating the application of Morse silent-running high-speed chains to line shafts, shapers, gear cutters, boring mills, engine lathes, punches and shears, rack cutting machines, grinding machines, screw machines, boring machines, blowers, bending rolls, milling machines, angle shears, forging machines, bolt threaders, etc.

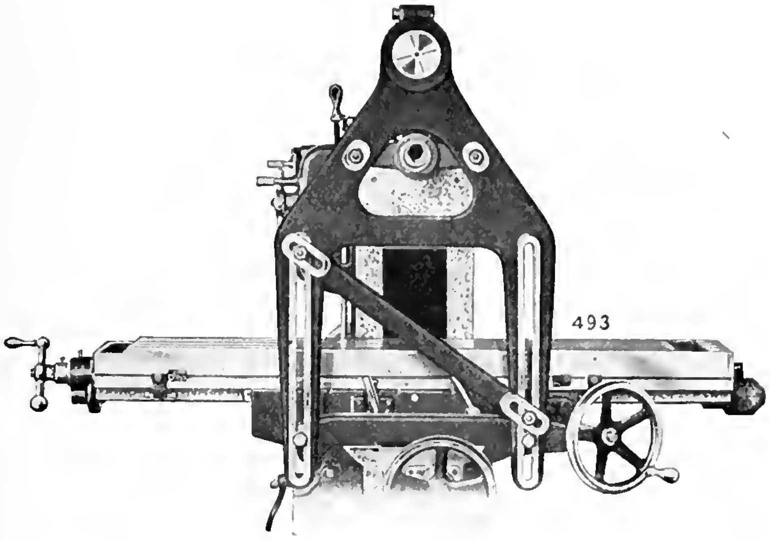
BUILDERS' IRON FOUNDRY, Povidence, R. I. Reprint from the journal of the American Society of Mechanical Engineers of the paper "A New Transmission Dynamometer" by Prof. W. H. Kenerson, Providence, R. I., which was presented before the Washington meeting, May, 1909, of the American Society of Mechanical Engineers. Copies will be sent free to all interested parties.

WESTINGHOUSE ELECTRIC & MFG. CO., Pittsburg, Pa. Booklet entitled "Electric Power for Domestic Purposes," which contains many suggestions for the use of small motors in the home. Among the many labor-saving applications of electric power are the sewing machine, vacuum cleaner, washing machine, ice-cream freezer, meat chopper, ironing machine, silver polisher, dish-washer, and pump.

CINCINNATI HIGH POWER ARBOR SUPPORTS



Usual position of table when doing heavy cutting



Unusual position of table.
Braces provided with an additional truss member

The importance of a rigid support for the outer arbor bearing is evident when we remember that this bearing gets as heavy pressures due to the cut, as does the main bearing of the machine.

The resultant of these pressures is approximately horizontal, in the direction of the table travel.

Our outer bearing support is designed to provide the greatest stiffness against this pressure.

It is made in one piece, truss form, bolted to its supporting member on the knee.

For work requiring the knee in a low position an additional diagonal brace makes it a double truss.

This is the principle on which bridges are designed.

It also applies in correct machine tool design.

WE HAVE APPLIED THIS PRINCIPLE IN EVERY IMPORTANT PART OF OUR HIGH POWER MILLERS.

Get the Catalog.

THE CINCINNATI MILLING MACHINE CO.

MILLING SPECIALISTS

CINCINNATI, OHIO

EUROPEAN AGENTS—Schuchardt & Schutte, Berlin, Vienna, Stockholm, St. Petersburg, Copenhagen and Budapest. Alfred H. Schutte, Cologne, Brussels, Liege, Milan, Paris, Turin, Barcelona and Bilbao. Chas. Churchill & Co., London, Birmingham, Manchester, Newcastle-on-Tyne and Glasgow.
CANADIAN AGENT—H. W. Petrie, Ltd., Toronto, Montreal and Vancouver.
AUSTRALIAN AGENTS—Thos. McPherson & Son, Melbourne.

NEW HAVEN MFG. CO., New Haven, Conn. Catalogue of engine lathes [illegible] to 65-inch swing, in all lengths of bed from 8 to 36 feet; [illegible] capacity 24 inches to 60 inches square and up to 20 [illegible], and slotters of 10 inches stroke. The catalogue [illegible] the construction of the New Haven lathe head-stock [illegible] change gear device, compound rest, double wall apron. [illegible] will be found an interesting catalogue by those concerned with [illegible] of equipment and use.

ELECTRIC CONTROLLER & MFG. CO., Cleveland, Ohio. Pamphlet entitled "Electric Motor Control," consisting of a series of five articles written by Mr. A. C. Eastwood, president of the company. The pamphlet treats of the importance of the controller, theory and operation of rheostatic controllers, series parallel controllers, magnetic switch controllers and dynamic braking. The pamphlet is of general interest to all interested in the matter of electric motor control.

HOGGSON & PETTIS MFG. CO., New Haven, Conn. Catalogue 8C of the Sweetland lathe chucks, which are made in a large variety of sizes and styles. The catalogue lists three and four-jaw combination chucks from 6 inches to 42 inches sizes; three and four-jaw universal chucks in 4 inches to 42 inches sizes. Independent chucks are listed in sizes from 1½ inches to 36 inches, and geared scroll chucks from 2½ to 15 inches. The company also makes special chucks for all sorts of service.

VEEDER MFG. CO., Hartford, Conn. Circular on Veeder die castings, which are made of an alloy having strength of 15,000 pounds per square inch section in tension and 20,000 pounds in compression. These die castings are exact in form and dimensions. It is possible to produce castings within a limit of one-thousandth inch length or less, depending on the size. These castings are largely used on speed counters, cyclometers, coin counting machines, cash registers, typewriters, voting machines, telephones, and other apparatus made in large quantities.

CAREY MACHINERY & SUPPLY CO., 119-121 East Lombard St., Baltimore, Md. General catalogue, sixth edition, of machinery and supplies, comprising Corliss engines, horizontal and vertical steam boilers, hoisting engines, steam water heaters and purifiers, steam separators, boiler fittings, fire pumps, vacuum pumps, steam pumps, centrifugal pumps, geared pumps, engine lathes, pulley lathes, precision lathes, hand and bench lathes, shapers, planers, milling machines, screw machines, grinding machines, polishing lathes, wood-working machinery, wood trimmers, chucks, drills, taps, reamers, machinists' tools, etc.

ROCKWELL FURNACE CO., 46 Cortlandt St., New York. Catalogue illustrating various products of the company, comprising boiler flue heaters, heaters for skin drying molds for foundry purposes, furnaces for annealing gold, silver and bronze strips for coinage purposes, portable annealing, hardening and tempering furnaces, core ovens, apparatus for heating circular saws, semi-steel melting furnaces, rivet furnaces for structural work, annealing ovens, melting furnaces for brass and other alloys, regenerative furnaces for high temperatures, etc.

LONG & ALLSTATTER CO., Hamilton, Ohio. Catalogue No. 21 of punching and shearing machinery, comprising a great variety of sizes and styles for bridge, structural steel, railway car and other shops requiring machinery for punching or shearing of materials. The machines listed and illustrated comprise angle iron shears, bar iron shears, beam punching machines, bending and forming machines, boiler punches, cross-cut shears, deep throated machines, disk notching machines, disk punching machines, drop hammers, gate shears, horizontal punches, lever punches, lever shears, etc.

KEUFFEL & ESSER CO., Hoboken, N. J. Booklet describing the origin, growth and present scope of the Keuffel & Esser Co., manufacturer of drawing materials, mathematical instruments, surveying instruments, measuring tapes, etc. The booklet contains a reproduction of the first monthly rent receipt for $5.50, given in 1867, which is an indication of the humble origin of the present great business which now employs 900 people. Interspersed throughout the booklet are various illustrations of the factory buildings and the departments devoted to the manufacture of drawing materials, mathematical instruments, surveying instruments, and measuring instruments. Fourteen buildings are comprised in the plant, covering 237,000 square feet of floor space.

J. H. WILLIAMS & CO., 150 Hamilton Ave. and Richards St., Brooklyn, New York. Catalogue of iron, steel, copper, bronze and aluminum drop forgings. The catalogue has a beautiful cover showing an open end drop forged wrench in striking relief on a black cover. The catalogue lists a full line of wrenches, comprising single head and double head engineers' wrenches, single head and double head set-screw wrenches, box wrenches, double head tool post wrenches, straight handle and track wrenches, pin spanners, construction wrenches, etc., for all classes of users; drop forged lathe dogs, general service clamps, crank handles, tool-post fittings, thumb nuts, crane hooks, wire sockets, yoke ends, etc. The company's line of Vulcan drop forged chain pipe wrenches, special forgings for automobile work, etc., are also listed.

AMERICAN EXPOSITION, Berlin, 1910. Catalogue listing names of members of American advisory committee, German advisory committee and prominent business men interested in the exposition. The exposition is intended to show Europeans the excellence of American manufactured products and to strengthen existing relations between America and Germany. The management announces that the exposition will be unique in that the price of space per square foot will include the usual incidental expenses; it will cover suitable foundations for machinery, carpets, water heat, light, and janitor service. The exhibitors will also be protected from loss by fire or theft by insurance to the extent of $25 per square foot. The rental including all extras is to be $4 per square foot. Exhibits will be held in the Exposition Palace, erected in 1907 at a cost of $1,500,000. It consists of two connected buildings of stone and steel construction and has a combined floor space of approximately 110,000 square feet.

JONES & LAMSON MACHINE CO., Springfield, Vt. Treatise entitled "Machine Building for Profit, and the Flat Turret Lathe." 252 pages, 6 x 9 inches. This publication touches on the economics of construction, principles of lathe design, turret lathe design, observation of running machines, views from various points, importance of adaptability, and contains extracts from "The Evolution of the Machine Shop," a work published by Mr. Hartness some years ago. The Hartness flat turret lathe is described in detail, its parts and the work produced being illustrated. The remarkable adaptability of the Hartness flat turret lathe to all classes of machine work is well illustrated by numerous halftone engravings. Diagrams follow, illustrating the operations on various classes of work and giving the dimensions and the time required. The treatise is unique and should claim the interested attention of every machine shop manager and foreman concerned with the economical production of manufactured products. A number of interesting hints will be found on machine shop management.

MANUFACTURERS NOTES

GOODELL-PRATT CO., Greenfield, Mass., has a new foundry in construction by the Aberthaw Construction Co., of Boston.

HOGGSON & PETTIS MFG. CO., New Haven, Conn., has moved its New York office from 107 Liberty St., to 103 Chambers St.

LINK-BELT CO., Philadelphia, Pa., announces that the Renold "silent" machinery driving belt, manufactured and sold by it, will hereafter be known as the "Maximum Silent Chain" (Renold type).

ROCKFORD MACHINE & SHUTTLE CO., Rockford, Ill., manufacturer of drill presses, milling machines, bench lathes, etc., has moved into its new factory, the improved facilities of which will largely increase its output.

AMERICAN PULLEY CO., 29th and Bristol Sts., Philadelphia, Pa., opened a store July 1 at 139 South Clinton St., Chicago, Ill., where a complete assortment of wrought steel belt and sash pulleys will be kept.

B. F. STURTEVANT CO., Hyde Park, Mass., reports that its fan and blower business has so increased that it was necessary to enlarge its plant to handle the increased business, and it intends to add still further to the plant next Spring.

RAY D. LILLIBRIDGE, technical publicity manager, has removed his office to 100 Broadway, eleventh floor, and has taken into partnership William L. Rickard. The business will be continued as heretofore under the name Ray D. Lillibridge.

THE NORTHWESTERN METAL MFG. CO., Minneapolis, Minn., has been appointed exclusive sales agent for the "plunger throttle plastic packing," which is a new packing material for locomotive throttle valve stems and similar purposes.

WHITMAN & BARNES MFG. CO., Akron, Ohio, has consolidated its offices at Akron, which is the headquarters of the company. Heretofore its business has been handled from several different points, and the change is made to give the trade better service.

CROCKER-WHEELER CO., Ampere, N. J., reports several orders received recently for large alternating current generators, one of which was for a 1,000 KVA, three-phase, 6,600 volt generator, for the De Laval Steam Turbine Co., Trenton, N. J.

CARLYLE JOHNSON MACHINE CO., formerly of Hartford, Conn., removed its business July 1 to Manchester, Conn., nine miles east of Hartford on the Willimantic division of the N. Y. N. H. & H. R. R., where its manufacturing facilities are much improved.

WELLS BROS. CO., Greenfield, Mass., invites all persons interested in the manufacture and use of screw cutting tools and machinery to visit its factory. It is suggested that vacationists make up their itineraries to include a visit to Greenfield and the company's works.

KEARNEY & TRECKER CO., Milwaukee, Wis., is building a new power plant in which an Allis-Chalmers Corliss engine is being installed. The company is otherwise making preparations to extend its machine equipment and plant generally to take care of the demands for the Milwaukee milling machines which are sold out far in advance.

BROWN & SHARPE MFG. CO., Providence, R. I., announces that its works will be closed from August 6 to 23 for the annual vacation and repairs. During the vacation the office will be open as usual and orders for machine tools, machinists' tools, and measuring tools will receive the same attention as at other periods of the year.

WESTERN ELECTRIC CO., 463 West St., New York, reports that for the first half of its fiscal year ending May 31 its business is running at the rate of approximately $46,000,000 yearly as compared with $33,000,000 for the fiscal year of 1908, and $53,000,000 for the fiscal year of 1907. Business thus has increased 40 per cent over 1908, and is 87 per cent of the 1907 record.

CROCKER-WHEELER CO., Ampere, N. J., directors held a meeting in July in the New York office of the company. Dr. Schuyler Skaats Wheeler was continued as president, and the other officers elected were: Gano Dunn, vice-president; A. S. Doremus, second vice-president; Gano Dunn, engineer; Rodman Gilder, secretary; W. L. Brownell, treasurer; G. W. Bower, assistant treasurer.

LINCOLN MOTOR WORKS CO., Cleveland, Ohio, has changed its corporate name to the Reliance Engineering & Electric Co., instead of the Reliance Engineering Co., as was erroneously stated in the July number. The management remains the same and the company will continue to manufacture the Lincoln variable speed motors and complete line of constant speed motors.

BROWN & SHARPE MFG. CO., Providence, R. I., is building a new power house, which will be a consolidation of the five separate power plants now in the works. The new power plant will have a capacity of about 3,000 horse-power, and will comprise up-to-date equipment such as Stirling water-tube boiler, Taylor gravity under-feed stokers, gas engines and producers, etc.

FOOS GAS ENGINE CO., Springfield, Ohio, reports that the United States Government recently placed an order for six Foos vertical gas engines to be used for the operation of locks on the Ohio River. The locks are worked by air, the engines being required for driving the air compressors, and are 100 horse-power each. The engines specified are the regular Foos vertical three-cylinder single-acting type, using natural gas as fuel.

CINCINNATI IRON & STEEL CO., Cincinnati, Ohio, has installed a 30-ton electric Case crane with the Cincinnati Traction Co., and has received an order for a 10-ton Case electric crane for the Nashville Railway & Light Co., Nashville, Tenn. The company also has an order for a 180,000 pound shear to cut six-inch square metal for the Goldberger Iron Co., Cincinnati, Ohio. The shear is being built by the Mesta Machine Co., Pittsburg, Pa.

INTERNATIONAL-ACHESON GRAPHITE CO., Niagara Falls, N. Y., received on the afternoon of July 2 a telegraphic order calling for a shipment by express of a carload of electrodes 8 x 48 inches. The shipment was immediately loaded on an express car, and at 5:30 P. M. the car was pulled out of the switch and delivered to the Michigan Central Railway, and early on Saturday, July 3, the electrodes were delivered to the consignee in Chicago.

WESTINGHOUSE MACHINE CO., Pittsburg, Pa., has made a contract with the Public Service Corporation of New Jersey for four 13 x 12 inch three-cylinder Westinghouse gas engines direct connected to Root positive blowers for their Hoboken and Passaic gas plants for the purpose of boosting the gas pressure in the mains. The engines are of the vertical type and develop 90 horse-power each, and use illuminating gas for fuel.

CUTLER-HAMMER MFG. CO. has purchased the plant, business and patents of the J. L. Schureman Co., of Chicago. The manufacture of the Schureman controller apparatus will be continued and Mr. S. M. McFedries, general manager of the Schureman Co., will remain in active charge of the manufacture of the Schureman apparatus. Mr. J. L. Schureman retires from business. Until further notice, customers of the Schureman Co. should direct orders or inquiries to the old address, J. L. Schureman Co., 70 West Jackson Boulevard, Chicago, Ill.

MCGRAW-HILL BOOK CO., 239 West 39th St., New York, is a consolidation effected July 1 of the book departments of the McGraw Publishing Co. and the Hill Publishing Co. The new company takes over the book departments of both houses with a list of about 250 titles, comprising industrial and college text-books and covering all lines of engineering. It will continue the retail, importing and jobbing business of the two houses. The officers are: President, J. A. Hill; vice-president, James H. McGraw; secretary, Edward Caldwell; treasurer, Martin Foss.

AMERICAN AIR COMPRESSOR WORKS, 26 Cortlandt St., New York, has engaged Mr. August Kittleberger, who for the past fifteen years has been associated with the Clayton Air Compressor Co., as superintendent of the American Air Compressor Works plant in Brooklyn, New York. The company regard the engagement of Mr. Kittleberger as an important addition to its manufacturing department, and with the

GENUINE
STUBS ENGLISH
REAMERS OR BROACHES

We have just imported an exceptionally large quantity of these Broaches in all sizes from No. 65 Stubs Drill Gauge to 21-64 in. diameter and are ready to make immediate shipment.

Send us your specifications and we will quote.

HAMMACHER, SCHLEMMER & CO.

Hardware, Tools and Supplies
NEW YORK, SINCE 1848

4th Ave. and 13th St.

CONTENTS FOR AUGUST

revival of trade conditions and increased business resulting therefrom, looks for an enhanced popularity of the American Fairhurst air compressors and vacuum pumps.

Pratt & Whitney Co., Hartford, Conn., has been awarded a contract for equipping a small arms factory in Australia for the Australian government. The contract was obtained in competition with British manufacturers, the Pratt & Whitney bid being $340,000 as against $500,000 by one British concern and the time of delivery one year as against three years required by a British concern. Minister of Defense Joseph Cook would willingly have been influenced to give the work to a British concern, but he was obliged to accept the American tender, as conditions all around were much better.

Builders' Iron Foundry, Providence, R. I., is making and marketing the Kenerson transmission dynamometer invented and patented by Prof. W. H. Kenerson, and illustrated and described by him in a paper read before the Washington meeting of the American Society of Mechanical Engineers, May, 1909. (See Machinery, June, 1909.) This dynamometer is a device which indicates by means of a pressure gage the amount of power transmitted through it. The dial on the gage is graduated to indicate H. P. per 100 revolutions per minute of the shaft to which the dynamometer is attached. In all probability it is the most sensitive and practical dynamometer designed for measuring transmitted power yet devised.

Technical Index, a comprehensive record of current technical literature published in Belgium, announces that hereafter it will be represented in the United States by the George H. Gibson Co., *Tribune* Building, New York City. The *Technical Index* appears monthly and gives a systematic descriptive record of original articles appearing in over 200 engineering and technical journals and reviews, also indexing the proceedings of technical societies and technical books issued in all countries. The method of indexing covers the name of the author, the title of the article in full, an explanatory note stating the contents of the article, the name and date of the publication in which the article appeared and the length of the article.

New York Leather Belting Co., 51 Beekman St., New York, is carrying on a campaign for the standardization of leather belting, and honesty of manufacture. In the manufacture of its "Phœnix" belting, a strip of leather about 30 inches wide and 4 feet long only is used from one hide, the remainder being rejected for other purposes. Care is taken to cut this section so as to get the best results. For belts 8 inches wide or over, absolute centers are used, this part being that immediately over the backbone. Narrow double belts, 2 to 4 inches wide, are made up from the section immediately adjoining, and the remaining section is devoted to double belts 4 to 6 inches wide. This division of material makes belts that wear evenly and stretch uniformly. Illustrated literature shows the approved and condemned methods of cutting hides into belting.

MISCELLANEOUS

Advertisements in this column, 25 cents a line, ten words to a line. The money should be sent with the order. Answers addressed to our care will be forwarded. Original letters of recommendation should not be enclosed to unknown correspondents.

DRAFTSMEN cannot know too much about shop practice—many of them know too little and are handicapped thereby. Machinery's Shop Operation Sheets can help greatly. They are direct, definite and practical. The set now comprises 108 distinct operations. Write for "Self-Education." Machinery, 49-55 Lafayette St., New York City.

DRAFTSMEN AND MACHINISTS.—American and foreign patents secured promptly; reliable researches made on patentability or validity; twenty years' practice; registered; responsible references. EDWIN GUTHRIE, Corcoran Building, Washington, D. C.

DRAFTSMAN.—Experienced mechanical draftsman. Apply MARKS & WOODWELL, Consulting Engineers, 103 Park Ave., New York.

DRAWINGS, TRACINGS, ETC., MADE.—Prices reasonable. Box 1302, Orange, Mass.

FORMULAS AND TABLES FOR SHOP AND DRAFTING ROOM is No. 35 in Machinery's Reference Series, and for practical use in mechanical work promises to be the most widely useful book published in years. Price 25 cents. Address Machinery, 49-55 Lafayette St., New York City.

GOOD AUTOMOBILE AND TOOL DRAFTSMAN wanted. No others need apply. Ask for Mr. Allen, Chief Draftsman, THE TOLEDO MOTOR CO., Toledo, Ohio.

Have you any intricate mechanical problems to solve? If you have let me solve them for you at a saving of money, time and trouble. Developing inventions to a practical and commercial basis my specialty. BENJAMIN BROWNSTEIN, Mechanical Engineer and Expert Designer, Gundling Bldg., Trenton, N. J.

LATHE, PLANER AND BORING MILL HANDS WANTED for night and day shift. No labor troubles. Increasing force. Applicants must state wages desired, past experience and if employed at present, to receive further consideration. Apply to INGERSOLL-RAND CO., Painted Post, New York.

MECHANICAL DRAWING.—An Eastern College will have a position open about September 1st for a technical graduate, as Junior Instructor of Mechanical Drawing. Applicant must state age, education, drawing office experience with references and salary expected. Address Box 221, care Machinery, 49 Lafayette St., New York.

PATENTS.—H. W. T. Jenner, patent attorney and mechanical expert, 608 F Street, Washington, D. C. Established 1883. I make an investigation and report if a patent can be had and the exact cost. Send for full information. Trade-marks registered.

TECHNICAL GRADUATE, progressive, practical, age 28, married, familiar with design and operation of electrical and mechanical power distributions, electric motor applications and electric lighting installations and who has done some work in power plant and industrial building design, now in engineering department of large industrial corporation, can swing a bigger job and wants one. Draughting-room, office and construction experience. Capable of developing labor-saving methods and devices. Good executive and correspondent. Salary $1,800, employer to pay moving expenses from near New York to new location. Address Box 217, care Machineay, 49 Lafayette St., New York.

USE OF FORMULAS and of Tables of Sines and Tangents, without a knowledge of Algebra or Trigonometry, is made easy to you by SHOP ARITHMETIC FOR THE MACHINIST, which is No. 18 in Machinery's Reference Series fully described in a pamphlet sent free on request. Machinery, 49-55 Lafayette St., New York City.

WANTED.—Agents in every shop to sell Calipers. Liberal pay. Address E. G. SMITH CO., Columbia, Pa.

WANTED.—Agents, machinists, toolmakers, draftsmen, attention! New and revised edition Saunders' "Handy Book of Practical Mechanics" now ready. Machinists say "Can't get along without it." Best in the land. Shop kinks, secrets from note books, rules, formulas, most complete reference tables, tough problems figured by simple arithmetic. Valuable information condensed in pocket size. Price postpaid $1.00 cloth; $1.25 leather with flap. Agents make big profits. Send for list of books. E. H. SAUNDERS, 216 Purchase St., Boston, Mass.

WANTED.—A firm long established, employing 2,000 men, desires a thoroughly practical and efficient general machine shop foreman. Must be capable of satisfactorily handling sub-foremen and able to supervise the output of 400 machinists. Unless at present employed, will not be considered. Address Box 220, care Machinery, 49 Lafayette St., New York.

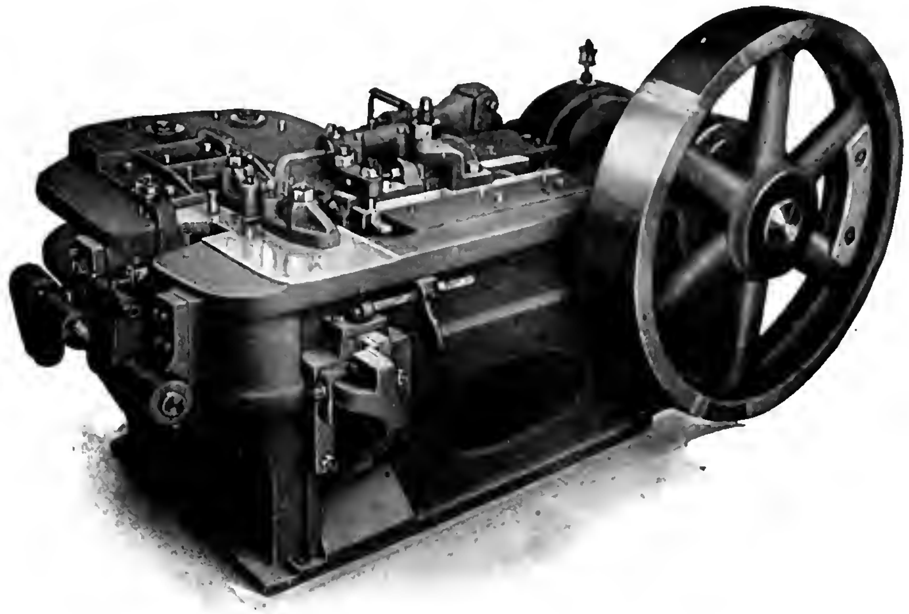
WANTED.—MACHINIST FOREMAN to do everything necessary to get out machines in good interchangeable condition. Must have experience. Write fully. Address Box 222, care Machineay, 49 Lafayette St., New York.

WANTED.—SUPERINTENDENT, an American, 30 to 45 years of age; good mechanic, good executive, systematic, progressive and aggressive; up on duplicate manufacturing with not less than three years' experience as superintendent of a gas engine factory; must have earned at least $1,800 per annum and saved something; to such a person we offer superintendency of our modern gas engine works, backed by all of the money, tools, appliances and material necessary to turn out 3,000 engines per year at least possible expense; time is an important consideration; give full and complete history and be prepared to pay us a visit, if apparently satisfactory. WITTE IRON WORKS CO., Kansas City, Mo.

WE CAN DESIGN YOUR COMPLICATED TOOLS, Drawings, tracings, blue prints. We also make tools, dies, jigs, models, etc. Experimental work. Inventions perfected. Send sample or blue print for estimate. Designers, draftsmen and toolmakers. BEACON TOOL WORKS, 146 Ward St., Naugatuck, Conn.

WE MANUFACTURE SPECIALTIES.—Let us figure on your metal stampings, punch press dies, tools, special machinery, etc. We guarantee to save you money. Address THE PENNSYLVANIA SPECIALTY MANUFACTURING CO., Cochranton, Pa.

SAVE MONEY ON YOUR RIVETS



Ajax Standard Rivet and Bolt Heading Machines

are not only exceedingly powerful, built from best materials, with extra large bearing and wearing areas, but each machine is equipped with the Ajax Absolute and Automatic Side Arm Relief to the Gripping Die Mechanism which prevents the destruction of the dies should the rivet be accidentally caught on the die faces.

This is one of the Ajax features that cuts down production costs—when such an accident occurs in our machines the relief mechanism acts instantly and the dies become dead until the rivet is dislodged.

We build these machines in five sizes, belt or motor driven as desired, and will send special circular on request.

The New High Speed Steel

NOVO SUPERIOR

THE LATEST INVENTION IN METALLURGY

Is now in stock in our Warehouses in all current sizes, flats, squares and rounds, annealed and unannealed.

It is claimed, for **NOVO SUPERIOR STEEL** that according to conditions, the speed can be increased over the present high speed steels, and sometimes 25, 50 and even 100 per cent. more speed has been obtained and the cutting edge has retained its sharpness from **four to six times longer** than on other high speed steels.

It cuts **harder material** than has heretofore been considered possible. Namely, steel castings, with vitrified sand blowholes, skidded tires, exceptionally hard and partly chilled cast iron.

It is **tougher than other high speed steel.** Therefore particularly adapted for tools that must stand a severe blow or pressure.

It is invaluable for automatic screw machine work where a **very fine cutting** edge is necessary.

Novo Superior steel is suitable for milling cutters, formed cutters, gear cutters, reamers, etc. Will wear from four to six times longer than other steels.

Novo Superior steel hardens in oil or water.

Send us a trial order. We guarantee results.

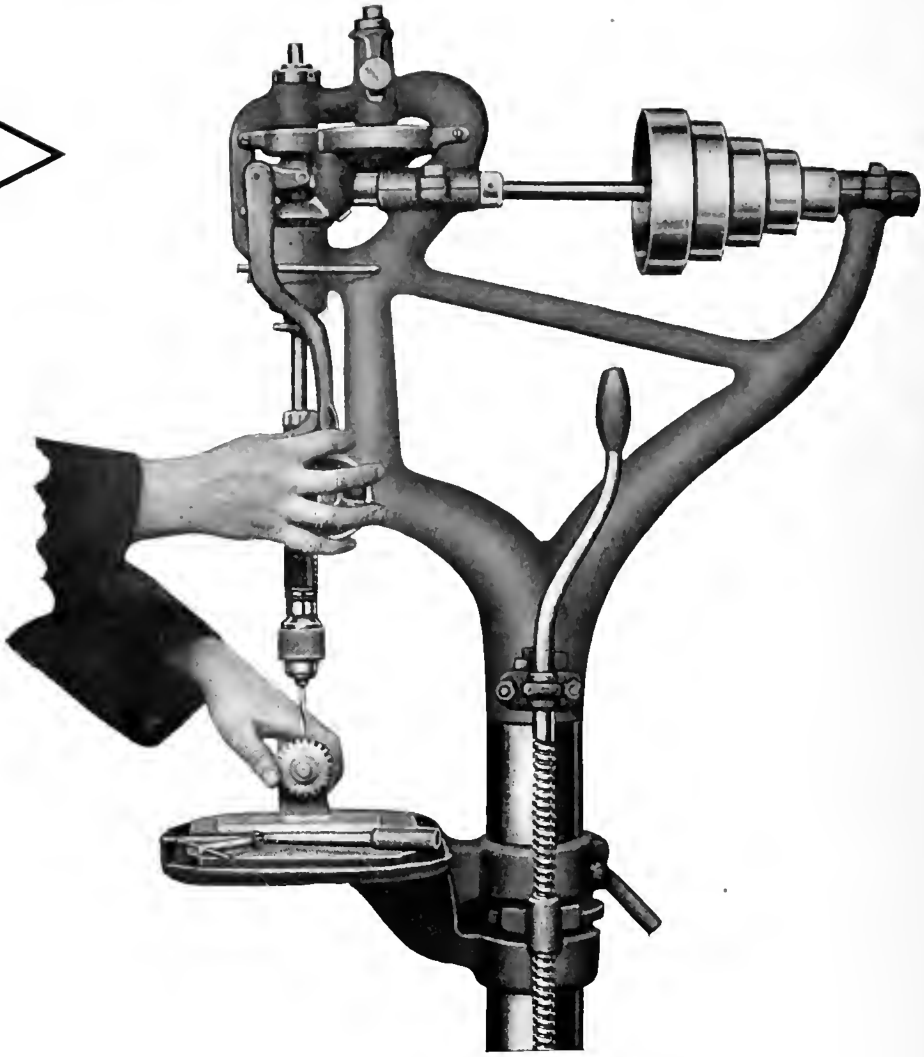
THE
ROCKFORD
DRILLING MACHINE Co
ROCKFORD
ILL., U.S.A.

The simplest and most easily controlled device of its kind in the market.



The Rockford Patented Geared Tapper

This new Tapper is not an attachment but a part of the machine. It is always in place and ready for work; though when the tool is required for straight drilling only, the tapper can be lifted out of mesh in a few seconds' time, and as quickly replaced. It is well designed, very strong, has few parts and nothing to get out of order. The piece to be tapped is held in the left hand, while the right hand controls the forward and reverse. The thumb and first finger control the operating lever, the forward movement of which throws the tap into the forward speed, and the backward movement gives instantaneous 2 to 1 reverse. One of the conveniences you cannot afford to be without. Efficient, durable and exceedingly moderate in price.

Write for the details.

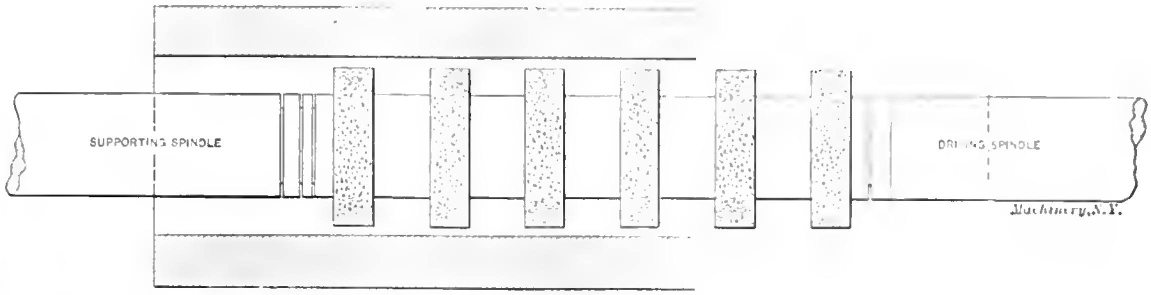
Grind your Bushings—Don't Bore Them!

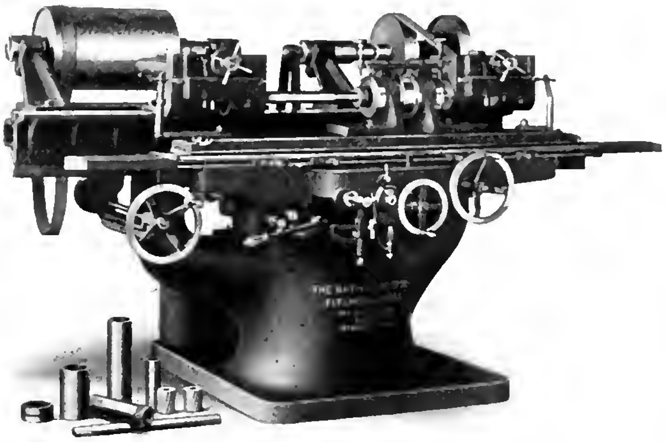
Use the Bath Internal Grinder with supported spindle carrying one to six grinding wheels. There's money in our method.



Cast iron bushing, 10¼" long, hole 3" diameter, internally ground on the Bath Grinder. The spindle is rigidly supported and has six wheels in simultaneous operation instead of one wheel—the usual method employed by the single head grinder.

The Bath Double-Headed Internal Grinder

marks a new departure in rapid hole grinding that is quite as remarkable in its own way as the perfection of high speed steel for its purpose. A number of wheels can be used, as shown above, with the supported spindle, or two independent spindles can be simultaneously employed on two pieces of work, or two diameters on the same piece may be accurately and rapidly ground. It is the most rigid machine of its class and adapted for a wide variety of internal grinding. By a special form of construction all vibration is absorbed and there are other advantages well worth your investigation.



Keep an eye on our announcements—they will give you more *practical* information on the subject of internal grinding than could be obtained from a small library of technical books.

BETTER INVESTIGATE **16-INCH CINCINNATI LATHES**

before purchasing to satisfy yourself of their wearing qualities and secret of superiority. All standard threads cut without removing or duplicating a gear. Furnish another **All Geared Feed Device** with an unlimited range of threads and feeds. Write for details.

THE CINCINNATI LATHE & TOOL CO.
CINCINNATI, OHIO, U. S. A.

ROBBINS ENGINE LATHES

Our 13, 15, 18 and 20" Engine Lathes are of massive and powerful design, are strongly back geared and furnished with compound rest and regular attachments. The range of feeds and speeds is ample, cone carries extra wide belt and operating convenience is a feature. We also make Pattern Makers' Lathes, 16, 20 and 24" sizes. *Send for circulars.*

THE ROBBINS MACHINE CO.
149 Lagrange Street Worcester, Mass., U. S. A.

THIS MACHINE will stand the highest speed and coarsest feed that can be applied to a milling machine for the economical production of articles of brass or cast iron. The machine has been tested for a spindle speed of 620 revolutions on brass, and was then feeding 75 inches per minute. When intended for heavy milling in iron, this machine is made with back gears.

THE DRIVING CONSTRUCTION is very powerful. The belt is easily tightened by a device which keeps equal tension of the belt in any position of the spindle.

THE SPINDLE is of crucible steel and runs in phosphor bronze boxes. Both boxes and spindle are provided with means to compensate for wear.

T-SLOTS can be made in table to specifications.

THE FEED PARTS are very strong, and ample facilities are provided for oiling. The feed is operated by a lever on the side of the slide and has automatic return of 3 to 1 for brass and 5 to 1 for cast iron. It is stopped automatically at each operation of the table. A light push on a pawl on the side of the slide will start the feed. There are six changes of feed in geometric progression to suit the conditions of the work.

THE COUNTERSHAFT has two drive pulleys and two sets of tight and loose pulleys, allowing two cutting speeds to the countershaft.

(Patented)

A few words, but to the point!

200 to 400 per cent. more holes can be produced in a given time with the Ball Bearing Drilling Machine than with any other drill press using same amount of power.

Hundreds of spindles—various makes—replaced by the Henry & Wright machines.

There are several good reasons—glad to explain.

THE HENRY & WRIGHT MFG. CO.
HARTFORD, CONN., U. S. A.

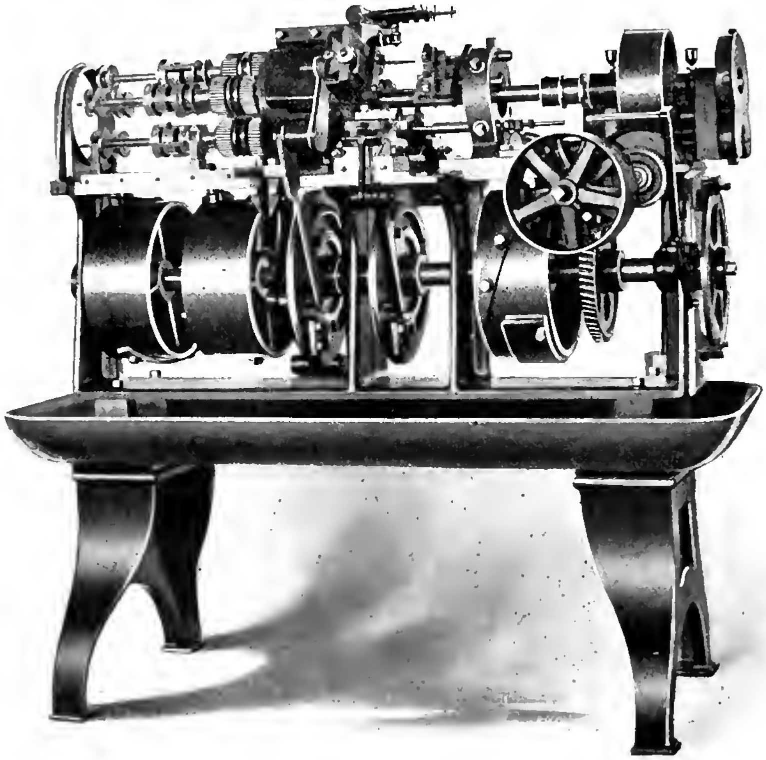
The Universal Multiple Spindle Automatic Screw Machine



For Screws and Screw Work of every description.

Send us your specifications for steel, iron or brass screws—any shape or size—and let us estimate the cost produced on the Universal.

Our machines are powerfully driven by one straight belt from the countershaft; have a gear driven threading mechanism which permits different speeds for various sizes and kinds of stock, and perform ten operations in the same time required by the ordinary machine to complete the longest single operation.

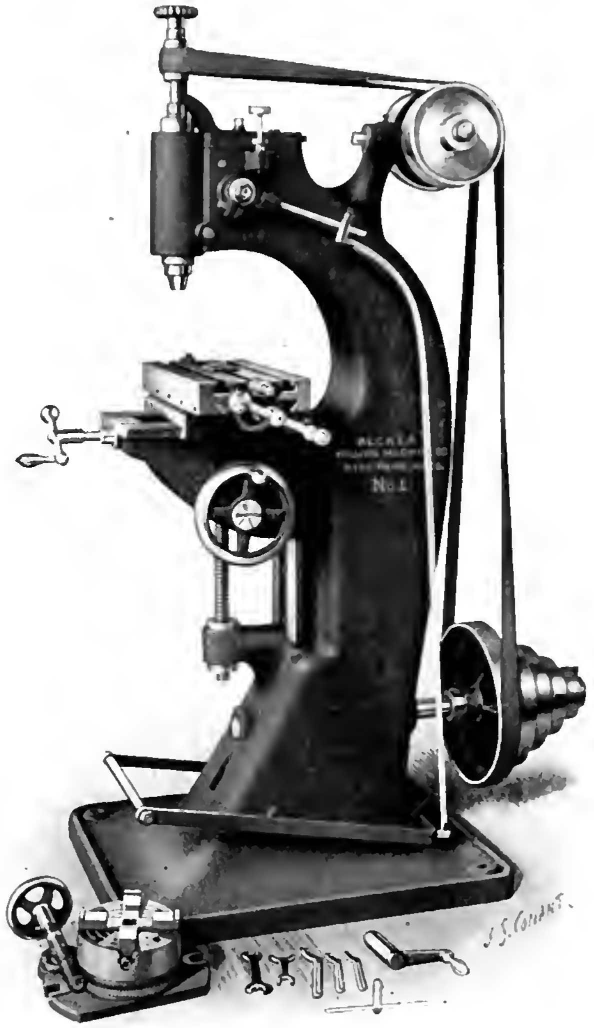
The height of perfection and economy in screw work.

THE UNIVERSAL MACHINE SCREW COMPANY, **Hartford, Conn.**

DOMESTIC AGENTS: Prentiss Tool & Supply Co., New York, Boston, Buffalo. Motch & Merryweather Machinery Co., Cleveland, Detroit, Cincinnati. Brown & Zortman Machinery Co., Pittsburg, Pa. Marshall & Huschart Machinery Co., Chicago, Ill.

How about your Light Milling?

Have you looked into costs on this class of work?



The No. 1 Becker Milling Machine

is a great money saver on the lighter grades of milling.

It is adapted for either wood or metal, handles the most delicate work, is especially adapted for such service as experimental work, model making, jewelers' dies, engravers' stamps, etc., and can also be advantageously used as a sensitive drill press.

The spindle is controlled by a foot lever, has a movement of one and one-half inches, an adjustable auxiliary bearing to relieve it from belt strain and may be speeded, to suit the work to be done, from 2,000 to 10,000 revolutions per minute.

The table on this machine is fitted with jaws made to suit and which are with or without screw adjustment. Four jaw chuck or circular table is provided for the rotary attachment, or both in combination.

Full description furnished on request.

The Output of the Reynolds Automatic Screw Driver is only limited by the ability of the operator to handle the work.

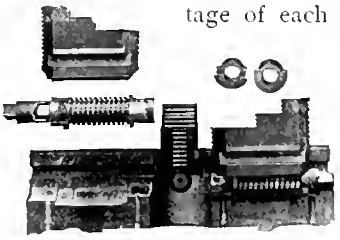
This novel machine has ample power to drive screws anywhere they can be driven by other means, and in many cases they can be set without boring.

Its simplicity makes skilled labor unnecessary, there is no danger of marring screw heads or work, it is strong, efficient, durable and will actually drive machine screws faster than you could drive nails.

Ask us for full description.

Reynolds Machinery Co.
MOLINE, ILL.

The Cincinnati Four Jaw Independent Chuck



Not only a thoroughly A-1 chuck in point of design, material and construction, but has the unique advantage of each screw being mounted in hardened steel bushings. Outwears other chucks, keeps its alignment, and is the most convenient and efficient Independent Chuck made.

Cleveland, Ohio
NEW YORK OFFICE: 126 Liberty Street.

Duplex Independent End Buffing Lathe

This new machine has all the good points of the ordinary double end buffing lathe without any of the well known faults, and is a boon to the trade employing buffing or polishing machines for any purpose. It is very compact in design, strong and simple. The polishing wheels can be independently thrown into or out of engagement by means of simple friction clutches which are operated by conveniently placed hand levers. Bearings and all working parts are protected by dust proof casings. Ends of spindles are detachable, and can be furnished in any length or form, making it possible to use the same machine for all classes of work.

Ask for full particulars. Machine can be run at 3500 R.P.M. and upwards.

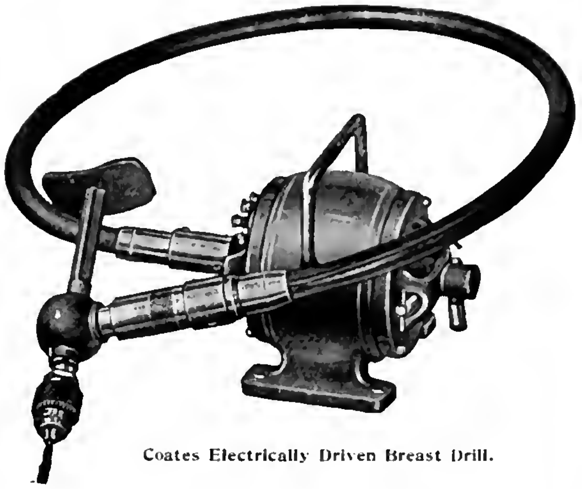
Price 25 cents. *Write for pamphlet.*

THE INDUSTRIAL PRESS
49-55 Lafayette Street, NEW YORK

"I got the job done and a half day off— me for a Coates Flexible every time!"

No doubt about it, the **COATES FLEXIBLE SHAFT** is one of the most adaptable tools you can put in the shop and one that will save more time and labor than is easily calculated. The motor can be put any old place, the shop boys can operate it, and for finishing drop forged dies, grinding wrinkles out of metal patterns, cleaning cast iron gear work and drilling in odd corners there's not a tool to equal—let alone surpass it. One outfit serves for grinding, drilling and polishing, and with the patent Multiplier you can increase the regular speed of the shaft 8½ times. Anything in this for you?



Coates Electrically Driven Breast Drill.

COATES

Bulletin 21 for Details.

COATES CLIPPER MFG. CO., Worcester, Mass.

Some of the Exclusive Features of the Schellenbach-Hunt Universal Micrometer and Surface Gage are:

Hardened Bar and Base.

Parts subject to wear that will affect the accuracy of the instrument, hardened and adjustable.

Measures 7 inches horizontally in thousandths.

Measures 8 inches vertically in thousandths

Will scribe lines in thousandths to the full range of the instrument.

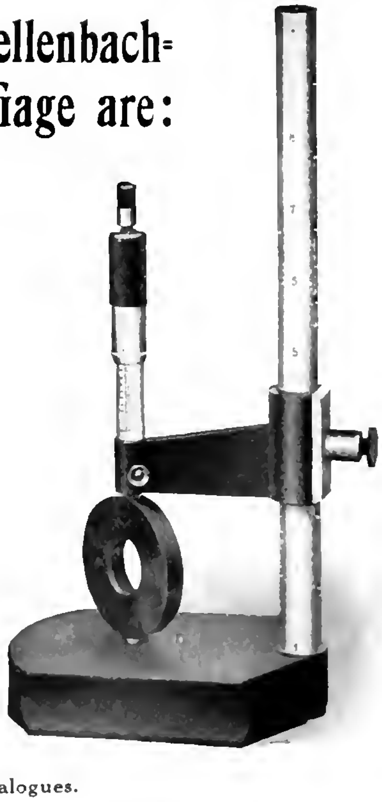
It can be set quicker and covers a greater range than six ordinary micrometers and will measure in positions where the regular micrometers cannot be used at all.

The sliding head is accurately positioned and locked to the bar at the same time. No extra screws or gibs required.

Jig and die work can be laid out in a fraction of the time required by the old methods.

The Instrument is warranted to be within the limits of accuracy of the *best* micrometers made, and is made to *stay* so

We will send for trial one of these tools to any responsible concern upon the above guarantee. If it fails to meet the above conditions, we pay the carriage both ways. We can't say more.



Now Mr. Shop Manager or Mr. Tool Room Man if you are interested in time saving, it is your move. Our circular tells about it. Ask your nearest dealer or write us direct.

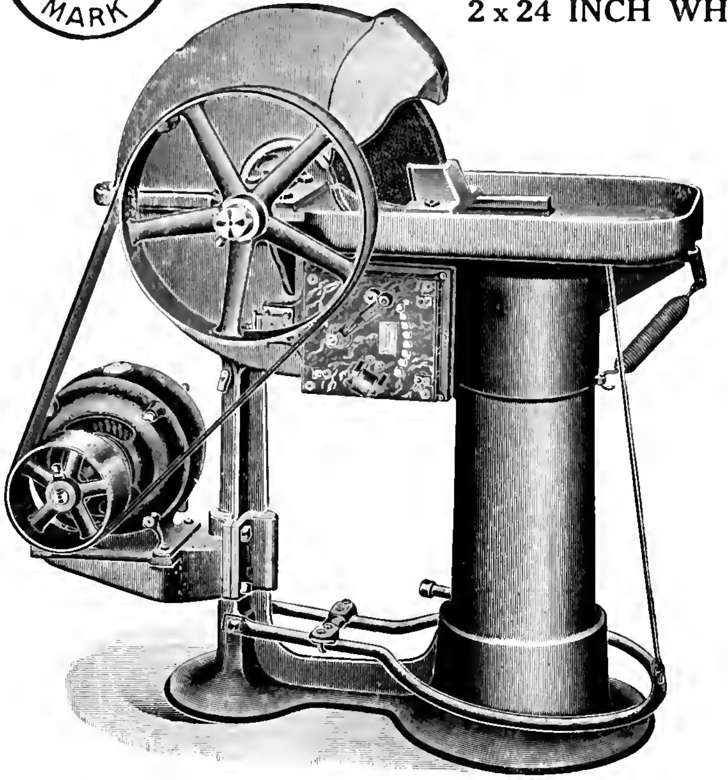
Water Emery Grinder

2 x 24 INCH WHEEL



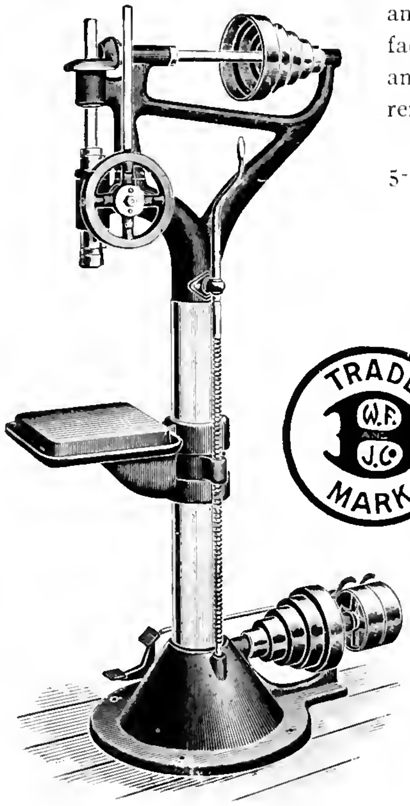
NO VALVES
NO PUMPS
Always ready for use

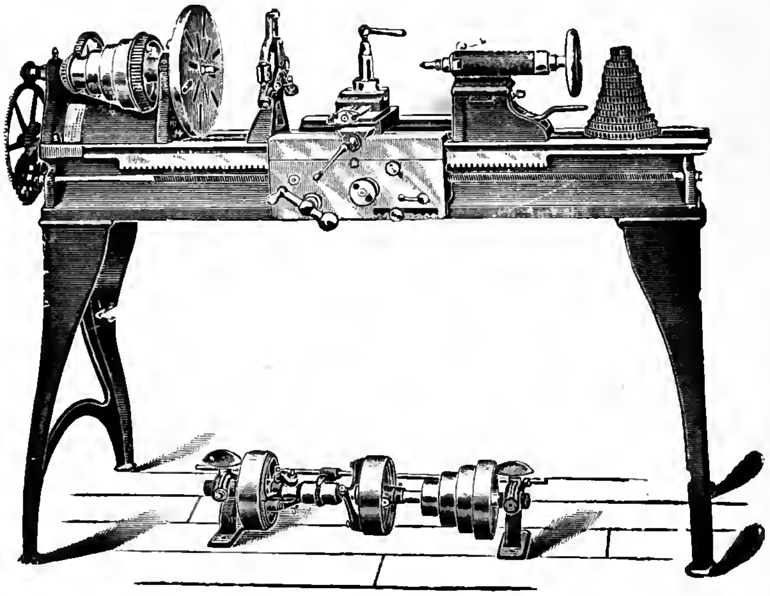
THIS grinder is most efficient in use, simplest in contsruction, and size of wheel best adapted for tool works; a wheel of less diameter or wider face gives all kinds of trouble; we know by experience and our experience saves the customer money.

Can furnish with
Electric or Countershaft Drive
For electric drive we use a 2-H.P. motor
SEND FOR CATALOGUE

These two tools make a pretty good start for a small machine shop. The drill is our No. 7—15-inch Swing Drill, a stiff tool for its size and well adapted for light medium work; just note the combined lever and wheel feed! The lathe is our No. 13 Lathe, swinging 13 inches over the face plate, and made in beds of 5 to 10 feet long; has automatic cross-feed and compound rest; very stiff tool carriage and changes of feed without removing a gear. We can furnish Lathe with foot power if wanted.

A good deal less than $200 will buy this Drill and the Lathe with 5-foot bed. Write for catalogue.

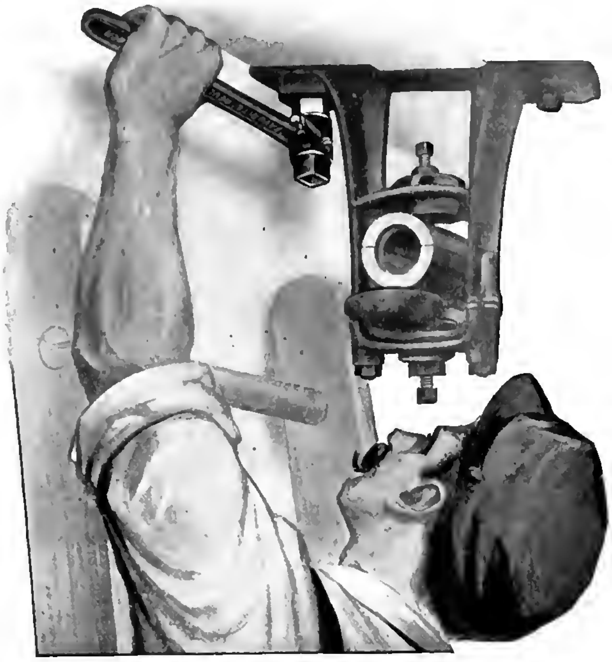


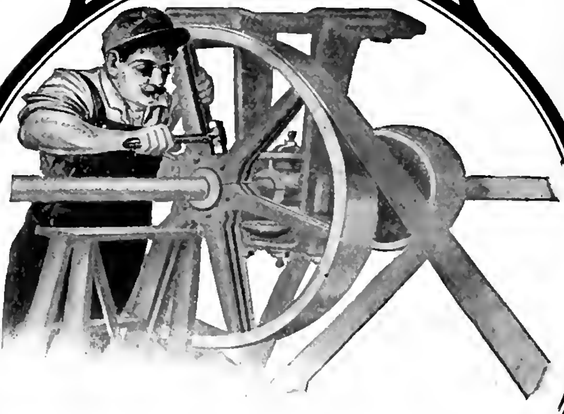


W. F. & JOHN BARNES CO.

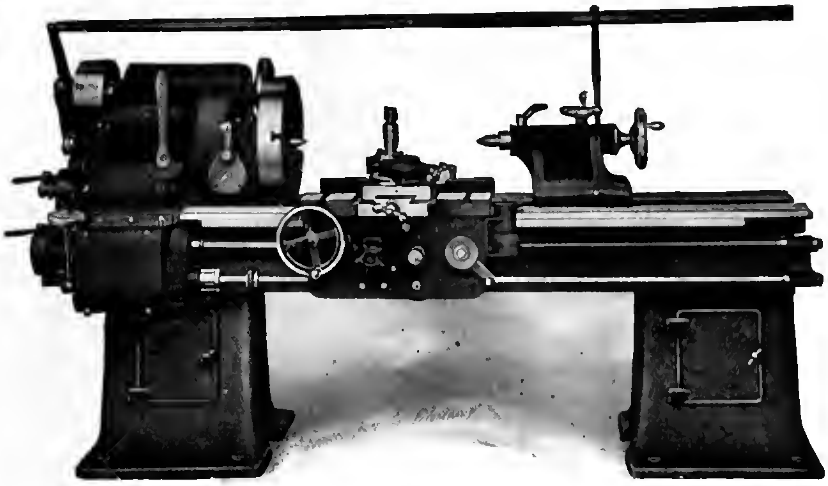
231 Ruby Street Established 1872 **Rockford, Illinois**

MAN WANTED





WHITCOMB



In this New 16-inch Geared Head Lathe

provision is made for 32 changes of feed for turning and threading, without removing or changing a gear. The drive through a single speed pulley with geared connections for speed changes is a conceded advantage, and the new form of clutch through which changes of speed are obtainable combines the good points of both the positive and friction types and at the same time overcomes the faults of both. The spindle is positively driven, yet without shock in engaging or disengaging and with no possibility of continued slipping, as the act of slipping only serves to tighten the clutch more firmly.

The lathe is smooth running, easily handled, has power for very heavy work and will stand up under hard service. The improved feed box, new chasing dial, adjustable apron friction, clamping arrangements for tailstock and special lubricating system, are other notable points which we shall be glad to explain in detail.

We are also makers of the Second Belt Drive Planers.

Grading Alundum

Alundum is graded to many sizes and numbered according to the meshes per linear inch of the screen. The numbers used in Norton Grinding Wheels are from 10 to 200.

The Right Grinding Wheel Grit

The peculiar structure of Alundum, its temper, or the character of its fracture, is what makes it the ideal grit for use in manufacturing grinding wheels.

In Alundum, the grit, lies much of the success of Norton Wheels.

In manufacturing Grinding Wheels, it is easy to make a wheel that will give long life. It is not so easy to make a wheel that will give **both long life and fast production.**

The success of Norton Wheels in the various kinds of grinding tends to prove that it comes nearer the maximum in both long life and fast-cutting quality—maximum efficiency—than any other grinding wheel made of any abrasive material.

DO THESE INTEREST YOU?

A Grinding Machine Manufacturer

writes us: "Referring to the wheel recently sent us, this wheel seems to cut better than any wheel we have tried for some time. It is, in fact, **the best wheel we have used on soft steel.** We do not think this is putting it too strong. The wheel cuts fast, cool, wears very little and seems to remain sharp." (Name on application.)

This wheel was 24" dia., 3" face and 12" hole, and was made of Pure Corundum.

A Manufacturer of Cutlery

says: "Replying to your favor, will say that the last 14 x 4" ring wheel shipped us has been in service about 4 weeks and **is proving very satisfactory.**" (Name on application.)

An Automobile Manufacturer

writes us under date of June 8, 1909: "In reply to your favor, beg to say that after **having tested a variety of different makes of wheels** we have been able to get **the best work from one of the samples you sent us,** namely the 4 x $\frac{3}{4}$ x $\frac{3}{8}$"—No. 36 grade K, hence we would ask you to ship us—etc." (The operation was internal grinding of cast iron cylinders.) (Name on request.)

A Large Card Manufacturer

writes: "We have finally completed the tests we were making with the samples of corundum wheels sent us some time ago, and would say they are about **the best** Corundum Wheels **we have ever had the pleasure of testing (and we have tested quite a few in our time.)**" Then follows an order for 430 wheels. (Name on request.)

Why don't **you** give **American** wheels a trial? No matter what your operation may be, we guarantee that **American Emery Wheels** or **Corundum Wheels** will show better results than any wheels you have ever used, or there will be no charge to you.

BESLY GRINDERS

LET US SHOW YOU WHAT WE CAN DO FOR YOU

Illustration shows grinding of Rifle Frame Castings.
Ground on 1905 Model No. 6 Besly Spiral Disc Grinder, grinding two sides of the casting at the same time.
Material—Malleable Iron.
Stock removed—about .025" on a side.
Rough ground 25 Rifle Frame Castings, or 50 sides.
Time:—one hour.
Used No. 5360, Grain No. 16, Helmet Spiral Cloth Circle.
Finish ground 25 Rifle Frame Castings, or 50 sides.
Time:—15 minutes.
Stock removed—.003" on a side.
Finished to .875".
Circles used for both roughing and finishing had a 9" hole in center, thus leaving a grinding zone of 4½" wide.
If these castings were to be ground in a manufacturing way, it would be advisable to reduce the amount of stock on the castings which is left for finish. This materially increases the speed of grinding.
THE PATENTED FEATURES of 1905 Model No. 6 Besly Spiral Disc Grinder, illustrated above, are the Spiral Grooved Steel Disc Wheels, Helmet Spiral Circles, Geared Lever Feed Mechanism and Sliding Motion of Spindle.
Furthermore, with this machine, if desired, we are prepared to furnish our Patented Hinged Nut Grinding Fixture or our Patented Open Top Nut Holder.
THE EXCLUSIVE FEATURES of this machine are the Bed Construction, Heads are mounted on V's planed on Bed Casting, Method of taking up end thrust of spindle, Bearing Construction and Micrometer Adjustment.
When so ordered, this machine is equipped with Automatically Telescoping Dust Hood. End play in Spindle Bearings is adjusted in such a way that machine can be run safely with practically all end play taken up: naturally grinding work to size WITHIN CLOSER LIMITS.
Among our 70 varieties of Besly Disc Grinders is one just suited to your work.
We would like to prove our claims on some of your samples. No charge for the demonstration.
Send us some samples and we'll grind them for you and report time and material used.

CHARLES H. BESLY & COMPANY

LE BLOND

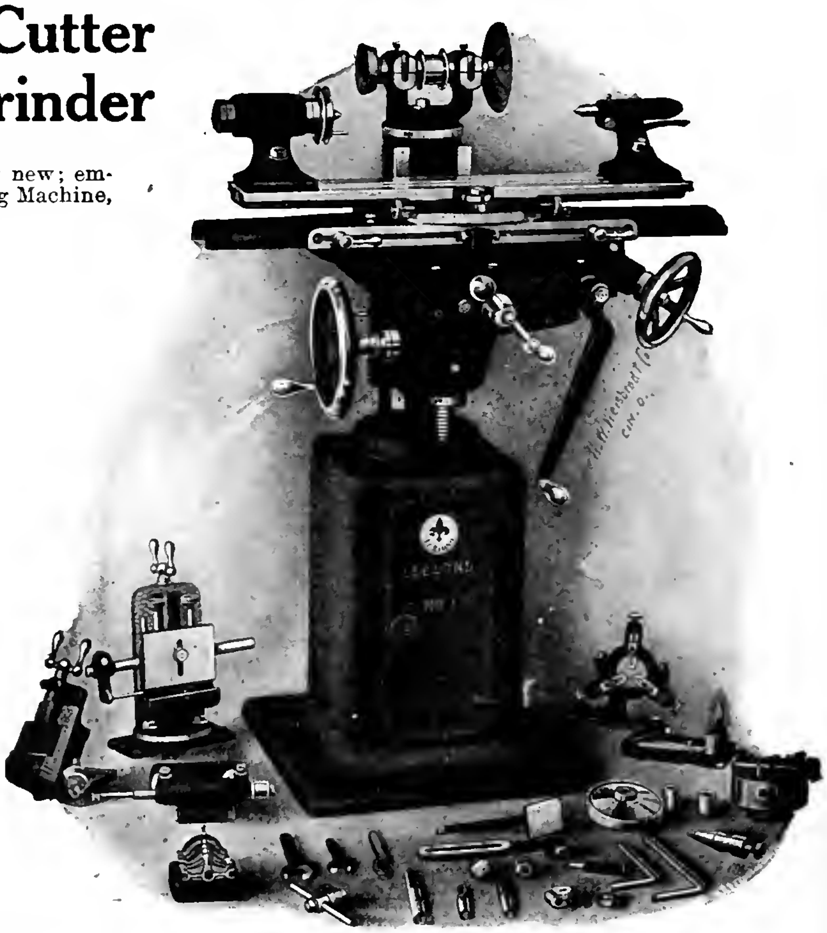
Universal Cutter and Tool Grinder

The Principle of the machine is entirely new; embodies the design of the Universal Milling Machine, consisting of a Knee, Saddle, Swivel, and Table. This gives rigidity that has heretofore been lacking in a Cutter Grinder, and adapts the machine to grind the large inserted-tooth mills of modern milling practice.

Capacity. It is absolutely universal; will grind any angle, taper or face. Grinds all kinds of cylindrical, internal faces and angular work ; face and end mills, reamers, counterbores, circular saws, gear cutters, gauges, flat surfaces and other tool room work.

Attachments include a complete line. Universal Attachment, Circular Grinding Attachment, Internal Grinding Attachment, Gear-cutter Grinding Attachment, Surface-grinding Attachment, etc.

Catalogue giving full description of construction and use, will be mailed upon application.



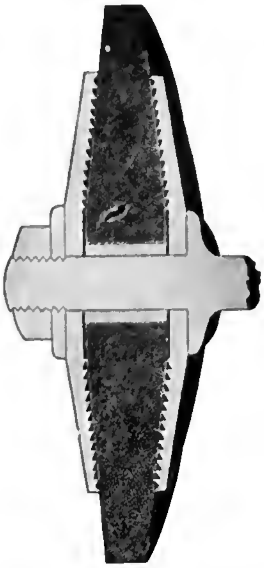
The R. K. LeBlond Machine Tool Co.

4609 Eastern Ave., Cincinnati, O.

RESULTS

are what you want from your grinding.

The greatest and best results can only be gotten



With Safety Wheels

Made of highest quality Emery, Corundum and Carbondite they are *not* pressed or tamped, but are porous and open in texture, even in hardness and absolutely free-cutting. A wheel made of the cement (or bond) used in holding the abrasive together would cut of itself alone.

Safety Wheels are not affected by air, water, dampness, acids, or time; require only half as much "truing up" as those of other makes, and are adapted for all grinding purposes, and all grinding machines.

No matter what your grinding need, we can fill it.

The Safety Emery Wheel Company

KEMPSMITH

No. 3 Milling Machine

The greatest work producer of its kind. Exceptional weight and ranges and capacities, massive at points of especial strain, powerful construction in every operative detail.

3 step cone pulley, all steps affording very liberal belt contact and double back gears. After all is said, this is the favorite construction. Maximum productive efficiency and most reliable in continued severe manufacturing milling.

THE KEMPSMITH MFG. CO., Milwaukee, Wis.

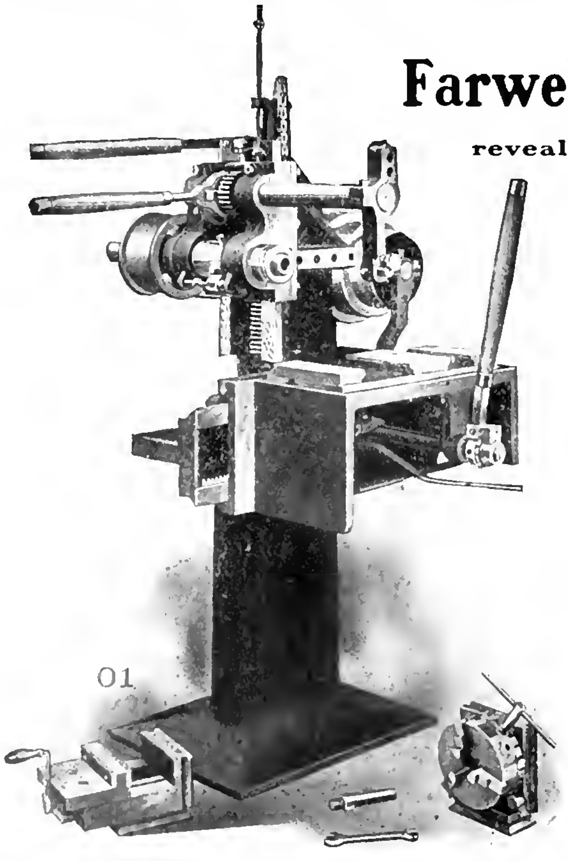
European Agents: Selig, Sonnenthal & Co., London, E. C. Canadian Agents: London Machine Tool Co., Ltd., Hamilton, Ont.

LOOKING UNDER THE TABLE

of the

Farwell Quick Change Miller

reveals no unstable stack of cross slides.



This accounts for the lack of chatter, the use of a rake on our milling cutters, the clean curly chips, the rapidity with which we remove metal and the accuracy of work turned out by our machine.

Note also the quick change clamps which instantly secure the chuck or vise in any of several positions. These fixtures are as rigid as the machine and the chuck is provided with an index for spacing cuts.

Catalog 68M shows it in use.

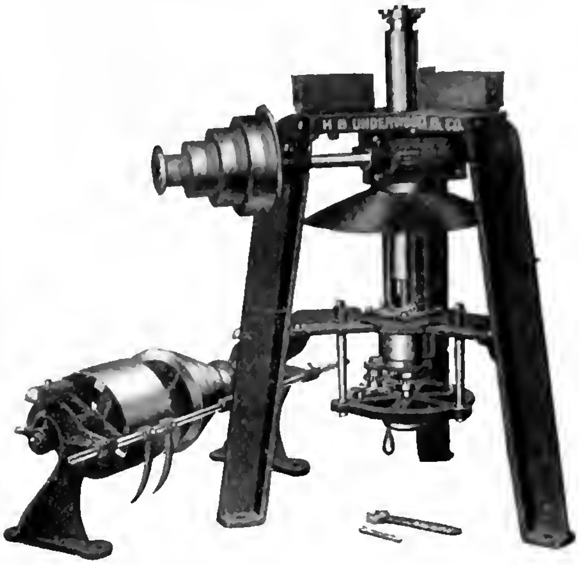
Vertical Boring Machine

(Automobile Cylinder Borer)

NEW
QUICK
SIMPLE
ACCURATE



Designed for boring and reboring cylinders, blind and open end, of automobile and motor boat engines, also air brake cylinders, etc.

The vertical spindle permits of the machine being used for a wide field of other work where ordinarily a large machine tool would be required, e. g., boring the hubs of large gears and fly wheels.

The work is easily set up and centered, without the use of expensive jigs and fixtures. The cutterhead leaves a smooth finish and bores very accurately. The machine is capable of rapid production, requires but little room and power, and is well built, with ample bearings to assure rigidity.

Our new catalogue explains in more detail and is yours for the asking.

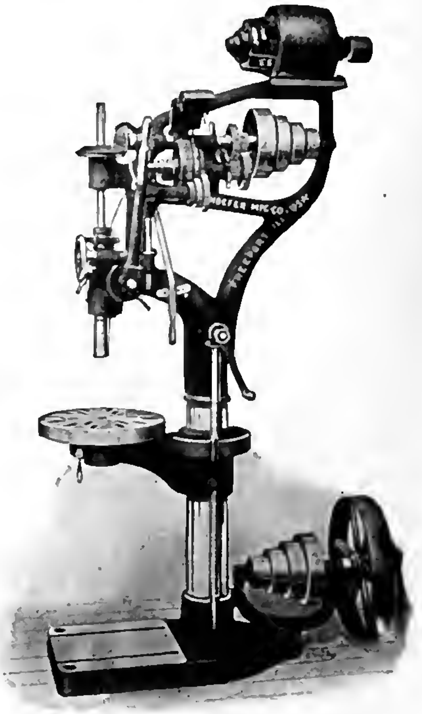
How an Accurate Drill Press is Built

THE BASE



The base plate of the HOEFER drill is heavy, substantial and broad enough to give a stable foundation. The upper surface is planed and slotted for the bolting down of work on all size machines down to and including 21-inch swing.

The most important point is the method of attaching the column to the base. Some people merely bolt it on, but we find that method not strong enough nor accurate enough. It is better to bore a socket in the base, square with the planed surface, and then turn the end of the column to fit in this socket so that you can be sure that the column, and therefore the spindle, are absolutely perpendicular to the base.

We make over 30 styles of boring and drilling machines, including, most likely, just the one you want.

Write for complete Catalog "X."

OAK

VIM

THE illustration shows a piece of VIM and one of oak bent at a sharp angle under the same conditions.

It will be noticed that the oak has cracked on the grain, while the VIM is still perfect.

This is because the oak process of tanning produces a weak grain.

The VIM process makes the grain the strongest portion of the leather.

All packings must be bent at a sharp angle in forming.

Because oak leather breaks so readily, it is soaked in water and made soft and mushy in order to form.

Because VIM Leather is so strong, it can be formed without softening.

As it is naturally water-proof, it would be impossible to soften VIM Leather with water if one wanted.

This is merely one of the many reasons why **VIM LEATHER PACKINGS** are giving from three to thirty times longer service than oak, and why we are perfectly safe in guaranteeing twice the wear for all

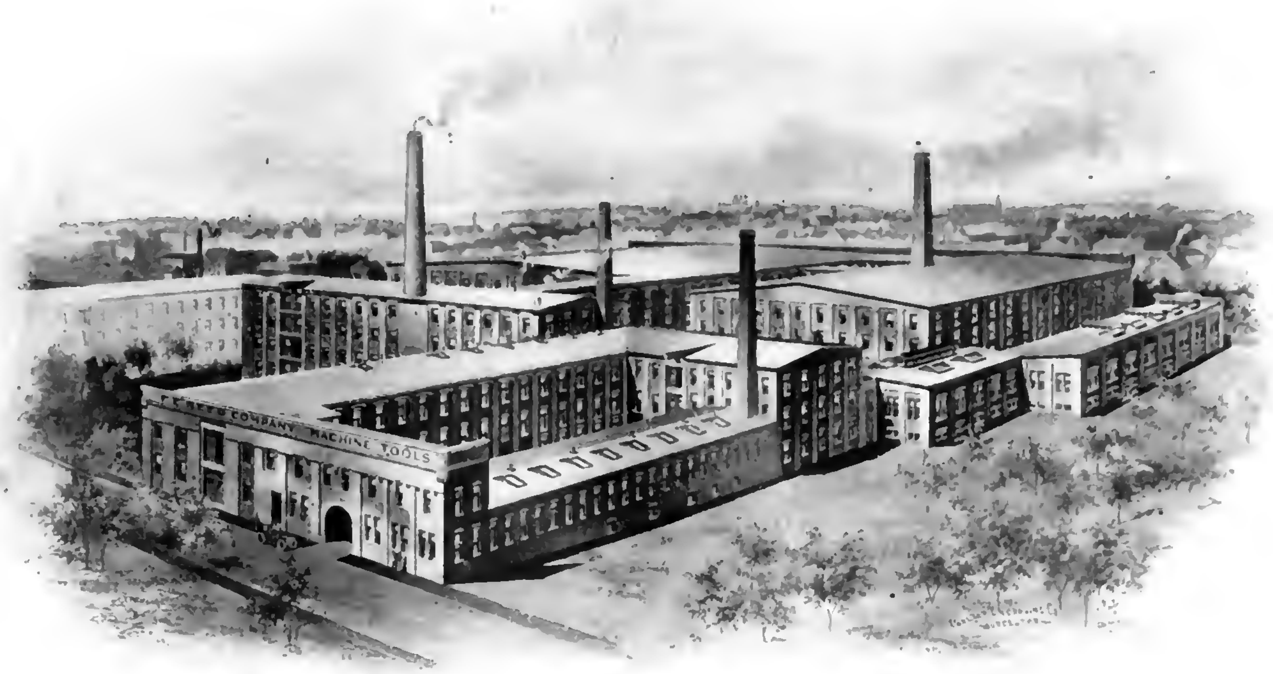
Where REED LATHES are made.



24,000 Reed Lathes

Built and sold in 27 years of LATHE building is our record—a record that speaks more strongly for the reputation of Reed Machines than reams of special claims and brilliant testimonials.

"Simplicity of Design—Best Material—Highest Grade Workmanship"—are the specifications to which our organization works. In design we have never sought to develop *talking points*, but have always met the demands of legitimate practice. In material, *Price* has never been considered *before Quality*; we have bought the best, subjected it to stringent tests and rejected every piece that failed to meet our high standard. Our workmen are experts each in his special branch, and every machine is practically tested before it leaves the works. These are a few of the reasons for the *Unanimous Verdict* of our friends, that—

REED LATHES ARE GOOD LATHES.

10" to 30" Swing. Belt or motor driven.

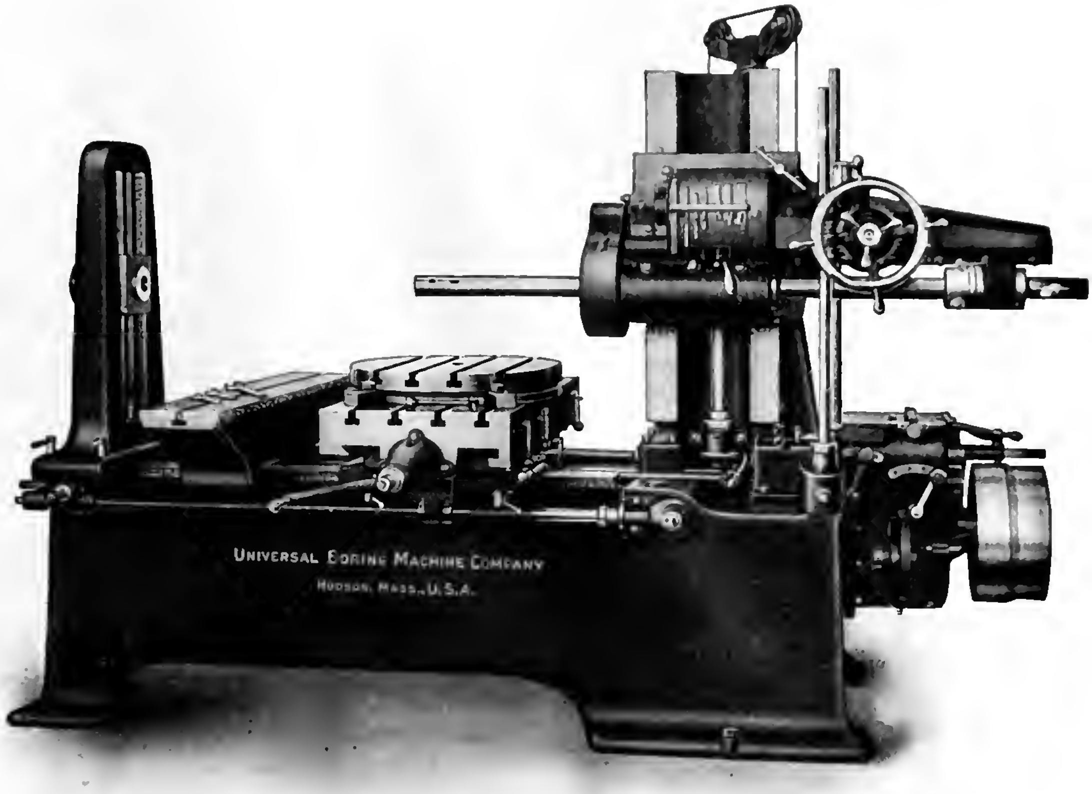
Name and Address...



UNIVERSAL (HORIZONTAL) BORING MACHINE

With Rapid Milling Feeds

When using the Rotary Table but one setting of the casting is necessary in the making of jigs. The machine itself may be used to lay out the work, saving considerable time and also securing an accurately laid out jig.

Particular attention has been given to the machining and fitting of all parts of the Universal (Horizontal) Boring Machine. All shafts have been brought into perfect alignment insuring accurate work. Great care has been taken in the adjustment of all feed screws, and each has a large collar on it graduated to one-thousandths of an inch, thus permitting fine adjustments.

Universal Boring Machine Co., Hudson, Mass.

Distributors

HILL, CLARKE & CO., INC.

Boston, New York, Cleveland, Philadelphia, Chicago

THE TILTED TURRET

In Fig. 1 is shown an engraving of the No. 3 size of The Tilted Turret Screw Machine, which has an automatic chuck capacity of 1¼ inch. This machine, manufactured by the Wood Turret Machine Company of Brazil, Ind., has a plain head, oil pump and pan, and continuous automatic bar feed, together with an automatic chuck and screw feed cut-off.

The Continuous Automatic Bar Feed used on this machine is simple in construction and of few parts. There are four jaws which hold the stock central in the roller feed case. These jaws have been so constructed that they are able to take round, square, hexagon or any other shaped stock that one may have occasion to use.

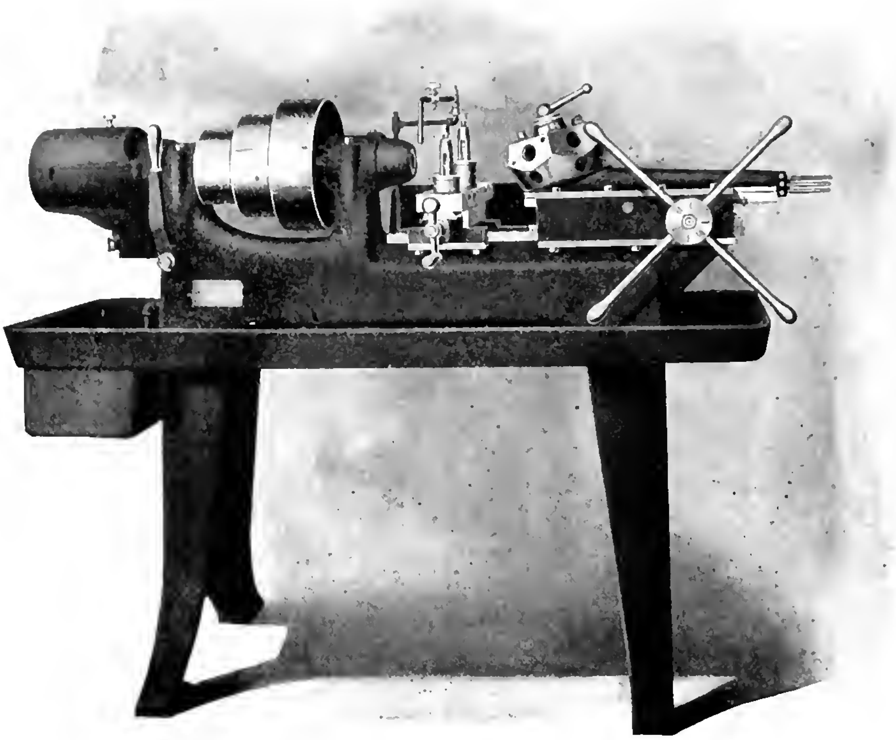


Fig. 1. The No. 3, 1 1-4 inch Complete Screw Machine

The old style high turret is shown in Fig. 2, while in Fig. 3 is shown The Tilted Turret. The machines are of the same capacity and the same swing. The two turrets each carry the same size of die head in the operating position, and also it may be seen what the respective positions would be, if swung around to the rear position. Thus is made clear one of the many purposes and advantages to be gained by having the turret tilted. The strain on the center bolt is minimized due to the fact that the tilt of the turret applies part of the thrust directly on the slide. This feature also causes a full bearing on the slide, and eliminates the tipping which usually occurred with the old style high turret.

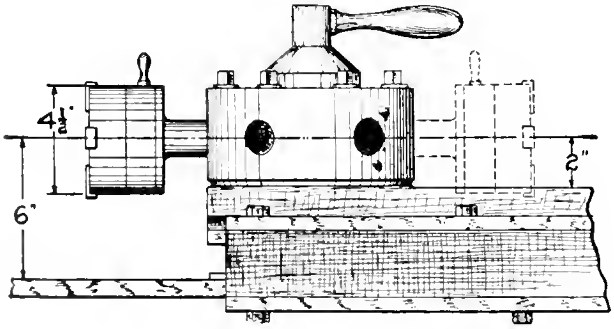

Fig 2. The Old Style High Turret

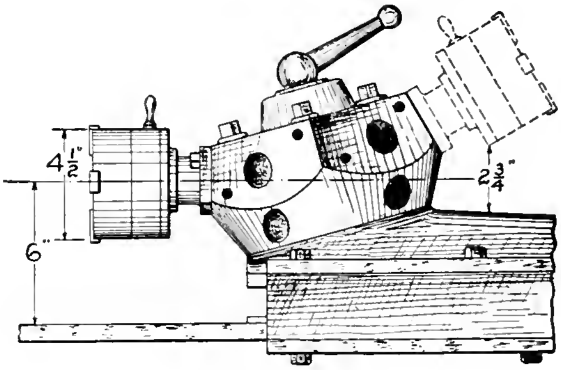

Fig. 3. The Tilted Turret

The stock may be passed into or through The Tilted Turret, since the center bolt has a hole directly through it. The die heads and box tools used on this machine require no shanks. They have a small boss on the back which fits into the counterbore of the turret hole, thus centering them. Two cap-screws hold the die head or box tool, as the case may be, against the turret face. By this arrangement long threading may be done, or long stock reducing cuts taken without interfering with a tool in the rear position on the turret.

The slide on this machine rests and moves in the saddle, being furnished with taper gibs fitted the whole length of the saddle on each side providing a means of adjusting the slide sideways. The backward movement of the slide, which is operated by a turnstile, rack and pinion automatically revolves the turret. The saddle is gibbed to the outer edges of the bed by flat gibs throughout its entire length. There is a supplementary taper base to the saddle by means of which the tool holes in the turret can be adjusted to the exact height of the center of the spindle.

A self-oiling counter-shaft is furnished with each machine. The two friction pulleys on the counter-shaft are of single piece construction. Oil reservoirs are cored out completely around the bearings, and the space is filled with cotton and oil. The hanger shaft bearings are supplied by oil boxes below them. Each of these bearings has a groove cut in it in which is laid a wicking, the ends of which dip into the oil reservoir below.

The Tilted Turret Screw Machine, manufactured by the Wood Turret Machine Company of Brazil, Indiana, may be seen in operation by a visit to one of the Demonstration Shops of Hill, Clarke & Co., Inc., of Boston and Chicago, and their branch offices at New York, Philadelphia and Cleveland.

Chicago (Duplex) Hand Millers

The Chicago Hand Millers, manufactured by the Chicago Machine Tool Company, are of the "Duplex" type, so called since a Vertical Attachment is regularly furnished with each machine. This combination of both horizontal and vertical spindles on the same machine, together with the exceptionally large range, adapts it for the quick handling of a large variety of work.

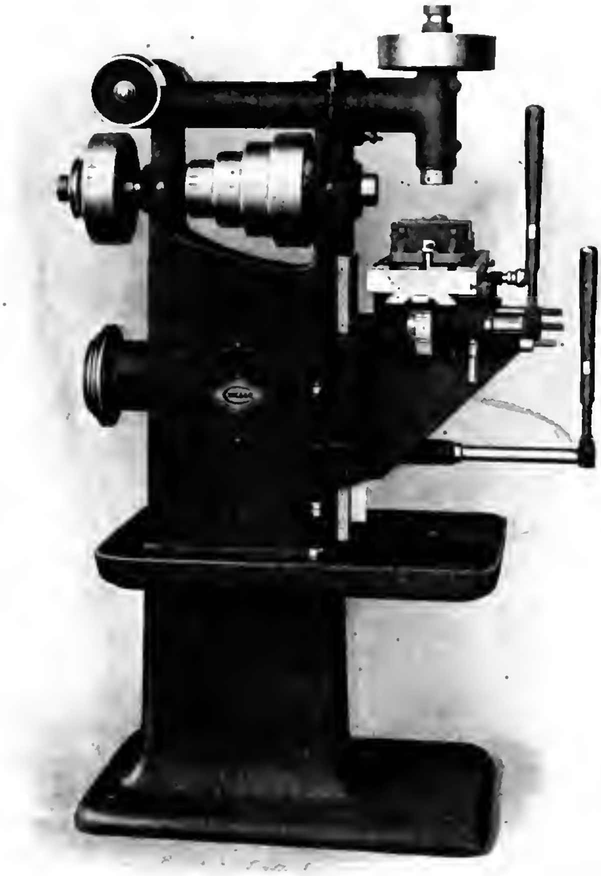

Fig. 1. The No. 3 Machine showing the Vertical Attachment in place

In Fig. 1 is shown the No. 3 Machine with the Vertical Attachment in place. This Vertical Attachment is among the important features of the machine, making it particularly adapted to tool room purposes, as well as brass workers and manufacturers of small parts. It is not practicable in general to use a heavy milling machine for the lighter class of milling machine work, that is, if the element of time is to be considered. The ability of the Chicago (Duplex) Hand Miller, due to its large range and equipment to quickly handle a large variety of work, indicates its time saving qualities.

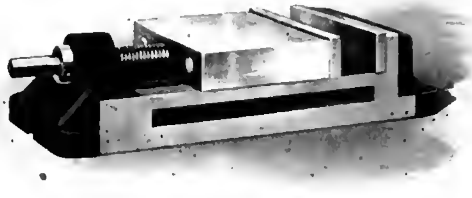

Fig. 2. The "Chicago" Vise

In Fig. 2 may be seen the Chicago vise. This vise is of proportionate design throughout to give it sufficient strength. The vise has supplementary hardened steel jaws held in place by fillster head cap screws.

The Vertical Spindle Attachment, which is regularly furnished, has no gears in connection with it, thus making it sensitive. Therefore, the full driving power is retained, hardly any being used up by friction. The Vertical Spindle runs in a split bronze bearing, provision being made for taking up any wear that may occur.

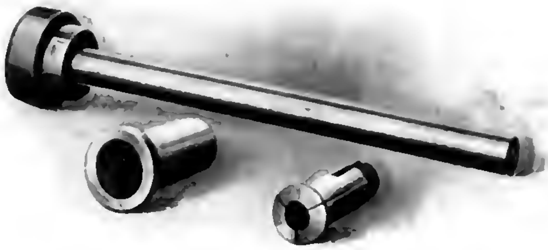

Fig. 3. The Draw Bar, Collet and Sleeve used for holding end mills and similar tools

The Horizontal Spindle runs in split bronze bearings fitted to taper bores in the column. Each bearing is provided with a threaded collar for drawing it into the taper bore, thus furnishing a means for taking up the wear evenly from all sides. This arrangement of the bearing insures great durability and smooth running of the spindle.

The horizontal and vertical spindles are each bored for No. 9 Brown & Sharpe taper. A draw bar, collet and sleeve are furnished for the vertical spindle, and a draw bar and sleeve for the horizontal spindle, the same collet fitting both spindles. Thus end mills and similar tools may be held in place on the machine.

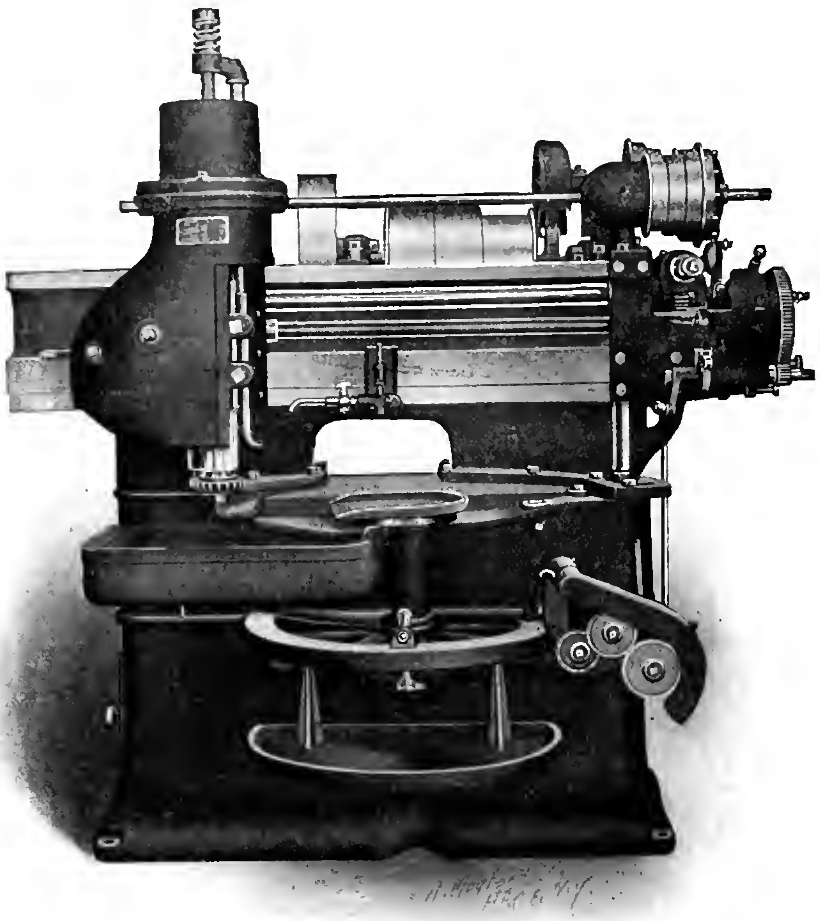
Fig. 4 The Feed-gear Box and Universal Joint Shaft

The Power Feed on the machine is of the most improved design and extremely powerful. It is taken from a cone pulley on the rear end of the spindle to a three-step cone pulley on the rear end of the gear box. From the gear box, the drive is through a universal joint shaft to a pair of 45-degree angle spiral gears in the saddle. A worm is fastened on the same shaft with one of the spiral gears, the pair of spiral gears and the worm being held in a rocker. This rocker throws the worm in and out of mesh with the rack on the table. The worm has at all times five teeth in working contact with the rack. No argument is needed as to power, durability and smooth running qualities of this type of feed; it is too well known.

These Chicago (Duplex) Hand Millers, manufactured by the Chicago Machine Tool Company, Chicago, Ill., may be seen in operation by a visit to one of the Demonstration Shops of Hill, Clarke & Co., Inc., of Boston and Chicago, and their branch offices at New York, Philadelphia and Cleveland.

THE DEMAND FOR THE GEAR SHAPER

has exceeded our capacity, and made necessary two shifts, regardless of the fact that we are constantly adding to our equipment. Don't wait until you need additional gear cutting machinery before you take up the matter with us. Get our prices and delivery, and so plan as to have Gear Shapers when you need them. If you have used this machine, you know that it is the fastest gear cutting machine on the market; if you haven't, let's get together and talk it over. Now is the time, if you will require one or more machines within the next few months.



Ask for book just out, "The Gear Shaper Cutter"

The "Norka" Two-Grooved High Speed Twist Drill

THE DRILL WITHOUT A TANG

This is the latest thing in the High Speed Twist Drill line and the Drill that will cut down your cost of drilling.

It has great strength because it is twisted while hot, therefore, the grain of the steel is not disturbed.

There are no tang troubles because a piece of the stock is left untwisted, forming the shank, and the jaws of the chuck fit perfectly into the grooves of the shank, not only holding the drill but also centering it.

TRADE MARK

THE SENECA FALLS MFG. COMPANY
330 Water Street, SENECA, FALLS, N. Y., U. S. A.

Lyon Racks with Bin Attachment showing variety of material stored.

Your Floor Space is Valuable

Figure out how much your floor space costs you. Now figure out what it is costing you to allow all those parts of machines, pieces of metal, unfinished work—to take up such valuable space. Space that might be used to increase your output if you had a system of **Lyon Steel Racks** along the wall. The space between the floor and ceiling—air space—costs nothing.

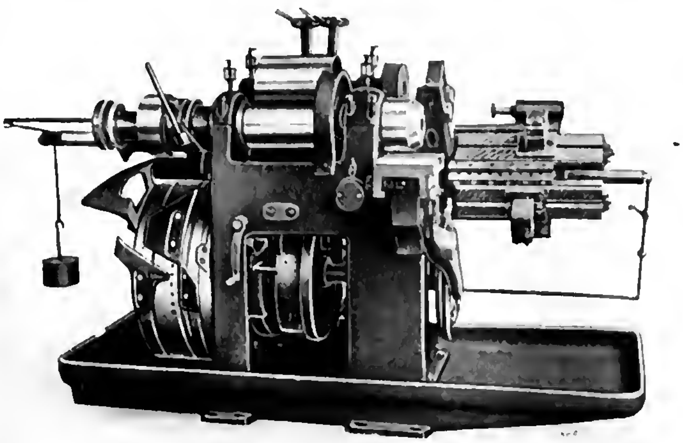
Lyon Steel Racks are designed upon the truss system. Compression and tension members are employed—involving the two cardinal principles of bridge-building, and are the strongest racks on the market.

Built on the Unit System, every part and attachment standardized. Shelves require no bracing. No danger from unequal loading. One of the best investments any manufacturer can make.

Ask for the bulletin today.

Lyon Metallic Mfg. Company
AURORA, ILLINOIS
Steel Racks, Lockers and Factory Equipment

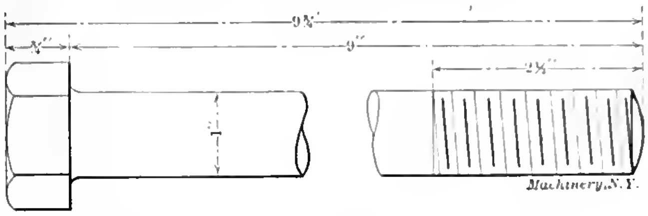
Try the Gridley Automatic Turret Lathe



For the hard work, the long pieces that cannot be handled on the ordinary turret machine, or the job that must be especially accurate

The peculiar construction of Gridley Automatics insures accuracy, covers a very wide range of turning and permits very rapid production. Cutting tools do not overhang and are rigidly held at the cutting point. High speeds, coarse feeds and heavy cuts, all part of the day's work.

The sample of work shown was completed on the Gridley in 10 **minutes and 10 seconds.** Material, cold rolled steel.



One man can operate several machines. Write for our new catalogue.

Die Stocks with Collets are costly—

in the beginning and to the end. Yet collets are necessary in almost all stocks except in

Carpenter's Patent Adjustable Stocks

for holding round dies. They guide the die onto the work by a pair of hardened tempered steel jaws. Jaws are adjusted by a ring with eccentric slots, and remain in the position set. Jaws can be brought into contact with the iron when being threaded, a vast improvement over the solid collet, which has to have an entrance large enough to receive the largest iron, hence is loose on smaller sizes, and allows the die to be lipped at an angle and cut a crooked thread. Why not profit by this in buying your next die stock? Carpenter's Catalog tells everything.

Pat. Dec. 19, 1905.

PHILIPS RIM LUG

THE RIM LUG

is usually a very weak point in the majority of split pulleys. The manufacturers know it and are very loath to speak of it, but not so with us—we're very glad to call attention to ours, for the

PHILIPS LUG

is the strongest point of our pulley rim. The rim lugs extend over the entire width of the pulley, and are formed by the ends of the sheets being turned inwardly from the face, thus making the strongest kind of joint and preventing the sharp ends of sheet from coming in contact with and cutting the belt.

This construction does not destroy with grooves or rivets the most important part of the pulley—the face.

That's another reason why Philips' Pulleys are so popular. They're built on the best mechanical principles and are uniform throughout.

Send today for descriptive circular.

THIS

Ball Bearing Tool

is designed to be used in

The National Riveting Machine.

The spindle of the machine in which it is fitted runs at 2000 R. P. M. When the tool is brought down to the rivet, those little rollers revolve vertically on their own axis.

The Process is Noiseless.

A Perfect Polished Head in One Second.

No Bending of Rivets or Breaking of Work.

Capacity ⅜" rivets. Manufacturing Simplified.

The Cincinnati Pulley Machinery Co., Cincinnati, O., U. S. A.

The Peerless Hoist

The latest type of spur geared hoist embodying special features that make it the most efficient device of its class.

Safety, Durability, Speed, and Economy

are prominent characteristics of the "Peerless"—all qualities that go to make up the perfect hoist. The single load chain tends to light weight and compact form; all working parts are protected by dust-proof cases; the hoisting mechanism—a train of compound balanced steel gears—insures smooth action and reduces wear to the minimum; and all danger of the load slipping is eliminated by a chain guide and stripper.

We shall be glad to furnish full particulars on request.

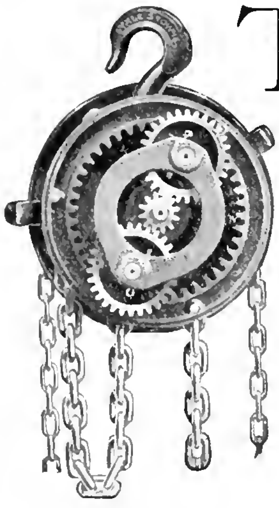
CINCINNATI, OHIO, U. S. A.

The Dust-Proofness

of the Triplex Block



Dust-proof Steel Gear Cover Removed.

THE dust-proof cover of the Triplex is *dust-proof*. It is not pierced to hold bearings and is of pressed steel, not cast iron.

It is absolutely independent of the gears and can be battered and dented to any extent without affecting the mechanism in the least.

This is a great improvement over the cast iron covers which are often broken by being struck against other blocks, causing great danger where the gear bearings depend on the cover for support.

The Triplex Block is made in 14 sizes, with a lifting capacity of from ¼ to 20 tons. Other types are the Duplex: 10 sizes; ½ to 10 tons. The Differential: 7 sizes; ⅛ to 3 tons. The Electric Hoist: 10 sizes; ¼ to 16 tons. Blocks are carried in stock by Hardware, Machinery and Mill Supply dealers. *Catalog with interesting technical information on request.*

RATHER SMALL

FOR A POWERFUL MACHINE

but this pump weighing less than 100 pounds is capable of delivering an operating pressure of 500 pounds per sq. in. to each of four hydraulic presses. It is also excellent for pumping oil in forced feed lubricating systems.

Each pair of cylinders (½ in. diameter by ½ in. stroke) delivers into a separate pressure chamber and line, any one of which can be thrown out of service by leaving the valves open.

We call your attention to these sizes and capabilities merely as an example of the widely varying conditions which we are constantly called upon to meet.

WATSON-STILLMAN HYDRAULIC PUMPS

are made to be driven by hand, belt, motor or steam engine, and to deliver any pressure up to 10,000 pounds per square inch.

We carry in stock those types and sizes which are in greatest demand and have patterns for others to meet most ordinary conditions. If your work requires special construction, our fifty years designing experience and complete mechanical facilities are at your service. We will build to order on short notice and at reasonable price.

Ask for Hydraulic Pump Catalog No. 71 and tell us what other hydraulic tools interest you.

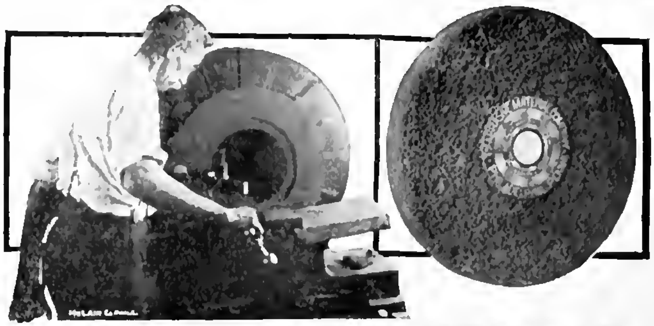
TAUNTON, MASS., U. S. A.



ABRASIVE

Care in Finishing the Product

is another feature that makes

**ABRASIVE
FAST GRINDING WHEELS**

so popular with the operators. Our wheels never leave the factory until they are as perfect as modern skill can make them, consequently when they reach your shop they are ready to show you that—

"They don't merely grind—they cut."

This is not altogether due to their finish, of course, it's the material and bond they're made of that does that; but the method of manufacture and finish helps—helps a lot.

Tell us your grinding troubles, we'll tell you how to remedy them.

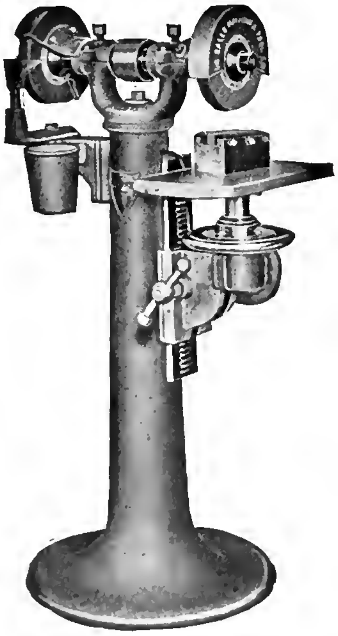
The LaSalle No. 1 Plain and Surface Grinder

Micrometer Feed

TRADE MARK.



With the advantage of absolute accuracy, strength to fully meet the demands of the wheel and every convenience for operating, this grinder will pay its way in any shop. It will handle much work now finished by filing, with a subsequent saving of time and labor, is admirably adapted for sharpening punches and dies, fitting keys and a wide range of similar work. The micrometer feed to table permits the finest adjustments to be easily and quickly made.

Catalogue mailed on request.

LaSalle Machine and Tool Company
LaSalle, Ill., U. S. A.

BAY STATE

TAPS & DIES

BACK of every success you'll find experience. That's one reason why Bay State Taps are being used exclusively by the best shops and mechanics.

They know that the superior temper, the correct lead and uniform pitch was never gotten by accident, but by hard work and experience.

It is the quality that makes them wear so long.

**Try just one "Bay State"
and you'll use no others.**

BAY STATE TAP AND DIE CO.
MANSFIELD, MASS., U. S. A.

The Abrasive Metal Cutter

Cuts off High Speed and Carbon Steel bars 5-16" diameter in 5 seconds without drawing the temper.

It is the most rapid machine for cutting metal ever invented. Effects a saving in time and material when cutting up stock, which is hard to credit until it is actually proved to you. Is designed to handle metal in any form and is especially adapted for tubing-cutting clean and true without burrs or irregularities.

Our Special Patent Cutting Wheel developing a speed of 4000 revolutions per minute does the cutting. Each wheel will cut up from 300 to 400 pounds of ½" high speed steel in lathe tool lengths.

Full description and reports of work done, sent on request.

Slack Manufacturing Co., Springfield, Vt.

Modern Pipe Machines.

PHILADELPHIA, PENNSYLVANIA

You've tried the rest. Now try the best

It is hard to make a man realize, when he has tried a lot of different things for his belts, that Cling-Surface will give him the results he has been looking for all the time.

You want your belts and ropes pliable, waterproof and preserved.

You want to run your belts easy or slack and carry full loads. You hear a good deal about slack belts.

Don't you know that it was Cling-Surface that started this movement towards slack belts? And before that time every one ran their belts tight and expected to?

Cling-Surface has made it possible and Cling-Surface is the only thing that ever has.

An occasional belt, underloaded, can be run slack without it but only Cling-Surface lets them *all* run easy or slack, some slacker than others—none tight.

It means long-lived belts, cool bearings, economy of oil, fuel, power and work and less worry on you.

We guarantee it. Write us and ask for photographs of belts and our trial terms. Write us now.

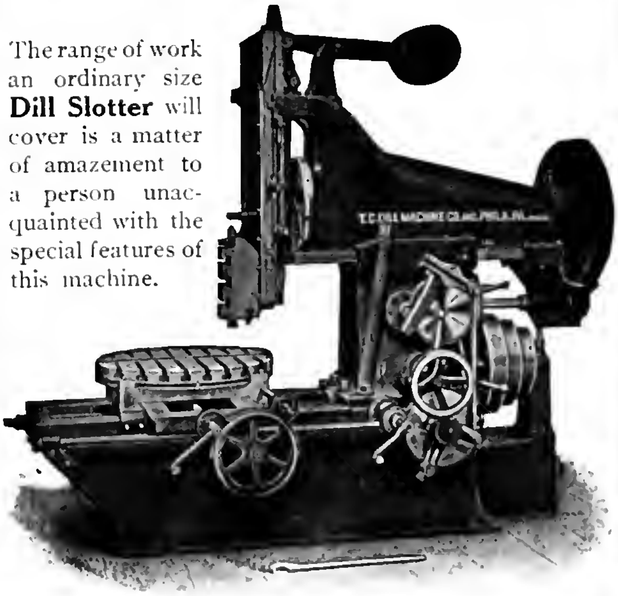
The All Embracing Dill

The range of work an ordinary size **Dill Slotter** will cover is a matter of amazement to a person unacquainted with the special features of this machine.



But a little consideration of the traveling head, quick traverse gear, new quick return, automatic knock-off, hand wheel controller, new intermittent feed and other exclusive Dill points, soon shows the reason and explains why it is the most economical tool of its class you can have in your shop.

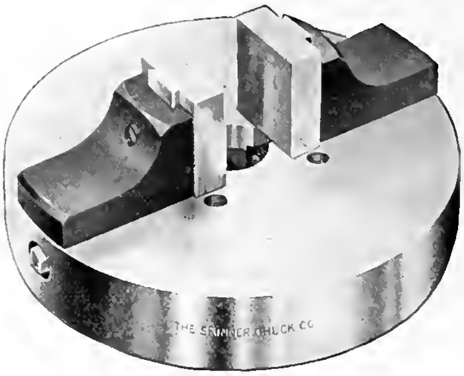
Also Drill Chucks.

Let us send you our catalogue and price list.

The Cushman Chuck Co.

179 Allyn St., Hartford, Conn.

Odd Shaped Pieces



How do you grip them? Do you get a firm bearing all around while they are being machined? If you would use a Skinner Two Jaw Chuck, Style "G", you could machine the steel slip jaws to bear on your work all around. Additional slips for additional pieces and only one chuck, as the slips are interchangeable. This is the chuck we recommend for brass workers for holding delicate pieces which would be crushed if gripped at points only. Jaw screws arranged to prevent clogging by chips.

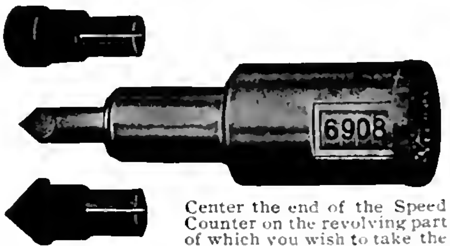
WATCH the WATCH

That is all you have to do when using a

Veeder Speed Counter



Center the end of the Speed Counter on the revolving part of which you wish to take the speed, let it run idle until the second hand comes to the point from which you wish to start to take the reading Then press the counter, which throws the clutch, and let it remain until the minute is up. Then read the counter and the trick is done.

Simple operation, isn't it?

You would think so if you used one.

The instrument is ball bearing and very durable.

Price, complete—$3.00.

Send for further information.

The Marvel No. 1 DRAW CUT

HACK SAW

Saws straight. It has a **quick acting vise** that saves time, a device that lifts saw to any angle, holds it in position, allowing both hands free in measuring. Slide bar is square steel set on the quarter which keeps saw motion straight. The cut is controlled by eccentric on crank, fitted to an arm automatically pressing and releasing against a coiled steel spring.

The only saw on the market with these valuable improvements.

Capacity 4x4 in. Blade 12 in. Weight 110 lbs.

ORDER NOW.

ARMSTRONG-BLUM MFG. CO.
113 N. Francisco Ave., Chicago, U. S. A.

For best results in cutting cold metal use

THE DRAW-CUT MACHINE SAWS

Accurate, rapid, always reliable. Automatic power feed, with automatic trip, geared drive, adjustable stroke of blade, and every up-to-date convenience.

No. 1, 6" x 6". No. 2, 10" x 10".

H. T. STORY

Just Oil, Clean, Start and Stop the

OTTO GAS ENGINE

That's all it needs and in return you get full power at once—or fire out, whichever you wish.

There is no money invested in coal, no ashes to remove, no necessity for a skilled operator and you don't run the risk of being blown sky-high because the boiler explodes.

It costs nothing when standing idle and when running idle consumes but a small fraction of what is required under full load, never increases insurance and is the cheapest motor known for intermittent work.

Tell us your needs and we will send our catalog.

The Otto Gas Engine Works, Philadelphia, Pa.

This is the Famous "VIXEN" Patent HAND MILLING TOOL

The way that the **"VIXEN"** Milling TOOL behaves, when dealing with that prince of file discouragers, PHOSPHOR-BRONZE, is enough single handed to render that tool famous.

Is it—content to simply glide over its Slick—almost greasy surface—with a scarcely perceptible—little scrape—file fashion. Eh? No! my friend, quite otherwise. It "sails"—into that discouraging metal and shreds off chips of it after a fashion that must be as much of a shock to the BRONZE as of a pleasure to the **"VIXEN"** PUSHER—With ALUMINUM it is precisely the same story of clean cut versus "Scrape."—and so too with Copper, a well-known "doer up" of ambitious files. Any man who uses FILES to cut anything "filable" would be wise to "get next" to a **"VIXEN"** MILLING TOOL as soon as may be if only to watch IT CUT DOWN HIS FILING—COSTS—!

"VIXEN" AGENTS—are all over the continent——Shall we send you the name of the one nearest YOU?

For soft metals, wood, etc., use coarse-cut **"VIXEN"** For harder materials use fine-cut ones.

THE BELT FOR WEAR

is **Shultz Sable Rawhide**

One of our 26-inch **Sable Belts** was in operation for 26 years, and then it wasn't worn out. It was cut up and made into narrower belts, which are still in use. Do you know of any other belt which will wear as long as this?

Our **Sable Rawhide Belting** is complete in itself. It is all leather; that is the reason it can be cut up. You don't have to coat it with some dressing to make it stick or make the insides of canvas to give it strength. The rawhide interior is so tough and pliable that the belt will stand any amount of service. The original texture of the hide is not destroyed and therefore it will cling to the pulley surface.

Write for our Booklet No. 32 telling of some other good qualities of this belt.

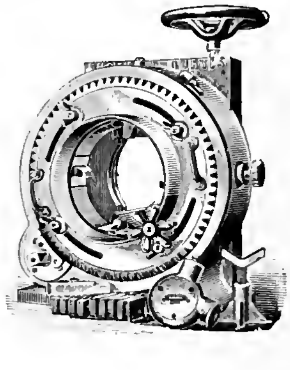
PIPE UP TO 15 INCHES CUT OFF AND THREADED BY HAND—AND ONLY ONE MAN ON THE JOB!

Forbes Patent Die Stocks



are what you require if you are handling any quantity of pipe cutting and threading. It is not only a "Triple X" labor saver, but it does the work cleanly, accurately and rapidly, can be taken any where to the work, used in the most cramped places, is complete in itself and amazingly durable.

VARIOUS SIZES. HAND AND POWER.

CURTIS & CURTIS CO., 8 Garden St., Bridgeport, Conn.

FERRACUTE PRESSES

The Ferracute Machine Company, of Bridgeton, New Jersey, builds hundreds of sizes and styles of presses from a small bench foot-press for steel pens and buttons to ponderous machines weighing a hundred tons, capable of exerting a pressure of a thousand tons and used for bathtubs, metallic coffins and boats. Many articles that are now cast or forged may be made more rapidly, cheaply and of better quality in presses and dies. All presses built by this company are scientifically designed, the metal being put where it belongs. Valuable improvements—the result of years of experience—have recently been made. The leading types are: "C," (Cutting), for tinware, cans of all kinds, lamps, cutlery and an endless variety of work in sheet-metal, paper, cloth, etc., "D," (Drawing), for cups, gong-bells, pans, pot-covers, automobile hubs, sinks and other deep work; "E," (Embossing or Coining), for watch cases, medals and coins; "G," (Gravity or Drop), for drop-forgings; "P," (Punching), for bar-metal; "S," (Stamping or Double-crank), for ceiling-plates, metallic shingles and armature disks. Send sample or specification and ask for catalog and photographs.

Genuine Armstrong Stocks and Dies

BUILT FOR ACCURATE WORK. BUILT FOR HARD WORK.

Engineers and Steam Fitters demand the best.

For sale by **ALL LEADING JOBBERS** in the country.

The complete catalog mailed upon request.

The Armstrong Mfg. Co., 297 Knowlton St., Bridgeport, Conn.

All genuine Armstrong Tools bear this trademark. Look for it and insist upon having it.

You know what you want—see that you get what you ask for.

YOU

cannot judge a Pipe Threading and Cutting Machine—or any other machine—by its first cost; or by the pretty pictures in the catalogues, or by the fond things said about it by "admiring friends."

You must find out in most cases the value of your purchase after you have bought it.

Therefore you are ofttimes stung accordingly.

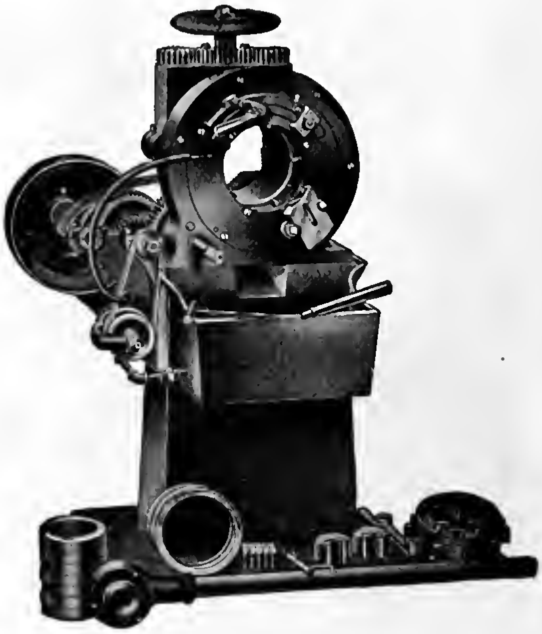
WE

do business differently.

We are sure of our Threaders. We build every blessed part and piece of the Merrell. We know they will give satisfaction.

Therefore we take no risks in sending you the Merrell for a thorough thirty days free trial in your own shops—before you buy it.

If, through any reason the Merrell does not please you, you are not out a penny. You are under no obligation to buy.



Let us tell you all about the Merrell in the Merrell catalogue —then let us send you a Merrell for **30 Days Free Trial.**

"TRIMO" PIPE WRENCH

TRADE MARK

STRONGEST MADE. Less expense for broken parts replaced as well as time saved. Drop-forged from specially selected steel. Inserted jaw in handle easily and cheaply replaced when worn out, displacing the out-of-date and unsatisfactory method of drawing temper, filing and re-hardening when teeth are cut in the handle.

GOLD MEDAL
St. Louis, 1904.

Pipe Threaders and Cutters

With efficiency as well as beauty.

Heavy—none more so; bed cast in one piece, no stands or legs to work loose. No oil soaked floors; fire risk reduced.

Single speed pulley; all gear speed changes through semi steel cut gears.

Deep chasers cutting long taper perfect threads in one cut as easily on steel as on iron pipe.

Let us prove to you that the higher cost of a modern tool is justified by the character and quantity of its product. Circulars for the asking.

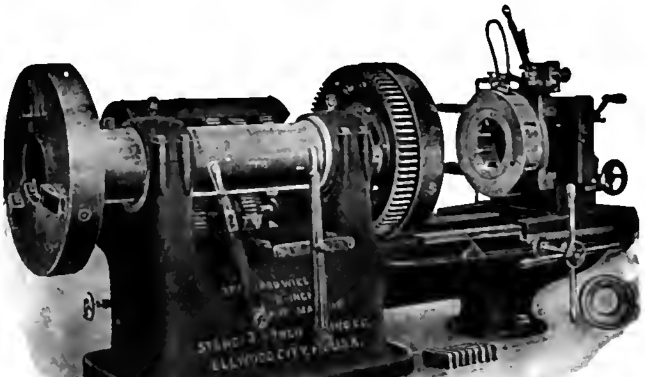
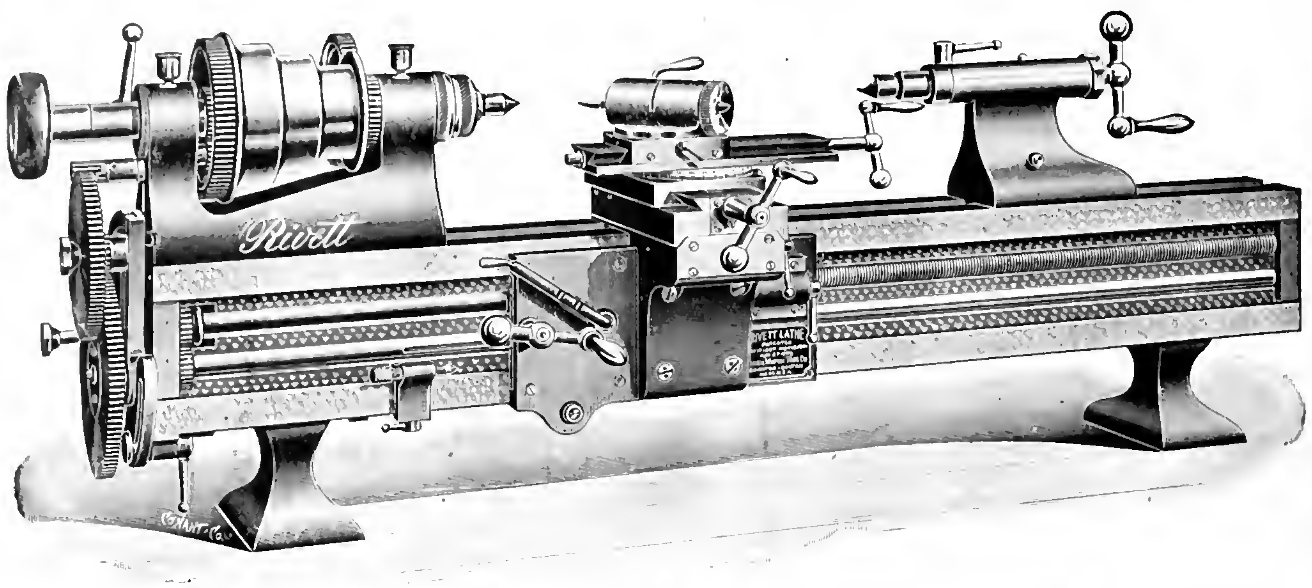
Ellwood City, Penna.
St. Louis Office: 1012 Chemical Building.





"RIVETT" PRECISION
The Lathe For Accuracy

A machine for toolmakers, inventors, scientists and others who produce small work of extreme accuracy, and because of its wide range, also adapted for a variety of work that ordinarily would be considered too heavy for a precision lathe. The Rivett has full adjustments on all movements, sliding surfaces accurately scraped and all bearings ground absolutely true. Lead screw is as perfect as skilled workman can make it, and of large diameter to avoid torsional strains. Full details for the asking.

We make 5 sizes of Bench and Tool Room Lathes for $100.00 and up.

Do you know the Rivett-Dock Thread Tool?
